Low (< 30)	Low (< 100)	Primary polydipsia Malnutrition Beer excess
Low	High (> 150)	Salt depletion Hypovolaemia
High (> 40)	Low	Diuretic action (acute phase)
High	High	SIADH Cerebral salt-wasting Adrenal insufficiency

*Urine analysis may give results of indeterminate significance, and in this case the diagnosis depends on a comprehensive clinical assessment.

Measurement of ADH is not generally helpful in distinguishing between these categories of hyponatraemia. This is because ADH is activated both in hypovolaemic states and in most chronic hypervolaemic states, as the impaired circulation in those disorders activates ADH release through non-osmotic mechanisms. Indeed, these disorders may have higher circulating ADH levels than patients with SIADH. The only disorders listed in Box 16.12 in which ADH is suppressed are primary polydipsia and iatrogenic water intoxication, where the hypo-osmolar state inhibits ADH release from the pituitary.

Management

The treatment of hyponatraemia is critically dependent on its rate of development, severity and underlying cause. If hyponatraemia has developed rapidly (over hours to days), and there are signs of cerebral oedema such as obtundation or convulsions, sodium levels should be restored to normal rapidly by infusion of hypertonic (3%) sodium chloride. A common approach is to give an initial bolus of 100 mL, which may be repeated once or twice over the initial hours of observation, depending on the neurological response and rise in plasma sodium.

On the other hand, rapid correction of hyponatraemia that has developed slowly (over weeks to months) can be hazardous, since brain cells adapt to slowly developing hypo-osmolality by reducing the intracellular osmolality, thus maintaining normal cell volume (see Fig. 16.6). Under these conditions, an abrupt increase in extracellular osmolality can lead to water shifting out of neurons, abruptly reducing their volume and causing them to detach from their myelin sheaths. The resulting 'myelinolysis' can produce permanent structural and functional damage to mid-brain structures, and is generally fatal. The rate of correction of the plasma Na concentration in chronic asymptomatic hyponatraemia should not exceed 10 mmol/L/day, and an even slower rate is generally safer.

The underlying cause should be treated. For hypovolaemic patients, this involves controlling the source of sodium loss, and administering intravenous saline if clinically warranted. Patients with dilutional hyponatraemia generally respond to fluid restriction in the range of 600–1000 mL/day, accompanied where

possible by withdrawal of the precipitating stimulus (such as drugs causing SIADH). If the response of plasma sodium is inadequate, treatment with demeclocycline (600–900 mg/day) may be of value by enhancing water excretion, through its inhibitory effect on responsiveness to ADH in the collecting duct. An effective alternative for subjects with persistent hyponatraemia due to prolonged SIADH is oral urea therapy (30–45 g/day), which provides a solute load to promote water excretion. Where available, oral vasopressin receptor antagonists such as tolvaptan may be used to block the ADH-mediated component of water retention in a range of hyponatraemic conditions. Hypervolaemic patients with hyponatraemia need treatment of the underlying condition, accompanied by cautious use of diuretics in conjunction with strict fluid restriction. Potassium-sparing diuretics may be particularly useful in this context where there is significant secondary hyperaldosteronism.

Hypernatraemia

Aetiology and clinical assessment

Just as hyponatraemia represents a failure of the mechanisms for diluting the urine during free access to water, so hypernatraemia (plasma Na > 148 mmol/L) reflects inadequate concentration of the urine in the face of restricted water intake. This can be due to failure to generate an adequate medullary concentration gradient (low GFR states, loop diuretic therapy), but more commonly it is due to failure of the ADH system, either because of pituitary damage (central or 'cranial' diabetes insipidus, p. 794) or because the collecting duct cells are unable to respond to circulating ADH (nephrogenic diabetes insipidus).

Patients with hypernatraemia generally have reduced cerebral function, either as a primary problem or as a consequence of the hypernatraemia itself, which results in dehydration of neurons and brain shrinkage. In the presence of an intact thirst mechanism and preserved capacity to obtain and ingest water, hypernatraemia may not progress very far. If adequate water is not obtained, dizziness, confusion, weakness and ultimately coma and death can result.

The causes of hypernatraemia are best grouped according to the associated disturbance, if any, in total body sodium content (Box 16.15). It is important to remember that hypernatraemia may be iatrogenic, and to reiterate that, whatever the underlying cause, sustained or severe hypernatraemia generally reflects an impaired thirst mechanism or responsiveness to thirst.

Management

Treatment of hypernatraemia depends on both the rate of development and the underlying cause. If there is reason to think that the condition has developed rapidly, neuronal shrinkage may be acute and relatively rapid correction may be attempted. This can be achieved by infusing an appropriate volume of intravenous fluid (isotonic 5% dextrose or hypotonic 0.45% saline) at an initial rate of 50–70 mL/hour. However, in older, institutionalised patients it is more likely that the disorder has developed slowly, and extreme caution should be exercised in lowering plasma sodium to avoid the risk of cerebral oedema. Where possible, the underlying cause should also be addressed (see Box 16.15).

16.15 Causes of hypernatraemia

Volume status	Examples
Hypovolaemic (sodium deficit with a relatively greater water deficit)	Renal sodium losses Diuretic therapy (especially osmotic diuretic, or loop diuretic during water restriction) Glycosuria (HONK, p. 814) Gastrointestinal Na losses Colonic diarrhoea Skin sodium losses Excessive sweating
Euvolaemic (water deficit alone)	Diabetes insipidus (central or nephrogenic) (p. 794)
Hypervolaemic (sodium retention with relatively less water retention)	Enteral or parenteral feeding IV or oral salt administration Chronic renal failure (during water restriction)

16.16 Hyponatraemia and hypernatraemia in old age

- **Decline in GFR:** older patients are predisposed to both hyponatraemia and hypernatraemia, mainly because, as GFR declines with age, the capacity of the kidney to dilute or concentrate the urine is impaired.
- **Hyponatraemia:** occurs when free water intake continues in the presence of a low dietary salt intake and/or diuretic drugs (particularly thiazides).
- **ADH release:** water retention is aggravated by any condition that stimulates ADH release, especially heart failure. Moreover, the ADH response to non-osmotic stimuli may be brisker in older subjects. Appropriate water restriction may be a key part of management.
- **Hypernatraemia:** occurs when water intake is inadequate, due to physical restrictions preventing access to drinks and/or blunted thirst. Both are frequently present in patients with advanced dementia or following a severe stroke.
- **Dietary salt:** hypernatraemia is aggravated if dietary supplements or medications with a high sodium content (especially effervescent preparations) are administered. Appropriate prescription of fluids is a key part of management.

Elderly patients are predisposed, in different circumstances, to both hyponatraemia and hypernatraemia, and a high index of suspicion of these electrolyte disturbances is appropriate in elderly patients with recent alterations in behaviour (Box 16.16).

DISORDERS OF POTASSIUM BALANCE

Potassium is the major intracellular cation (see Fig. 16.1, p. 429), and the steep concentration gradient for potassium across the cell membrane of excitable cells plays an important part in generating the resting membrane potential and allowing the propagation of the action potential that is crucial to normal functioning of nerve, muscle and cardiac tissues. Control of body potassium balance is described below.

Changes in the distribution of potassium between the ICF and ECF compartments can alter plasma potassium concentration, without any overall change in total body potassium content. Potassium is driven into the cells by

extracellular alkalosis and by a number of hormones, including insulin, catecholamines (through the β_2 receptor) and aldosterone. Any of these factors can produce hypokalaemia, whereas extracellular acidosis, lack of insulin, and insufficiency or blockade of catecholamines or aldosterone can cause hyperkalaemia due to efflux of potassium from the intracellular compartment.

Functional anatomy and physiology of renal potassium handling

In the steady state, the kidneys excrete some 90% of the daily intake of potassium, typically 80–100 mmol/day. Potassium is freely filtered at the glomerulus; around 65% is reabsorbed in the proximal tubule and a further 25% in the thick ascending limb of the loop of Henle. Little potassium is transported in the early distal tubule but a significant secretory flux of potassium into the urine occurs in the late distal tubule and cortical collecting duct to ensure that the amount removed from the blood is proportional to the ingested load.

The mechanism for potassium secretion in the distal parts of the nephron is shown in Figure 16.3D (p. 431). Movement of potassium from blood to lumen is dependent on active uptake across the basal cell membrane by the Na,K-ATPase, followed by diffusion of potassium through a luminal membrane potassium channel (ROMK) into the tubular fluid. The electrochemical gradient for potassium movement into the lumen is contributed to both by the high intracellular potassium concentration and by the negative luminal potential difference relative to the blood.

A number of factors influence the rate of potassium secretion. Luminal influences include the rate of sodium delivery and fluid flow through the late distal tubule and cortical collecting ducts. This is a major factor responsible for the increased potassium loss that accompanies diuretic treatment. Agents interfering with the generation of the negative luminal potential also impair potassium secretion, and this is the basis of reduced potassium secretion associated with potassium-sparing diuretics such as amiloride. Factors acting on the blood side of this tubular segment include plasma potassium and pH, such that hyperkalaemia and alkalosis both enhance potassium secretion directly. However, the most important factor in the acute and chronic adjustment of potassium secretion to match metabolic potassium load is aldosterone.

As shown in Figure 16.7, a negative feedback relationship exists between the plasma potassium concentration and aldosterone. In addition to its regulation by the renin–angiotensin system (see Fig. 20.19, p. 771), aldosterone is released from the adrenal cortex in direct response to an elevated plasma potassium. Aldosterone then acts on the kidney to enhance potassium secretion, hydrogen secretion and sodium reabsorption, in the late distal tubule and cortical collecting ducts. The resulting increased excretion of potassium maintains plasma potassium within a narrow range (3.3–4.7 mmol/L). Factors that reduce angiotensin II levels may indirectly affect potassium balance by blunting the rise in aldosterone that would otherwise be provoked by hyperkalaemia. This accounts for the increased risk of hyperkalaemia during therapy with ACE inhibitors and related drugs.

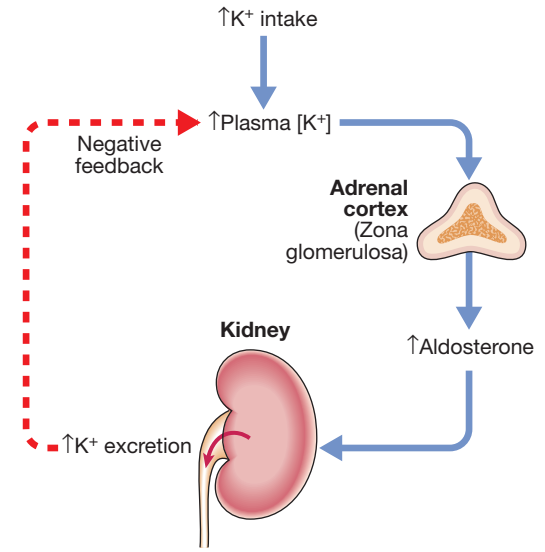

Fig. 16.7 Feedback control of plasma potassium concentration.

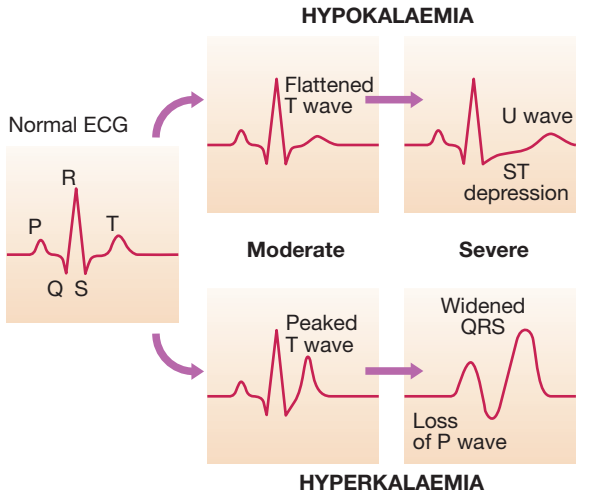

Fig. 16.8 The ECG in hypokalaemia and hyperkalaemia.

Presenting problems in disorders of potassium balance

Hypokalaemia

Aetiology and clinical assessment

Patients with mild hypokalaemia (plasma K 3.0–3.3 mmol/L) are generally asymptomatic, but more profound reductions in plasma potassium often lead to muscular weakness and associated tiredness. Ventricular ectopic beats or more serious arrhythmias may occur and the arrhythmogenic effects of digoxin may be potentiated. Typical ECG changes occur, affecting the T wave in particular (Fig. 16.8). Functional bowel obstruction may occur due to paralytic ileus. Long-standing hypokalaemia causes renal tubular damage (hypokalaemic nephropathy) and interferes with the tubular response to ADH (acquired nephrogenic diabetes insipidus), resulting in polyuria and polydipsia.

The main causes of hypokalaemia and an approach to the differential diagnosis are shown in Figure 16.9.

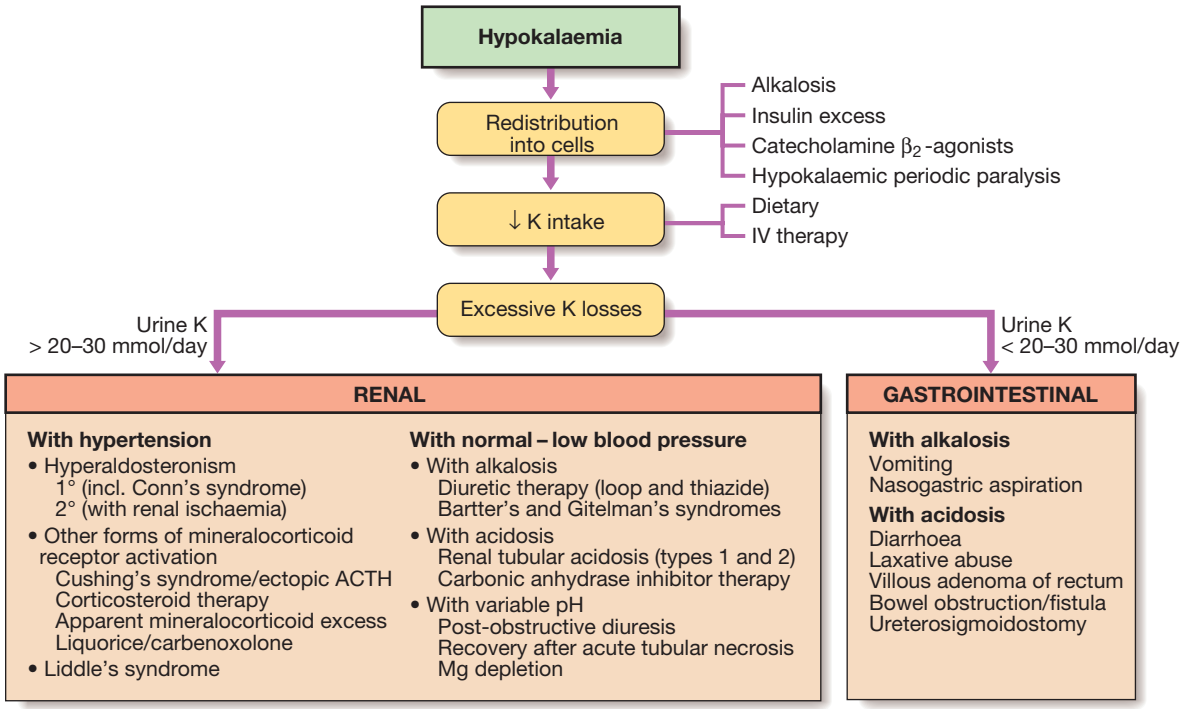

Fig. 16.9 Diagnostic decision tree for hypokalaemia. (ACTH = adrenocorticotrophic hormone)

Redistribution of potassium into cells should be considered, since correction of the factors involved (see above) may be sufficient to correct the plasma concentration. An inadequate intake of potassium can contribute to hypokalaemia but is unlikely to be the only cause, except in extreme cases. Generally, hypokalaemia is indicative of abnormal potassium loss from the body, either through the kidney or the gastrointestinal tract. When there is no obvious clinical clue to which pathway is involved, measurement of urinary potassium may be helpful; if the kidney is the route of potassium loss, the urine potassium is high (> 30 mmol/day), whereas if potassium is being lost through the gastrointestinal tract, the kidney retains potassium, resulting in a lower urinary potassium (generally < 20 mmol/day). It should be noted, however, that if gastrointestinal fluid loss is also associated with hypovolaemia, activation of the renin–angiotensin–aldosterone system may occur, causing increased loss of potassium in the urine.

Renal causes of hypokalaemia can be divided into those with and those without hypertension. Hypokalaemia in the presence of hypertension may be due to increased aldosterone secretion in Conn's syndrome (p. 780) or a genetic defect affecting sodium channels in the distal nephron (Liddle's syndrome). Excessive intake of liquorice or treatment with carbenoxolone may result in a similar clinical picture, due to inhibition of the renal 11βHSD2 enzyme, which inactivates cortisol in peripheral tissues.

If blood pressure is normal or low, hypokalaemia can be classified according to the associated change in acid–base balance. Inherited defects in tubular transport should be suspected when hypokalaemia occurs in association with alkalosis, provided that diuretic use has been excluded. One such disease is Bartter's syndrome, in which sodium reabsorption in the thick ascending limb of Henle is defective, usually due to a loss-of-function mutation of the NKCC2 transporter. The clinical and biochemical features are similar to chronic treatment with furosemide. In Gitelman's syndrome there is a loss-of-function mutation affecting the NCCT transporter in the early distal tubule. The clinical and biochemical features are similar to chronic thiazide treatment. Note that while both Bartter's and Gitelman's syndromes are characterised by hypokalaemia and hypomagnesaemia, urinary calcium excretion is increased in Bartter's syndrome but decreased in Gitelman's syndrome, analogous to the effects of the loop and thiazide diuretics, respectively, on calcium transport (see Box 16.11, p. 436).

If hypokalaemia occurs in the presence of a normal blood pressure and metabolic acidosis, renal tubular acidosis (proximal or 'classical' distal) should be suspected (p. 446).

When hypokalaemia is due to potassium wasting through the gastrointestinal tract, the cause is usually obvious clinically. In some cases, when there is occult induction of vomiting, the hypokalaemia is characteristically associated with metabolic alkalosis, due to loss of gastric acid. If, however, potassium loss has occurred through the surreptitious use of aperients, the hypokalaemia is generally associated with metabolic acidosis. In both cases, urinary potassium excretion is low unless there is significant extracellular volume depletion, which can raise urinary potassium levels by stimulating aldosterone production.

Investigations

Measurement of plasma electrolytes, bicarbonate, urine potassium and sometimes of plasma calcium and magnesium is usually sufficient to establish the diagnosis. If the diagnosis remains unclear, plasma renin should be

measured. Levels are low in patients with primary hyperaldosteronism (p. 780) and other forms of mineralocorticoid excess, but raised in other causes of hypokalaemia.

The cause of hypokalaemia may remain unclear despite the above investigations when urinary potassium measurements are inconclusive and the history is incomplete or unreliable. Many such cases are associated with metabolic alkalosis, and in this setting the measurement of urine chloride concentration can be helpful. A low urine chloride (< 30 mmol/L) is characteristic of vomiting (spontaneous or self-induced, in which chloride is lost in HCl in the vomit), while a urine chloride > 40 mmol/L suggests diuretic therapy (acute phase) or a tubular disorder such as Bartter's or Gitelman's syndrome. Differentiation between occult diuretic use and primary tubular disorders can be achieved by performing a screen of urine for diuretic drugs.

Management

Treatment of hypokalaemia involves first determining the cause and then correcting this where possible. If the problem is mainly one of redistribution of potassium into cells, reversal of this (for example, correction of alkalosis) may be sufficient to restore plasma potassium without providing supplements. In most cases, however, some form of potassium replacement will be required. This can generally be achieved with slow-release potassium chloride tablets, but in more acute circumstances intravenous potassium chloride may be necessary. The rate of administration depends on the severity of hypokalaemia and the presence of cardiac or neuromuscular complications, but should generally not exceed 10 mmol of potassium per hour. In patients with severe, life-threatening hypokalaemia, the concentration of potassium in the infused fluid may be increased to 40 mmol/L if a peripheral vein is used, but higher concentrations must be infused into a large 'central' vein with continuous cardiac monitoring.

In the less common situation where hypokalaemia occurs in the presence of systemic acidosis, alkaline salts of potassium, such as potassium bicarbonate, can be given by mouth. If magnesium depletion is also present, replacement of magnesium may also be required for hypokalaemia to be corrected since low cell magnesium can enhance the mechanism for tubular potassium secretion, causing ongoing urinary losses. In some circumstances, potassium-sparing diuretics, such as amiloride, can assist in the correction of hypokalaemia, hypomagnesaemia and metabolic alkalosis, especially when loop or thiazide diuretics are the underlying cause.

Hyperkalaemia

Aetiology and clinical assessment

Hyperkalaemia can present with progressive muscular weakness, but sometimes there are no symptoms until cardiac arrest occurs. The typical ECG changes are shown in Figure 16.8. Peaking of the T wave is an early ECG sign, but widening of the QRS complex presages a dangerous cardiac arrhythmia.

Hyperkalaemia may occur either because of redistribution of potassium between the ICF and ECF or because intake exceeds excretion. It is also important to remember that hyperkalaemia can also be artefactual due to in vitro haemolysis of blood specimens. An approach to defining the underlying cause of hyperkalaemia is shown in Figure 16.10. Redistribution of potassium from the ICF to the ECF may occur in the presence of systemic acidosis, or when the circulating levels of insulin, catecholamines and aldosterone are reduced or when the effects of these hormones are blocked (p. 440). High potassium intake may contribute to hyperkalaemia, but is seldom the only explanation unless renal excretion mechanisms are impaired.

Impaired excretion of potassium into the urine may be associated with a reduced GFR, as in acute kidney injury or chronic kidney disease. Acute kidney injury can be associated with severe hyperkalaemia when there is a concomitant potassium load, such as in rhabdomyolysis or in sepsis, particularly when acidosis is present. In chronic kidney disease, adaptation to moderately elevated plasma potassium levels commonly occurs. However, acute rises in potassium triggered by excessive dietary intake, hypovolaemia or drugs (see below) may occur and destabilise the situation.

Hyperkalaemia can also develop when tubular potassium secretory processes are impaired, even if the GFR is well maintained. In some cases, this is due to low levels of aldosterone, as occurs in Addison's disease or with ACE inhibitor therapy. Another cause is hyporeninaemic hypoaldosteronism where the renin–angiotensin system is inactivated. This condition typically occurs in association with diabetic nephropathy with neuropathy, and is thought to be due to impaired β-adrenergic stimulation of renin release. Other causes include angiotensin receptor antagonists, non-steroidal anti-inflammatory drugs (NSAIDs) and β-blocking drugs. In another group of conditions, tubular potassium secretion is impaired as the result of aldosterone resistance. This can occur in a variety of diseases in which there is inflammation of the tubulointerstitium, such as systemic lupus erythematosus; following renal transplantation; during treatment with potassium-sparing diuretics; and in a number of inherited disorders of tubular transport.

In all conditions of aldosterone deficiency or aldosterone resistance, hyperkalaemia may be associated with acid retention, giving rise to the pattern of hyperkalaemic distal ('type 4') renal tubular acidosis (p. 446).

Investigations

Measurement of electrolytes, creatinine and bicarbonate, when combined with clinical assessment, usually provides the explanation for hyperkalaemia. In aldosterone deficiency, plasma sodium concentration is characteristically low, although this can occur in many causes of hyperkalaemia. Addison's disease should be excluded unless there is an obvious alternative diagnosis, as described on page 777.

Management

Treatment of hyperkalaemia depends on its severity and the rate of development. In the absence of neuromuscular symptoms or ECG changes, reduction of potassium intake and correction of underlying abnormalities may be sufficient. However, in acute and/or severe hyperkalaemia (plasma K > 6.5–7.0 mmol/L) more urgent measures must be taken (Box 16.17).

If ECG changes are present, the first step should be infusion of 10 mL 10% calcium gluconate to stabilise conductive tissue membranes (calcium has the opposite

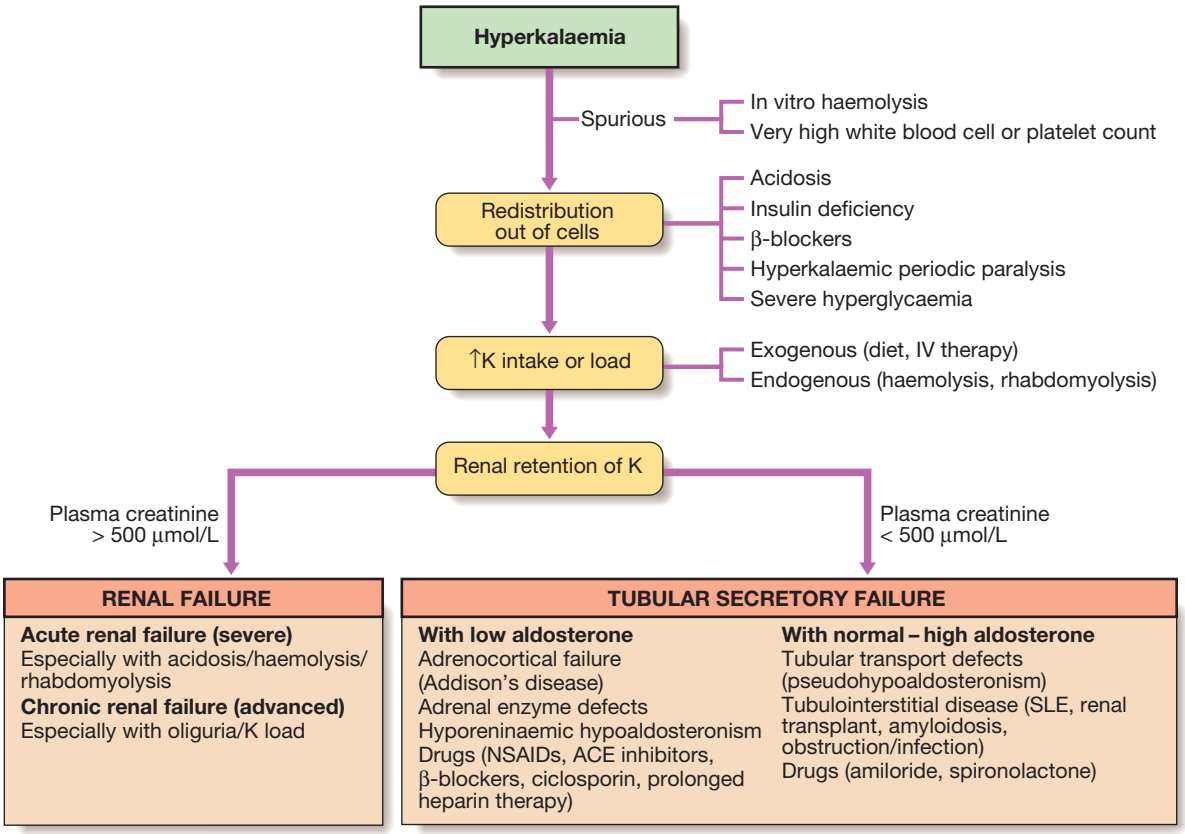

Fig. 16.10 Diagnostic decision tree for hyperkalaemia. Creatinine of 500 µmol/L = 5.67 mg/dL.

16.17 Treatment of severe hyperkalaemia

Objective	Therapy
Stabilise cell membrane potential[1]	IV calcium gluconate (10 mL of 10% solution)
Shift K into cells	Inhaled β_2-adrenoceptor agonist (e.g. salbutamol) IV glucose (50 mL of 50% solution) and insulin (5 U Actrapid®) IV sodium bicarbonate[2]
Remove K from body	IV furosemide and normal saline[3] Ion-exchange resin (e.g. Resonium®) orally or rectally Dialysis

[1]If ECG changes suggestive of hyperkalaemia (K typically > 7 mmol/L)
[2]If acidosis present. [3]If adequate residual renal function.

effect to potassium on conduction of an action potential). Measures to shift potassium from the ECF to the ICF should also be taken, as they generally act rapidly and may avert arrhythmias. Ultimately, a means of removing potassium from the body is generally necessary. When renal function is reasonably preserved, loop diuretics (accompanied by intravenous saline if hypovolaemia is present) may be effective; in established renal failure, ion-exchange resins acting through the gastrointestinal tract and urgent dialysis may be required.

DISORDERS OF ACID–BASE BALANCE

The pH of the arterial plasma is normally 7.40, corresponding to a H^+ concentration of 40 nmol/L. An increase in H^+ concentration corresponds to a decrease in pH. Under normal circumstances, H^+ concentrations do not vary outside the range of 36–44 nmol/L (pH 7.44–7.36), but abnormalities of acid–base balance occur in a wide range of diseases.

Functional anatomy and physiology of acid–base homeostasis

A variety of physiological mechanisms maintain pH of the ECF within narrow limits. The first is the action of blood and tissue buffers, of which the most important involves reaction of H^+ ions with bicarbonate to form carbonic acid, which, under the influence of the enzyme carbonic anhydrase (CA), dissociates to form CO_2 and water:

$$CO_2 + H_2O \underset{CA}{\rightleftharpoons} H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

This buffer system is important because bicarbonate is present at relatively high concentration in ECF (21–28 mmol/L), and two of its key components are under physiological control: CO_2 by the lungs, and bicarbonate by the kidneys. These relationships are illustrated in Figure 16.11 (a form of the Henderson–Hasselbalch equation).

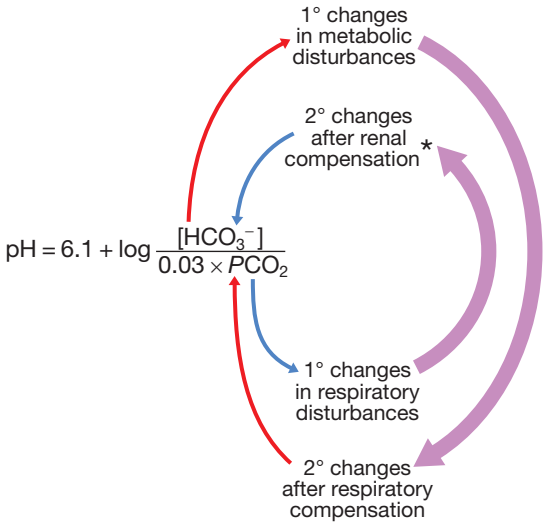

Fig. 16.11 Relationship between pH, PCO_2 (in mmHg) and plasma bicarbonate concentration (in mmol/L). *Note that changes in HCO_3^- concentration are also part of the renal correction for sustained metabolic acid–base disturbances as long as the kidney itself is not the cause of the primary disturbance.

Respiratory compensation for acid–base disturbances can occur quickly. In response to acid accumulation, pH changes in the brainstem stimulate ventilatory drive, serving to reduce PCO_2 and increase pH (p. 653). Conversely, systemic alkalosis leads to inhibition of ventilation, causing a rise in PCO_2 and reduction in pH, although it should be noted that this mechanism has limited capacity to change pH because hypoxia provides an alternative stimulus to drive ventilation.

The kidney provides a third line of defence against disturbances of arterial pH. When acid accumulates due to chronic respiratory or metabolic (non-renal) causes, the kidney has the long-term capacity to enhance urinary excretion of acid, effectively increasing the plasma bicarbonate.

Renal control of acid–base balance

Regulation of acid–base balance occurs at several sites in the kidney. The proximal tubule reabsorbs some 85% of the filtered bicarbonate ions, through the mechanism for H^+ secretion illustrated in Figure 16.3A (p. 431). This is dependent on the enzyme carbonic anhydrase both in the cytoplasm of the proximal tubular cells and on the luminal surface of the brush border membranes. The system has a high capacity but does not lead to significant acidification of the luminal fluid.

Distal nephron segments have an important role in determining net acid excretion by the kidney. In the intercalated cells of the cortical collecting duct and the outer medullary collecting duct cells, acid is secreted into the lumen by an H^+-ATPase. This excreted acid is generated in the tubular cell from the hydration of CO_2 to form carbonic acid, which dissociates into an H^+ ion secreted luminally, and a bicarbonate ion that passes across the basolateral membrane into the blood. The secreted H^+ ions contribute to the reabsorption of any residual bicarbonate present in the luminal fluid, but also contribute net acid for removal from the body, bound to a variety of urinary buffers, of which phosphate and ammonia are the most important. Filtered phosphate (HPO_4^{2-}) combines with H^+ in the distal tubular lumen to form dihydrogen phosphate ($H_2PO_4^-$), which is excreted in the urine with sodium. Ammonia (NH_3) is generated within tubular cells by deamination of the amino acid glutamine by the enzyme glutaminase. The NH_3 then reacts with secreted H^+ in the tubular lumen to form ammonium (NH_4^+), which becomes trapped in the luminal fluid and is excreted with chloride ions.

These two mechanisms remove approximately 1 mmol/kg of hydrogen ions from the body per day, which equates to the non-volatile acid load arising from the metabolism of dietary protein. The slightly alkaline plasma pH of 7.4 (H^+ 40 nmol/L) that is maintained during health can be accounted for by the kidney's ability to generate an acidic urine (pH typically 5–6), in which the net daily excess of metabolic acid produced by the body can be excreted.

Presenting problems in disorders of acid–base balance

Patients with disturbances of acid–base balance may present clinically either with the effects of tissue malfunction due to disturbed pH (such as altered cardiac and central nervous system function), or with secondary changes in respiration as a response to the underlying metabolic change (such as Kussmaul respiration during metabolic acidosis). The clinical picture is often dominated by the cause of the acid–base change, such as uncontrolled diabetes mellitus or primary lung disease. Frequently the acid–base disturbance only becomes evident when the venous plasma bicarbonate concentration is noted to be abnormal, or when a full arterial blood gas analysis shows abnormalities in pH, PCO_2 or bicarbonate. The 'base excess' or 'base deficit' can also be calculated from these data. This is the difference between the patient's bicarbonate level and the normal bicarbonate, measured in vitro with the PCO_2 adjusted to 5.33 kPa (40 mmHg). Calculation of the base excess or deficit is particularly useful in patients with combined respiratory and metabolic disorders (p. 187).

The most common patterns of abnormality in blood gas parameters are shown in Box 16.18. (Note that the terms acidosis and alkalosis strictly refer to the underlying direction of the acid–base change, while acidaemia and alkalaemia more correctly refer to the net change present in the blood). Interpretation of arterial blood gases is also described on page 653.

In metabolic disturbances, respiratory compensation is almost immediate, so that the predicted compensatory change in PCO_2 is achieved soon after the onset of the metabolic disturbance. In respiratory disorders, on the other hand, a small initial change in bicarbonate occurs as a result of chemical buffering of CO_2, largely within red blood cells, but over days and weeks the kidney achieves further compensatory changes in bicarbonate concentration as a result of long-term adjustments in acid secretory capacity. When the clinically obtained acid–base parameters do not accord with the predicted compensation shown, a mixed acid–base disturbance should be suspected (p. 447).

16.18 Principal patterns of acid–base disturbance

Disturbance	Blood H^+	Primary change	Compensatory response	Predicted compensation
Metabolic acidosis	> 40[1]	HCO_3^- < 24 mmol/L	PCO_2 < 5.33 kPa[2]	PCO_2 fall in kPa = 0.16 × HCO_3^- fall in mmol/L
Metabolic alkalosis	< 40[1]	HCO_3^- > 24 mmol/L	PCO_2 > 5.33 kPa[2,3]	PCO_2 rise in kPa = 0.08 × HCO_3^- rise in mmol/L
Respiratory acidosis	> 40[1]	PCO_2 > 5.33 kPa[2]	HCO_3^- > 24 mmol/L	Acute: HCO_3^- rise in mmol/L = 0.75 × PCO_2 rise in kPa Chronic: HCO_3^- rise in mmol/L = 2.62 × PCO_2 rise in kPa
Respiratory alkalosis	< 40[1]	PCO_2 < 5.33 kPa[2]	HCO_3^- < 24 mmol/L	Acute: HCO_3^- fall in mmol/L = 1.50 × PCO_2 fall in kPa Chronic: HCO_3^- fall in mmol/L = 3.75 × PCO_2 fall in kPa

[1]H^+ of 40 nmol/L = pH of 7.40. [2]PCO_2 of 5.33 kPa = 40 mmHg. [3]PCO_2 does not rise above 7.33 kPa (55 mmHg) because hypoxia then intervenes to drive respiration.

Metabolic acidosis

Aetiology and assessment

Metabolic acidosis occurs when an acid other than carbonic acid (due to CO_2 retention) accumulates in the body, resulting in a fall in the plasma bicarbonate. The pH fall that would otherwise occur is blunted by hyperventilation, resulting in a reduced PCO_2. If the kidneys are intact and the primary cause of acidosis is not renal in origin, the kidney can gradually increase acid secretion over days to weeks and restore a new steady state.

Two patterns of metabolic acidosis are recognised (Box 16.19), depending on the nature of the accumulating acid:

- In *pattern A*, when a mineral acid such as hydrochloric acid accumulates, or when there is a primary loss of bicarbonate buffer from the ECF, there is no addition to the plasma of a new acidic anion. In this case, the 'anion gap' (calculated as the difference between the main measured cations (Na^+ + K^+) and the anions (Cl^- + HCO_3^-)) is normal, since the plasma chloride increases to replace the depleted bicarbonate levels. This 'gap' is normally around 12–16 mmol/L (12–16 meq/L) and is made up of anions such as phosphate, sulphate and multiple negative charges on plasma protein molecules. Normal anion gap metabolic acidosis (pattern A) is usually due either to bicarbonate loss in diarrhoea, where the clinical diagnosis is generally obvious, or to renal tubular acidosis (see below).
- In *pattern B*, an accumulating acid is accompanied by its corresponding anion, which adds to the unmeasured anion gap, while the chloride concentration remains normal. The cause is usually apparent from associated clinical features such as uncontrolled diabetes mellitus, renal failure or shock, or may be suggested by associated symptoms, such as visual complaints in methanol poisoning (p. 222). It is noteworthy that a number of causes of increased anion gap acidosis are associated with alcoholism, including starvation ketosis, lactic acidosis and intoxication by methanol or ethylene glycol.

16.19 Causes of metabolic acidosis

Disorder	Mechanism
A. Normal anion gap	
Ingestion or infusion of inorganic acid	Therapeutic infusion of or poisoning with NH_4Cl, HCl
Gastrointestinal HCO_3 loss	Loss of HCO_3 in diarrhoea, small bowel fistula, urinary diversion procedure
Renal tubular acidosis (RTA)	Urinary loss of HCO_3 in proximal RTA; impaired tubular acid secretion in distal RTA
B. Increased anion gap	
Endogenous acid load	
Diabetic ketoacidosis	Accumulation of ketones[1] with hyperglycaemia (p. 811)
Starvation ketosis	Accumulation of ketones without hyperglycaemia (p. 800)
Lactic acidosis	Shock, liver disease, drugs
Renal failure	Accumulation of organic acids
Exogenous acid load	
Aspirin poisoning	Accumulation of salicylate[2]
Methanol poisoning	Accumulation of formate
Ethylene glycol poisoning	Accumulation of glycolate, oxalate

[1]Ketones include acid anions acetoacetate and β-hydroxybutyrate (p. 802). [2]Salicylate poisoning is also associated with respiratory alkalosis due to direct ventilatory stimulation.

Lactic acidosis

The diagnosis of lactic acidosis can be confirmed by the measurement of plasma lactate, which is increased over the normal maximal level of 2 mmol/L (20 mg/dL) by as much as tenfold. Two types of lactic acidosis have been defined:

- *type 1*, due to tissue hypoxia and peripheral generation of lactate, as in patients with circulatory failure and shock
- *type 2*, due to impaired metabolism of lactate, as in liver disease or by a number of drugs and toxins, including metformin, which inhibit lactate metabolism (p. 823).

Renal tubular acidosis

Renal tubular acidosis (RTA) should be suspected when there is a hyperchloraemic acidosis with a normal anion gap and no evidence of gastrointestinal disturbance. The urine pH is inappropriately high (> 5.5) in the presence of systemic acidosis. RTA can be caused by a defect in one of three processes: impaired bicarbonate reabsorption in the proximal tubule (proximal RTA); impaired acid secretion in the late distal tubule or cortical collecting duct intercalated cells (classical distal RTA); or impaired sodium reabsorption in the late distal tubule or cortical collecting duct, which is associated with reduced secretion of both potassium and H^+ ions (hyperkalaemic distal RTA).

Various subtypes of RTA are recognised and the most common causes are shown in Box 16.20. The inherited forms of RTA are due to mutations in the genes that regulate acid or bicarbonate transport in the renal tubules (see Fig. 16.3, p. 431). However, RTA is often an acquired disorder and in these circumstances the metabolic acidosis may serve as an early clue to the underlying diagnosis.

Sometimes distal RTA is 'incomplete' and the plasma bicarbonate concentration is normal under resting conditions. However, in incomplete distal RTA the urine pH fails to fall below 5.3 after an acid challenge test, involving the ingestion of ammonium chloride sufficient to lower the plasma bicarbonate.

A number of features allow differentiation of types of RTA. Proximal RTA is frequently associated with urinary wasting of amino acids, phosphate and glucose (Fanconi's syndrome), as well as bicarbonate and potassium. Patients with this disorder can lower the urine pH when the acidosis is severe and plasma bicarbonate levels have fallen below 16 mmol/L since distal H^+ secretion mechanisms are intact. In the classical form of distal RTA, however, acid accumulation is relentless and progressive, resulting in mobilisation of calcium from bone and consequent osteomalacia with hypercalciuria, renal stone formation and nephrocalcinosis. Potassium is also lost in classical distal RTA, while it is retained in hyperkalaemic distal RTA.

16.20 Causes of renal tubular acidosis

Proximal renal tubular acidosis	
• Inherited Fanconi's syndrome Cystinosis Wilson's disease	• Heavy metal toxicity Lead, cadmium and mercury poisoning
• Paraproteinaemia Myeloma	• Drugs Carbonic anhydrase inhibitors Ifosfamide
• Amyloidosis	
• Hyperparathyroidism	
Classical distal renal tubular acidosis	
• Inherited	• Hyperglobulinaemia
• Autoimmune diseases Systemic lupus erythematosus Sjögren's syndrome	• Toxins and drugs Toluene Lithium Amphotericin
Hyperkalaemic distal renal tubular acidosis	
• Hypoaldosteronism (primary or secondary)	• Drugs Amiloride Spironolactone
• Obstructive nephropathy	
• Renal transplant rejection	

Management

The first step in management of metabolic acidosis is to identify and correct the underlying cause when possible (see Box 16.19). This may involve controlling diarrhoea, treating diabetes mellitus, correcting shock, stopping drugs that might cause the condition, or using dialysis to remove toxins. Since metabolic acidosis is frequently associated with sodium and water depletion, resuscitation with intravenous fluids is often needed. Use of intravenous bicarbonate in this setting is controversial. Because rapid correction of acidosis can induce hypokalaemia or a fall in plasma ionised calcium, the use of bicarbonate infusions is best reserved for situations where the underlying disorder cannot be readily corrected and acidosis is severe (H^+ > 100 nmol/L, pH < 7.00) or associated with evidence of tissue dysfunction.

The acidosis in RTA can sometimes be controlled by treating the underlying cause (see Box 16.20), but supplements of sodium and potassium bicarbonate are usually also necessary in types 1 and 2 RTA to achieve a target plasma bicarbonate level of above 18 mmol/L and normokalaemia. In type 4 RTA, loop diuretics, thiazides or fludrocortisone (as appropriate to the underlying diagnosis) may be effective in correcting the acidosis and the hyperkalaemia.

Metabolic alkalosis

Aetiology and clinical assessment

Metabolic alkalosis is characterised by an increase in the plasma bicarbonate concentration and the plasma pH (see Box 16.18). There is a compensatory rise in PCO_2 due to hypoventilation but this is limited by the need to avoid hypoxia. The causes are best classified by the accompanying changes in ECF volume.

Hypovolaemic metabolic alkalosis is the most common pattern. This can be caused by sustained vomiting, in which acid-rich fluid is lost directly from the body, or by treatment with loop diuretics or thiazides. In the case of sustained vomiting, loss of gastric acid is the immediate cause of the alkalosis, but several factors act to sustain or amplify this in the context of volume depletion (Fig. 16.12). Loss of sodium and fluid leads to hypovolaemia and secondary hyperaldosteronism, triggering proximal sodium bicarbonate reabsorption and additional acid secretion by the distal tubule. Hypokalaemia occurs due to potassium loss in the vomitus and by the kidney as the result of secondary hyperaldosteronism, and itself is a stimulus to acid secretion. Additionally, the compensatory rise in PCO_2 further enhances tubular acid secretion. The net result is sustained metabolic alkalosis with an inappropriately acid urine, which cannot be corrected until the deficit in circulating volume has been replaced.

Normovolaemic (or hypervolaemic) metabolic alkalosis occurs when bicarbonate retention and volume expansion occur simultaneously. Classical causes include primary hyperaldosteronism (Conn's syndrome, p. 780), Cushing's syndrome (p. 773) and corticosteroid therapy (p. 776). Occasionally, overuse of antacid salts for treatment of dyspepsia produces a similar pattern.

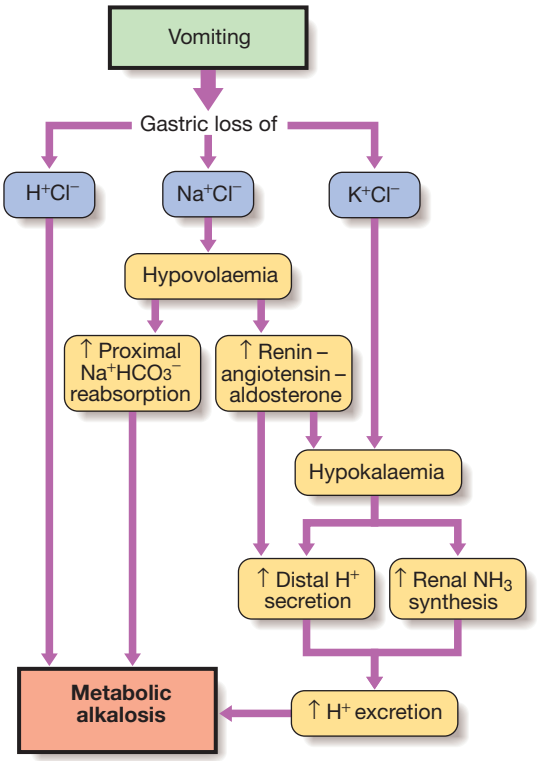

Fig. 16.12 Generation and maintenance of metabolic alkalosis during prolonged vomiting. Loss of H^+Cl^- generates metabolic alkalosis, which is maintained by renal changes.

Clinically, apart from manifestations of the underlying cause, there may be few symptoms or signs related to alkalosis itself. When the rise in systemic pH is abrupt, plasma ionised calcium falls and signs of increased neuromuscular irritability, such as tetany, may develop (p. 768).

Management

Metabolic alkalosis with hypovolaemia can be corrected by intravenous infusions of 0.9% saline with potassium supplements. This reverses the secondary hyperaldosteronism and allows the kidney to excrete the excess alkali in the urine.

In metabolic alkalosis with normal or increased volume, treatment should focus on management of the underlying endocrine cause (Ch. 20).

Respiratory acidosis

Respiratory acidosis occurs when there is accumulation of CO_2 due to type II respiratory failure (p. 663). This results in a rise in the PCO_2, with a compensatory increase in plasma bicarbonate concentration, particularly when the disorder is of long duration and the kidney has fully developed its capacity for increased acid excretion.

This acid–base disturbance can arise from lesions anywhere along the neuromuscular pathways from the brain to the respiratory muscles that result in impaired ventilation. It can also arise during intrinsic lung disease if there is significant mismatching of ventilation and perfusion.

Clinical features are primarily those of the underlying cause of the respiratory disorder such as paralysis, chest wall injury or chronic obstructive lung disease, but the CO_2 accumulation may itself lead to drowsiness that further depresses respiratory drive.

Management involves correction of causative factors where possible, but ultimately ventilatory support may be necessary.

Respiratory alkalosis

Respiratory alkalosis develops when there is a period of sustained hyperventilation, resulting in a reduction of PCO_2 and increase in plasma pH. If the condition is sustained, renal compensation occurs, such that tubular acid secretion is reduced and the plasma bicarbonate falls.

Respiratory alkalosis is usually of short duration, occurring in anxiety states or as the result of overvigorous assisted ventilation. It can be prolonged in the context of pregnancy, pulmonary embolism, chronic liver disease, and ingestion of certain drugs such as salicylates that directly stimulate the respiratory centre in the brainstem.

Clinical features are those of the underlying cause but agitation associated with perioral and digital tingling may also occur, due to a reduction in ionised calcium concentrations because of increased binding of calcium to albumin as the result of the alkalosis. In severe cases, Trousseau's sign and Chvostek's sign may be positive, and tetany or seizures may develop (p. 768).

Management involves correction of identifiable causes, reduction of anxiety, and a period of rebreathing into a closed bag to allow CO_2 levels to rise.

Mixed acid–base disorders

It is not uncommon for more than one disturbance of acid–base metabolism to be present at the same time in the same patient: for example, respiratory acidosis due to narcotic overdose with metabolic alkalosis due to vomiting. In these situations, the arterial pH will represent the net effect of all primary and compensatory changes. Indeed, the pH may be normal, but the presence of underlying acid–base disturbances can be gauged from concomitant abnormalities in the PCO_2 and bicarbonate concentration.

In assessing these disorders, all clinical influences on the patient's acid–base status should be identified, and reference should be made to the table of predicted compensation given in Box 16.18. If the compensatory change is discrepant from the rules of thumb provided, more than one disturbance of acid–base metabolism may be suspected.

DISORDERS OF DIVALENT ION METABOLISM

The present section excludes discussion of calcium disorders, which are considered in Chapters 20 (pp. 767–770) and 25 (p. 1125).

Functional anatomy and physiology of magnesium metabolism

Like potassium, magnesium is mainly an intracellular cation. It is important to the function of many enzymes,

including the Na,K-ATPase, and can regulate both potassium and calcium channels. Its overall effect is to stabilise excitable cell membranes.

Renal handling of magnesium involves filtration of free plasma magnesium at the glomerulus (about 70% of the total) with extensive reabsorption (50–70%) in the loop of Henle, and other parts of the proximal and distal renal tubule. Magnesium reabsorption is also enhanced by parathyroid hormone (PTH).

Presenting problems in disorders of magnesium metabolism

Hypomagnesaemia

Aetiology and clinical assessment

Hypomagnesaemia exists when plasma magnesium concentrations are below the reference range of 0.75–1.0 mmol/L (1.5–2.0 meq/L). This is usually a reflection of magnesium depletion (Box 16.21), which can be caused by excessive magnesium loss from the gastrointestinal tract (notably in chronic diarrhoea) or the kidney (during prolonged use of loop diuretics). Excessive alcohol ingestion can cause magnesium depletion through both gut and renal losses. Some inherited tubular transport disorders, such as Gitelman's syndrome, can also result in urinary magnesium wasting (p. 440).

Hypomagnesaemia is frequently associated with hypocalcaemia, probably because magnesium is required for the normal secretion of PTH in response to a fall in serum calcium, and because hypomagnesaemia causes end-organ resistance to PTH. The clinical features of hypomagnesaemia and hypocalcaemia are similar in that tetany, cardiac arrhythmias (notably torsades de pointes, p. 570), central nervous excitation and seizures, vasoconstriction and hypertension may all occur. Magnesium depletion is also associated (through uncertain mechanisms) with hyponatraemia and hypokalaemia, which may contribute to some of the clinical manifestations.

16.21 Causes of hypomagnesaemia

Mechanism	Examples
Inadequate intake	Starvation Malnutrition (esp. alcoholism) Parenteral alimentation
Excessive losses	
Gastrointestinal	Prolonged vomiting/nasogastric aspiration Chronic diarrhoea/laxative abuse Malabsorption Small bowel bypass surgery Fistulae
Urinary	Diuretic therapy (loop, thiazide) Alcohol Tubulotoxic drugs (gentamicin, cisplatin) Volume expansion (e.g. primary hyperaldosteronism) Diabetic ketoacidosis Post-obstructive diuresis Recovery from acute tubular necrosis Inherited tubular transport defect (Bartter's syndrome, Gitelman's syndrome Primary renal magnesium wasting)
Miscellaneous	Acute pancreatitis Foscarnet therapy Proton pump inhibitor therapy (prolonged) Hungry bone syndrome Diabetes mellitus

Management

The underlying cause should be identified and treated where possible. When symptoms are present, the treatment of choice is intravenous magnesium chloride at a rate not exceeding 0.5 mmol/kg in the first 24 hours. When intravenous access is not available, magnesium sulphate can be given intramuscularly. Oral magnesium salts have limited effectiveness due to poor absorption and may cause diarrhoea. If hypomagnesaemia is due to diuretic treatment, adjunctive use of a potassium-sparing agent can also help by reducing magnesium loss into the urine.

Hypermagnesaemia

This is a much less common abnormality than hypomagnesaemia. Predisposing conditions include acute kidney injury and chronic kidney disease, and adrenocortical insufficiency. The condition is generally precipitated in patients at risk by an increased intake of magnesium, or through the use of magnesium-containing medications, such as antacids, laxatives and enemas.

Clinical features include bradycardia, hypotension, reduced consciousness and respiratory depression.

Management involves ceasing all magnesium-containing drugs and reducing dietary magnesium intake, improving renal function if possible, and promoting urinary magnesium excretion using a loop diuretic with intravenous hydration, if residual renal function allows. Calcium gluconate may be given intravenously to ameliorate cardiac effects. Dialysis may be necessary in patients with poor renal function.

Functional anatomy and physiology of phosphate metabolism

Inorganic phosphate (mainly present as HPO_4^{2-}) is intimately involved in cell energy metabolism, intracellular signalling and bone and mineral balance (Ch. 25). The normal plasma concentration is 0.8–1.4 mmol/L (2.48–4.34 mg/dL). It is freely filtered at the glomerulus and approximately 65% is reabsorbed by the proximal tubule, via an apical sodium–phosphate co-transport carrier. A further 10–20% is reabsorbed in the distal tubules, leaving a fractional excretion of some 10% to pass into the urine, usually as $H_2PO_4^-$. Proximal reabsorption is decreased by PTH, fibroblast growth factor 23 (FGF-23), volume expansion, osmotic diuretics and glucose infusion.

Presenting problems in disorders of phosphate metabolism

Hypophosphataemia

The causes of hypophosphataemia are shown in Box 16.22. Phosphate may redistribute into cells during

16.22 Causes of hypophosphataemia

Mechanism	Examples
Redistribution into cells	Refeeding after starvation Respiratory alkalosis Treatment for diabetic ketoacidosis
Inadequate intake or absorption	Malnutrition Malabsorption Chronic diarrhoea Phosphate binders (antacids) Vitamin D deficiency or resistance
Increased renal excretion	Hyperparathyroidism ECF volume expansion with diuresis Osmotic diuretics Fanconi's syndrome Familial hypophosphataemic rickets Tumour-induced hypophosphataemic rickets

periods of increased energy utilisation (such as refeeding after a period of starvation) and during systemic alkalosis. However, severe hypophosphataemia usually represents an overall body deficit due to either inadequate intake or absorption through the gut, or excessive renal losses, most notably in primary hyperparathyroidism (p. 769) or as the result of acute plasma volume expansion, osmotic diuresis and diuretics acting on the proximal renal tubule. Less common causes include inherited defects of proximal sodium–phosphate co-transport and tumour-induced osteomalacia due to ectopic production of the hormone FGF-23 (p. 1125).

The clinical manifestations of phosphate depletion are wide-ranging, reflecting the involvement of phosphate in many aspects of metabolism. Defects appear in the blood (impaired function and survival of all cell lines), skeletal muscle (weakness, respiratory failure), cardiac muscle (congestive cardiac failure), smooth muscle (ileus), central nervous system (decreased consciousness, seizures and coma) and bone (osteomalacia in severe prolonged hypophosphataemia, p. 1125).

Management involves administering oral phosphate supplements and high-protein/high-dairy dietary supplements that are rich in naturally occurring phosphate. Intravenous treatment with sodium or potassium phosphate salts can be used in critical situations, but there is a risk of precipitating hypocalcaemia and metastatic calcification.

Hyperphosphataemia

Phosphate accumulation is usually the result of acute kidney injury or chronic kidney disease (pp. 768 and 483, and p. 768). Phosphate excretion is also reduced in hypoparathyroidism and pseudohypoparathyroidism (p. 770). Redistribution of phosphate from cells into the plasma can also be a contributing factor in the 'tumour lysis' syndrome and in catabolic states. Phosphate accumulation is aggravated in any of these conditions if the patient takes phosphate-containing preparations or inappropriate vitamin D therapy.

The clinical features relate to hypocalcaemia and metastatic calcification, particularly in chronic renal failure with tertiary hyperparathyroidism (when a high calcium–phosphate product occurs).

If renal function is normal, intravenous normal saline should be given to promote phosphate excretion. Hyperphosphataemia in patients with renal failure should be treated with dietary phosphate restriction and the use of oral phosphate binders (p. 486).

DISORDERS OF AMINO ACID METABOLISM

Congenital disorders of amino acid metabolism usually present in the neonatal period and may involve life-long treatment regimens. However, some disorders, particularly those involved in amino acid transport, may not present until later in life.

Phenylketonuria

Phenylketonuria (PKU) is inherited as an autosomal recessive disorder caused by loss-of-function mutations in the *PAH* gene, which encodes phenylalanine hydroxylase, an enzyme required for degradation of phenylalanine. As a result, phenylalanine accumulates at high levels in the neonate's blood, causing mental retardation.

The diagnosis of PKU is almost always made by routine neonatal screening (p. 64). Treatment involves life-long adherence to a low-phenylalanine diet. Early and adequate dietary treatment prevents major mental retardation, although there may still be a slight reduction in IQ.

Homocystinuria

Homocystinuria is an autosomal recessive disorder caused by loss-of-function mutations in the *CBS* gene, which encodes cystathionine beta–synthase. The enzyme deficiency causes accumulation of homocysteine and methionine in the blood. Many cases of homocystinuria are diagnosed through newborn screening programmes.

Clinical manifestations are wide-ranging and involve the eyes (ectopia lentis – displacement of the lens), central nervous system (mental retardation, delayed developmental milestones, seizures, psychiatric disturbances), skeleton (resembling Marfan's syndrome, and also with generalised osteoporosis), vascular system (thrombotic lesions of arteries and veins) and skin (hypopigmentation).

Treatment is dietary, involving a methionine-restricted, cystine-supplemented diet, as well as large doses of pyridoxine.

DISORDERS OF CARBOHYDRATE METABOLISM

The most common disorder of carbohydrate metabolism is diabetes mellitus, which is discussed in Chapter 21. There are also some rare inherited defects.

Galactosaemia

Galactosaemia is caused by loss-of-function mutations in the *GALT* gene, which encodes galactose-1-phosphate uridyl transferase. It is usually inherited as an autosomal recessive disorder. The neonate is unable to metabolise galactose, one of the hexose sugars contained in lactose.

Vomiting or diarrhoea usually begins within a few days of ingestion of milk, and the neonate may become jaundiced. Failure to thrive is the most common clinical presentation. The classic form of the disease results in hepatomegaly, cataracts and mental retardation, and fulminant infection with *Escherichia coli* is a frequent complication. Treatment involves life-long avoidance of galactose- and lactose-containing foods.

The widespread inclusion of galactosaemia in newborn screening programmes has resulted in the identification of a number of milder variants.

Glycogen storage diseases

Glycogen storage diseases (GSD, or glycogenoses) result from an inherited defect in one of the many enzymes responsible for the formation or breakdown of glycogen, a complex carbohydrate that can be broken down quickly to release glucose during exercise or between meals.

There are several major types of GSD, which are classified by a number, by the name of the defective enzyme or eponymously after the physician who first described the condition (Box 16.23). Most forms of GSD are inherited as autosomal recessive disorders.

A diagnosis of GSD is made on the basis of the symptoms, physical examination and results of biochemical tests. Occasionally, a muscle or liver biopsy is required to confirm the enzyme defect. Different types of GSD present at different ages, and some may require life-long modifications of diet and lifestyle.

DISORDERS OF COMPLEX LIPID METABOLISM

Complex lipids are key components of the cell membrane (p. 47) that are normally catabolised in organelles called lysosomes. The lysosomal storage diseases are a heterogeneous group of disorders caused by loss-of-function mutations in various lysosomal enzymes (Box 16.24), resulting in an inability to break down complex glycolipids or other intracellular macromolecules. These disorders have diverse clinical manifestations, typically including mental retardation. Some can be treated with enzyme replacement therapy, while others (such as Tay–Sachs disease) can be prevented through community participation in genetic carrier screening programmes (p. 64).

DISORDERS OF BLOOD LIPIDS AND LIPOPROTEINS

The three most important classes of lipid are cholesterol, which is composed of hydrocarbon rings; triglycerides (TG), which are esters composed of glycerol linked to three long-chain fatty acids; and phospholipids, which are composed of a hydrophobic 'tail' consisting of two long-chain fatty acids linked through glycerol to a hydrophilic head containing a phosphate group. Phospholipids are present in cell membranes and are important signalling molecules.

Despite their poor water solubility, lipids need to be absorbed from the gastrointestinal tract and transported throughout the body. This is achieved by incorporating lipids within lipoproteins. Plasma cholesterol and TG are clinically important because they are major treatable risk factors for cardiovascular disease, whilst severe hypertriglyceridaemia also predisposes to acute pancreatitis.

Functional anatomy, physiology and investigation of lipid metabolism

Lipids are transported and metabolised by apolipoproteins, which combine with lipids to form spherical or disc-shaped lipoproteins, consisting of a hydrophobic core and a less hydrophobic coat (Fig. 16.13). The structure of some apolipoproteins also enables them to act as enzyme co-factors or cell receptor ligands. Variations in lipid and apolipoprotein composition result in distinct classes of lipoprotein that perform specific metabolic functions.

Processing of dietary lipid

The intestinal absorption of dietary lipid is described on page 841 (see also Fig. 16.14). Enterocytes lining the gut extract monoglyceride and free fatty acids from micelles and re-esterify them into TG, which are combined with a truncated form of apolipoprotein B (Apo B48) as it is synthesised. Intestinal cholesterol derived from dietary

16.23 Glycogen storage diseases

Type	Eponym	Enzyme deficiency	Clinical features and complications
I	Von Gierke	Glucose-6-phosphatase	Childhood presentation, hypoglycaemia, hepatomegaly
II	Pompe	α-glucosidase (acid maltase)	Classical presentation in infancy, muscle weakness (may be severe)
III	Cori	Glycogen debrancher enzyme	Childhood presentation, hepatomegaly, mild hypoglycaemia
IV	Andersen	Brancher enzyme	Presentation in infancy, severe muscle weakness (may affect heart), cirrhosis
V	McArdle	Muscle glycogen phosphorylase	Exercise-induced fatigue and myalgia
VI	Hers	Liver phosphorylase	Mild hepatomegaly
VII	Tarui	Muscle phosphofructokinase	Exercise-induced fatigue and myalgia
IX*		Liver phosphorylase kinase	Mild hepatomegaly
0		Hepatic glycogen synthase	Fasting hypoglycaemia, post-prandial hyperglycaemia

*Note that type VIII has been merged into type IX and no longer exists as a separate entity.

16.24 Lysosomal storage diseases

Lysosomal storage disease	Clinical features	Enzyme deficiency	Human enzyme replacement therapy
Fabry disease	Variable age of onset Neurological (pain in extremities) Dermatological (hypohidrosis, angiokeratomas) Cerebrovascular (renal, cardiac, central nervous system)	α-galactosidase A	In clinical practice
Gaucher disease (various types)	Splenic and liver enlargement, with variable severity of disease Some types also have neurological involvement	Glucocerebrosidase	In clinical practice for some types
Mucopolysaccharidosis (MPS) (various types, including Hurler's, Hunter's, Sanfilippo's and Morquio's syndromes)	Vary with syndrome. Can cause mental retardation, skeletal and joint abnormalities, abnormal facies, obstructive respiratory diseases and recurrent respiratory infections	Each MPS type has a different enzyme deficiency	In clinical practice for some types; clinical trials under way for other types
Niemann–Pick disease	Most common presentation is as a progressive neurological disorder, accompanied by organomegaly Some variants do not have neurological symptoms	Acid sphingomyelinase	Clinical trials planned for some types
GM2-gangliosidosis (various types, including Tay–Sachs and Sandhoff diseases)	Severe progressive neurological disorder. Sandhoff disease also characterised by organomegaly	Hexosaminidase A, B	

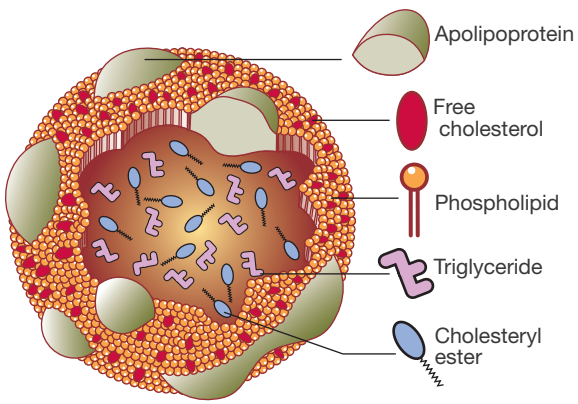

Fig. 16.13 Structure of lipoproteins.

and biliary sources is also absorbed via a specific intestinal membrane transporter termed NPC1L1. This produces chylomicrons containing TG and cholesterol ester that are secreted basolaterally into lymphatic lacteals and carried to the circulation through the thoracic duct. Upon entering the blood stream, nascent chylomicrons are modified by further addition of apolipoproteins. Chylomicron TG are hydrolysed by lipoprotein lipase located on the endothelium of tissue capillary beds. This releases fatty acids that are used locally for energy production or stored as TG in muscle or fat. The residual 'remnant' chylomicron particle is avidly cleared by low-density lipoprotein (LDL)-receptors in the liver, which recognise Apo E on the remnant lipoproteins. Complete absorption of dietary lipids takes about 6–10 hours, so chylomicrons are usually undetectable in the plasma after a 12-hour fast.

The main dietary determinants of plasma cholesterol concentrations are the intake of saturated and trans-unsaturated fatty acids, which reduce LDL-receptor activity (see below). Dietary cholesterol has surprisingly little effect on fasting cholesterol levels. Plant sterols and drugs that inhibit cholesterol absorption are effective because they also reduce the re-utilisation of biliary cholesterol. The dietary determinants of plasma TG concentrations are complex since excessive intake of carbohydrate, fat or alcohol may all contribute to increased plasma TG by different mechanisms.

Endogenous lipid synthesis

In the fasting state, the liver is the major source of plasma lipids (see Fig. 16.14). The liver may acquire lipids by uptake, synthesis or conversion from other macronutrients. These lipids are transported to other tissues by secretion of very low-density lipoproteins (VLDL), which are rich in TG but differ from chylomicrons in that they contain full-length Apo B100. Following secretion into the circulation, VLDL undergo metabolic processing similar to that of chylomicrons. Hydrolysis of VLDL TG releases fatty acids to tissues and converts VLDL into 'remnant' particles, referred to as intermediate-density lipoproteins (IDL). Most IDL are rapidly cleared by LDL receptors in the liver, but some are processed by hepatic lipase, which converts the particle to an LDL by removing TG and most materials other than Apo B100, and free and esterified cholesterol.

The LDL particles act as a source of cholesterol for cells and tissues (see Fig. 16.14). LDL cholesterol is internalised by receptor-mediated endocytosis via the LDL receptor. Delivery of cholesterol via this pathway down-regulates further expression of the LDL receptor gene and reduces the synthesis and activity of

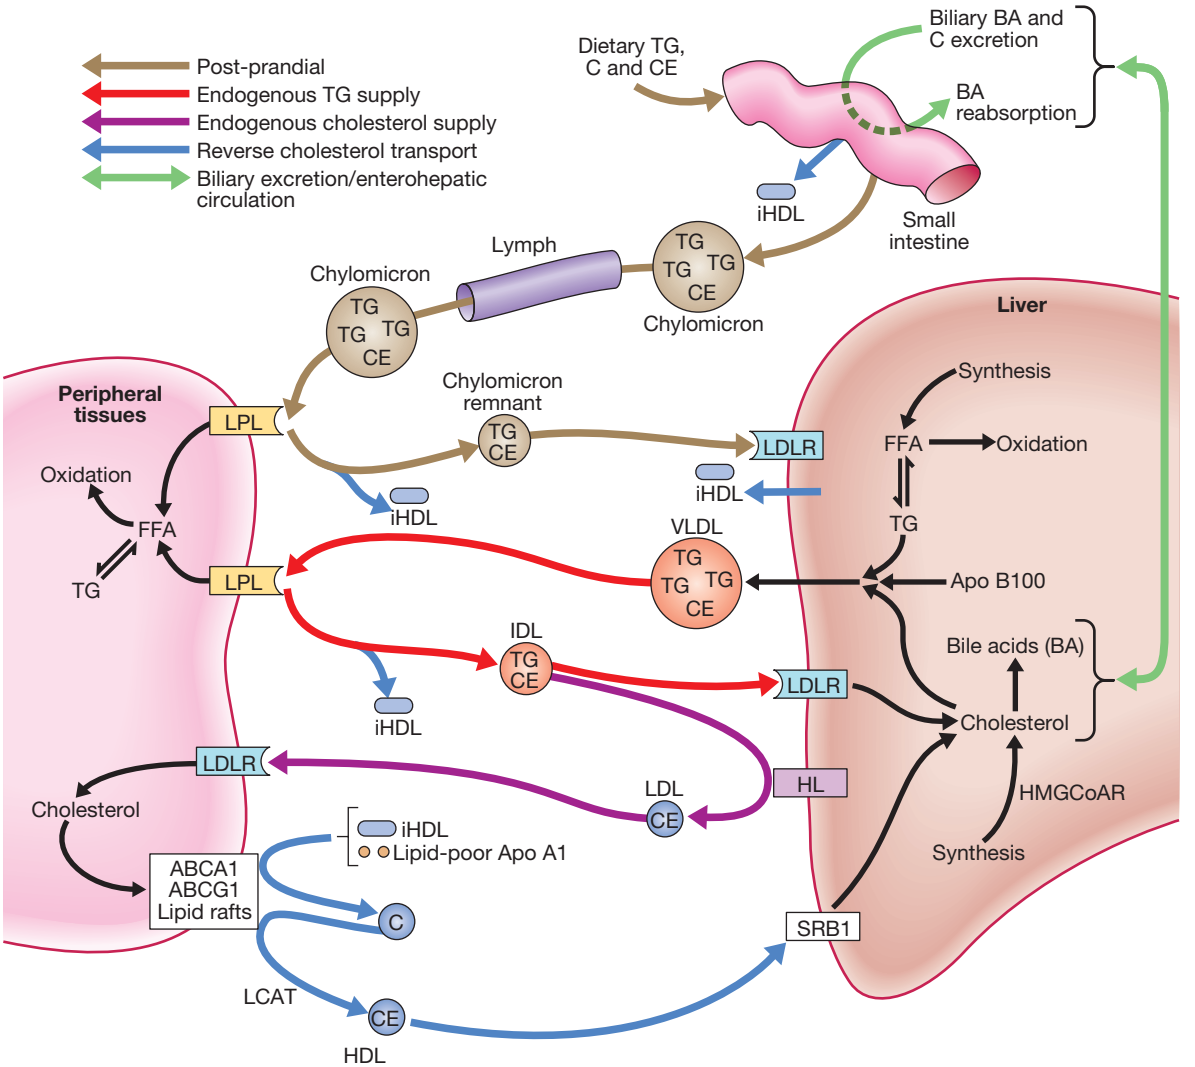

Fig. 16.14 Absorption, transport and storage of lipids. Pathways of lipid transport are shown; in addition, cholesterol ester transfer protein exchanges triglyceride and cholesterol ester between VLDL/chylomicrons and HDL/LDL, and free fatty acids released from peripheral lipolysis can be taken up in the liver. (ABCA1/ABCG1 = ATP-binding cassette A1/G1; Apo = apolipoprotein; BA = bile acids; C = cholesterol; CE = cholesterol ester; FFA = free fatty acids; HDL = mature high-density lipoprotein; HL = hepatic lipase; HMGCoAR = hydroxy-methyl-glutaryl-coenzyme A reductase; IDL = intermediate-density lipoprotein; iHDL = immature high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor (Apo B100 receptor); LPL = lipoprotein lipase; SRB1 = scavenger receptor B1; TG = triglyceride; VLDL = very low-density lipoprotein)

the rate-limiting enzyme for cholesterol synthesis, HMGCoA reductase. This negative feedback loop, together with the modulation of cholesterol esterification, controls the intracellular free cholesterol level within a narrow range.

Reverse cholesterol transport

Peripheral tissues are further guarded against excessive cholesterol accumulation by high-density lipoproteins (HDL; see Fig. 16.14). Lipid-poor Apo A1 (derived from the liver, intestine and the outer layer of chylomicrons and VLDL) accepts cellular cholesterol and phospholipid from a specific membrane transporter known as the ATP-binding cassette A1 (ABCA1). This produces small HDL that are able to accept more free cholesterol from cholesterol-rich regions of the cell membrane known as 'rafts' via another membrane transporter (ABCG1). The cholesterol that has been accepted by these small HDL is esterified by lecithin cholesterol acyl transferase (LCAT), thus maintaining an uptake gradient and remodelling the particle into a mature spherical HDL. These HDL release their cholesterol to the liver and other cholesterol-requiring tissues via the scavenger receptor B1 (SRB1).

The cholesterol ester transfer protein (CETP) in plasma allows transfer of cholesterol from HDL or LDL to VLDL or chylomicrons in exchange for TG. When TG is elevated, the action of CETP may reduce HDL cholesterol and remodel LDL into 'small, dense' LDL particles that appear to be more atherogenic in the blood vessel wall. Animal species that lack CETP are resistant to atherosclerosis.

Lipids and cardiovascular disease

Plasma lipoprotein levels are major modifiable risk factors for cardiovascular disease. Increased levels of

atherogenic lipoproteins (especially LDL, but also IDL, lipoprotein(a) and possibly chylomicron remnants) contribute to the development of atherosclerosis (p. 579). Increased plasma concentration and reduced diameter favour subendothelial accumulation of these lipoproteins. Following chemical modifications such as oxidation, Apo B-containing lipoproteins are no longer cleared by normal mechanisms. They trigger a self-perpetuating inflammatory response during which they are taken up by macrophages to form foam cells, a hallmark of atherosclerotic lesions. These processes also have an adverse effect on endothelial function.

Conversely, HDL removes cholesterol from the tissues to the liver, where it is metabolised and excreted in bile. HDL may also counteract some components of the inflammatory response, such as the expression of vascular adhesion molecules by the endothelium. Consequently, low HDL cholesterol levels, which are often associated with TG elevation, also predispose to atherosclerosis.

Lipid measurement

Abnormalities of lipid metabolism most commonly come to light following routine blood testing. Measurement of plasma cholesterol alone is not sufficient for comprehensive assessment. Levels of total cholesterol (TC), triglyceride (TG) and HDL cholesterol (HDL-C) need to be obtained after a 12-hour fast to permit accurate calculation of LDL cholesterol (LDL-C) according to the Friedewald formula (LDL-C = TC – HDL-C – (TG/2.2) mmol/L; or LDL-C = TC – HDL-C – (TG/5) mg/dL). The formula becomes unreliable when TG levels exceed 4 mmol/L (350 mg/dL). Other risk markers, such as NHDL-C (non-HDL-C, calculated as the difference between TC and HDL-C levels) or Apo B, may assess risk of cardiovascular disease more accurately than LDL-C when TG levels are increased. Furthermore, non-fasting samples are often used to guide therapeutic decisions since they are unaffected in terms of TC and measured LDL-C, albeit that they differ from fasting samples in terms of TG, HDL-C and, to some extent, calculated LDL-C. Consideration must be given to confounding factors, such as recent illness, after which cholesterol, LDL and HDL levels temporarily decrease in proportion to severity. Results that will affect major decisions, such as initiation of drug therapy, should be confirmed with a repeat measurement.

Elevated levels of TG are common in obesity, diabetes and insulin resistance (Chs 5 and 21), and are frequently associated with low HDL and increased 'small, dense' LDL. Under these circumstances, LDL-C may underestimate risk. This is one situation in which measurement of Apo B may provide additional useful information.

Presenting problems in disorders of lipids

Lipid measurements are usually performed for the following reasons:

- screening for primary or secondary prevention of cardiovascular disease
- investigation of patients with clinical features of lipid disorders (Fig. 16.15) and their relatives
- monitoring of response to diet, weight control and medication.

Aetiology and clinical assessment

The first step is to consider the effect of other diseases and drugs (Box 16.25). Overt or subclinical hypothyroidism (p. 743) may cause hypercholesterolaemia, and so measurement of thyroid function is warranted in most cases, even in the absence of typical symptoms and signs.

Once secondary causes are excluded, primary lipid abnormalities may be diagnosed. Primary lipid abnormalities can be classified according to the predominant lipid problem: hypercholesterolaemia, hypertriglyceridaemia or mixed hyperlipidaemia (Box 16.26). Although single-gene disorders are encountered in all three categories, most cases are due to multiple-gene (polygenic) loci interacting with environmental factors. Clinical consequences of dyslipidaemia vary somewhat between these causes (see Fig. 16.15).

16.25 Causes of secondary hyperlipidaemia

Secondary hypercholesterolaemia

Moderately common

- Hypothyroidism
- Pregnancy
- Cholestatic liver disease
- Drugs (diuretics, ciclosporin, corticosteroids, androgens, antiretroviral agents)

Less common

- Nephrotic syndrome
- Anorexia nervosa
- Porphyria
- Hyperparathyroidism

Secondary hypertriglyceridaemia

Common

- Diabetes mellitus (type 2)
- Chronic renal disease
- Abdominal obesity
- Excess alcohol
- Hepatocellular disease
- Drugs (β-blockers, retinoids, corticosteroids, anti-retroviral agents)

Predominant hypercholesterolaemia

Polygenic hypercholesterolaemia is the most common cause of a mild to moderate increase in LDL-C (see Box 16.26). Physical signs, such as corneal arcus and xanthelasma, may be found in this as well as other forms of lipid disturbance (see Fig. 16.15). The risk of cardiovascular disease is proportional to the degree of LDL-C (or Apo B) elevation, but is modified by other major risk factors, particularly low HDL-C.

Familial hypercholesterolaemia (FH) causes moderate to severe hypercholesterolaemia and has a prevalence of at least 0.2% in most populations. It is usually caused by a loss-of-function mutation in the LDL receptor gene, which results in an autosomal dominant pattern of inheritance. A similar syndrome can arise with loss-of-function mutations in the ligand-binding domain of Apo B100 or gain-of-function mutations in the *PCSK9* gene. The latter increases the activity of the PCSK9 protein, which is a sterol-sensitive protease that targets the LDL receptor for degradation. Causative mutations can be detected in one of these three genes by genetic testing in about 70% of patients with FH. Most patients with these types of FH have LDL levels that are approximately twice as high as in normal

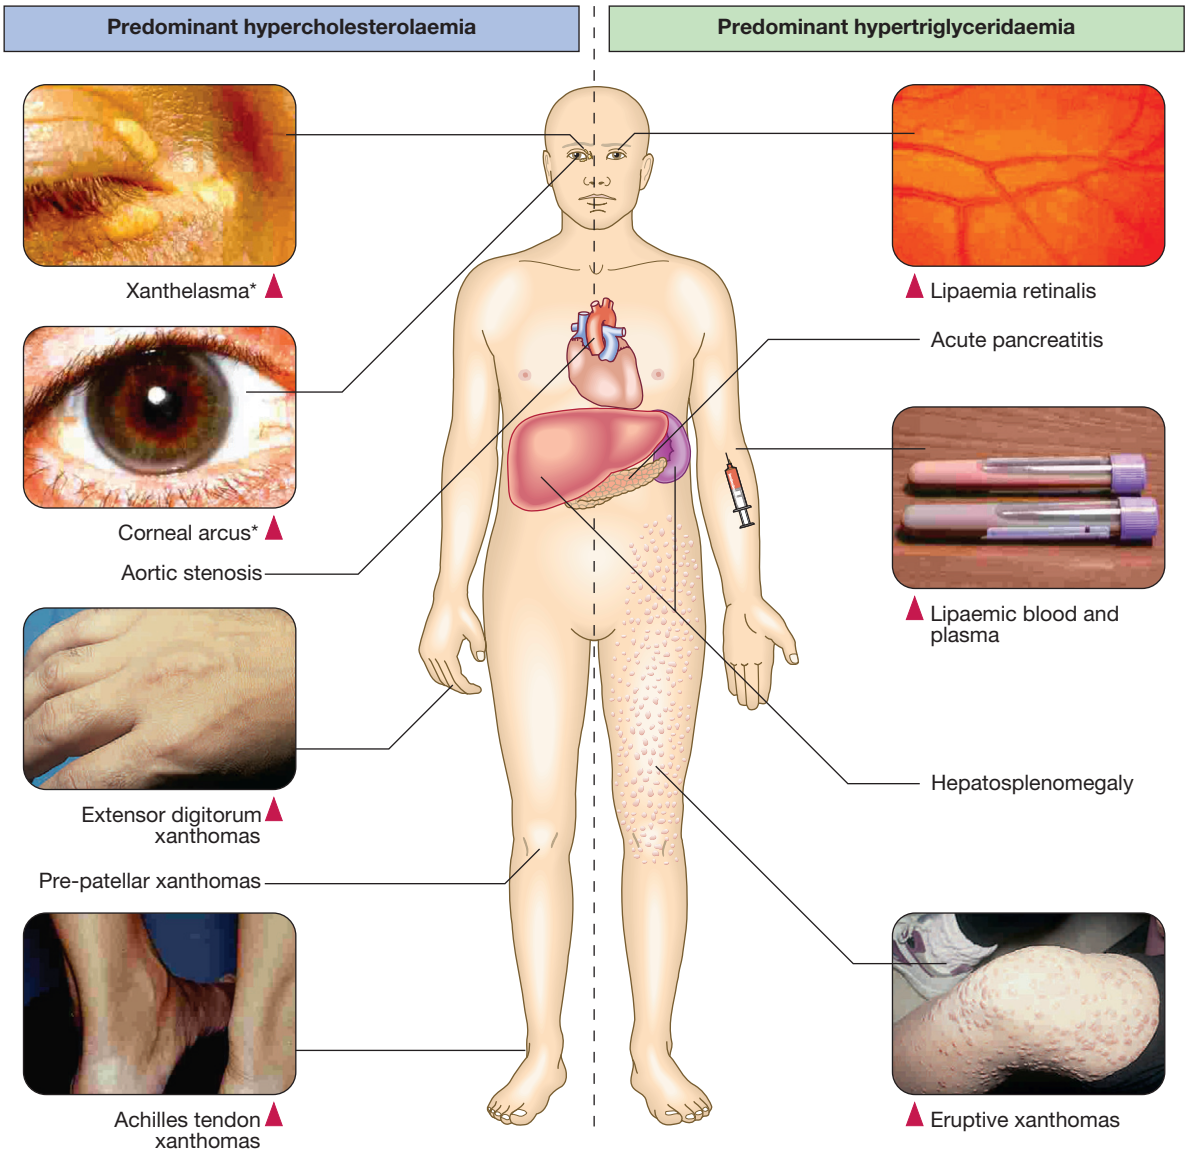

Fig. 16.15 Clinical manifestations of hyperlipidaemia. *Note that xanthelasma and corneal arcus may be non-specific, especially in later life.

16.26 Classification of hyperlipidaemia

Disease	Elevated lipid results	Elevated lipoprotein	CHD risk	Pancreatitis risk
Predominant hypercholesterolaemia				
Polygenic (majority)	TC ± TG	LDL ± VLDL	+	–
Familial hypercholesterolaemia (LDL receptor defect, defective Apo B100, increased function of PCSK-9)	TC ± TG	LDL ± VLDL	+++	–
Hyperalphalipoproteinaemia	TC ± TG	HDL	–	–
Predominant hypertriglyceridaemia				
Polygenic (majority)	TG	VLDL ± LDL	Variable	+
Lipoprotein lipase deficiency	TG >> TC	Chylo	?	+++
Familial hypertriglyceridaemia	TG > TC	VLDL ± Chylo	?	++
Mixed hyperlipidaemia				
Polygenic (majority)	TC + TG	VLDL + LDL	Variable	+
Familial combined hyperlipidaemia*	TC and/or TG	LDL and/or VLDL	++	+
Dysbetalipoproteinaemia*	TC and/or TG	IDL	+++	+

+ = slightly increased risk; ++ = increased risk; +++ = greatly increased risk.
*Familial combined hyperlipidaemia and dysbetalipoproteinaemia may also present as predominant hypercholesterolaemia or predominant hypertriglyceridaemia.
(CHD = coronary heart disease; Chylo = chylomicrons; TC = total cholesterol; TG = triglycerides)

16.27 Familial hypercholesterolaemia in adolescence

- **Statin treatment**: may be required from the age of about 10. It does not compromise normal growth and maturation.
- **Tobacco**: patients should be strongly advised to avoid this.

subjects of the same age and gender. Affected subjects suffer from severe hypercholesterolaemia and premature cardiovascular disease. FH may be accompanied by xanthomas of the Achilles or extensor digitorum tendons (see Fig. 16.15), which are strongly suggestive of FH. The onset of corneal arcus before age 40 is also suggestive of this condition. Identification of an index case of FH (the first case of FH in a family) should trigger genetic and biochemical screening of other family members, which is a cost-effective method for case detection. Affected individuals should be managed from childhood (Box 16.27).

Homozygous FH may occur in populations in which there is a 'founder' effect or consanguineous marriage, resulting in more extensive xanthomas and precocious cardiovascular disease in childhood. Hyperalphalipoproteinaemia refers to increased levels of HDL-C. In the absence of an increase in LDL-C, this condition does not cause cardiovascular disease, so it should not be regarded as pathological.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypercholesterolaemia (see 'Mixed hyperlipidaemia' below).

Predominant hypertriglyceridaemia

Polygenic hypertriglyceridaemia is the most common cause of a raised TG level (see Box 16.26). Other common causes include excess alcohol intake, medications (such as β-blockers and retinoids), type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance (p. 805) and impaired absorption of bile acids. It is often accompanied by post-prandial hyperlipidaemia and reduced HDL-C, both of which may contribute to cardiovascular risk. Excessive intake of alcohol or dietary fat, or other exacerbating factors may precipitate a massive increase in TG levels, which, if they exceed 10 mmol/L (880 mg/dL), may pose a risk of acute pancreatitis.

Inherited forms of hypertriglyceridaemia also occur. Loss-of-function mutations in the *LPL* gene, which encodes lipoprotein lipase, or the *APOC2* gene, which encodes the Apo C2 protein that acts as a co-factor for lipoprotein lipase, may cause recessively inherited forms of hypertriglyceridaemia. These mutations cause massive hypertriglyceridaemia that is not readily amenable to drug treatment. It often presents in childhood and is associated with episodes of acute abdominal pain and pancreatitis. In common with other causes of severe hypertriglyceridaemia, it may result in hepatosplenomegaly, lipaemia retinalis and eruptive xanthomas (see Fig. 16.15).

Familial hypertriglyceridaemia may also be inherited in a dominant manner due to mutations in the *APOA5* gene, which encodes Apo A5 – a co-factor that is essential for lipoprotein lipase activity. This disorder may be associated with high levels of TG that predispose to cardiovascular disease and pancreatitis.

Familial combined hyperlipidaemia, and dysbetalipoproteinaemia, may present with the pattern of predominant hypertriglyceridaemia (see 'Mixed hyperlipidaemia', below).

Mixed hyperlipidaemia

It is difficult to define quantitatively the distinction between predominant hyperlipidaemias and mixed hyperlipidaemia. The term 'mixed' usually implies the presence of hypertriglyceridaemia, as well as an increase in LDL or IDL. Treatment of massive hypertriglyceridaemia may improve TG faster than cholesterol, thus temporarily mimicking mixed hyperlipidaemia.

Primary mixed hyperlipidaemia is usually polygenic and, like predominant hypertriglyceridaemia, often occurs in association with type 2 diabetes, impaired glucose tolerance, central obesity or other manifestations of insulin resistance (p. 805). Both components of mixed hyperlipidaemia may contribute to the risk of cardiovascular disease.

Familial combined hyperlipidaemia is a term used to identify an inherited tendency towards the overproduction of atherogenic Apo B-containing lipoproteins. It results in elevation of cholesterol, TG or both in different family members at different times. It is associated with an increased risk of cardiovascular disease but it does not produce any pathognomonic physical signs. In practice, this relatively common condition is substantially modified by factors such as age and weight. It may not be a monogenic condition, but rather one end of a heterogeneous spectrum that overlaps insulin resistance (p. 805).

Dysbetalipoproteinaemia (also referred to as type 3 hyperlipidaemia, broad-beta dyslipoproteinaemia or remnant hyperlipidaemia) involves accumulation of roughly equimolar levels of cholesterol and TG. It is caused by homozygous inheritance of the Apo E2 allele, which is the isoform least avidly recognised by the LDL receptor. In conjunction with other exacerbating factors, such as obesity and diabetes, it leads to accumulation of atherogenic IDL and chylomicron remnants. Premature cardiovascular disease is common and it may also result in the formation of palmar xanthomas, tuberous xanthomas or tendon xanthomas.

Rare dyslipidaemias

Several rare disturbances of lipid metabolism have been described (Box 16.28). They provide important insights into lipid metabolism and its impact on risk of cardiovascular disease.

Fish eye disease, Apo A1 Milano and LCAT deficiency demonstrate that very low HDL levels do not necessarily cause cardiovascular disease, but Apo A1 deficiency, and possibly Tangier disease, demonstrate that low HDL-C can be atherogenic under some circumstances. Autosomal recessive FH and *PCSK9* gain-of-function mutations reveal the importance of proteins that chaperone the LDL receptor. Sitosterolaemia and cerebrotendinous xanthomatosis demonstrate that sterols other than cholesterol can cause xanthomas and cardiovascular disease, while *PCSK9* loss-of-function mutations, abetalipoproteinaemia and hypobetalipoproteinaemia suggest that low levels of Apo B-containing lipoproteins reduce the risk of cardiovascular disease. The only adverse health outcomes associated with

16.28 Miscellaneous and rare forms of hyperlipidaemia

Condition	Lipoprotein pattern	CVD risk
Tangier disease	Very low HDL, low TC	+
Apo A1 deficiency	Very low HDL	++
Apo A1 Milano	Very low HDL	–
Fish eye disease	Very low HDL, high TG	–
LCAT deficiency	Very low HDL, high TG	?
Autosomal recessive FH	Very high LDL	++
Sitosterolaemia	High plant sterols including sitosterol	+
Cerebrotendinous xanthomatosis	Bile acid defect (cholestanol accumulation)	+

+ = slightly increased risk; ++ = increased risk.
(CVD = cardiovascular disease; FH = familial hypercholesterolaemia; HDL = high-density lipoprotein; LCAT = lecithin cholesterol acyl transferase; TC = total cholesterol; TG = triglycerides)

extremely low plasma lipid levels in the latter two conditions are attributable to fat-soluble vitamin deficiency, or impaired transport of lipid from intestine or liver.

Management of dyslipidaemia

Lipid-lowering therapies have a key role in the secondary and primary prevention of cardiovascular diseases (p. 581). Assessment of absolute risk, treatment of all modifiable risk factors and optimisation of lifestyle, especially diet and exercise, are central to management in all cases.

Patients with the greatest absolute risk of cardiovascular disease will derive the greatest absolute benefit from treatment. Public health organisations recommend thresholds for the introduction of lipid-lowering therapy based on the identification of patients in very high-risk categories, or those calculated to be at high absolute risk according to algorithms or tables such as the Joint British Societies Coronary Risk Prediction Chart (see Fig. 18.62, p. 582). These tables, which are based on large epidemiological studies, should be recalibrated for the local population, if possible. In general, patients who have cardiovascular disease, diabetes mellitus, chronic renal impairment, familial hypercholesterolaemia or an absolute risk of cardiovascular disease of greater than 20% in the ensuing 10 years are arbitrarily regarded as having sufficient risk to justify drug treatment.

Public health organisations also recommend target levels for patients receiving drug treatment. High-risk patients should aim for HDL-C > 1 mmol/L (38 mg/dL) and fasting TG < 2 mmol/L (approximately 180 mg/dL), whilst target levels for LDL-C have been reduced from 2.5 to 2.0 mmol/L (76 mg/dL) or less. In general, total cholesterol should be < 5 mmol/L (190 mg/dL) during treatment, and < 4 mmol/L (approximately 150 mg/dL) in high-risk patients and in secondary prevention of cardiovascular disease.

Non-pharmacological management

Patients with lipid abnormalities should receive medical advice and, if necessary, dietary counselling to:

- reduce intake of saturated and trans-unsaturated fat to less than 7–10% of total energy
- reduce intake of cholesterol to < 250 mg/day
- replace sources of saturated fat and cholesterol with alternative foods, such as lean meat, low-fat dairy products, polyunsaturated spreads and low glycaemic index carbohydrates
- reduce energy-dense foods such as fats and soft drinks, whilst increasing activity and exercise to maintain or lose weight
- increase consumption of cardioprotective and nutrient-dense foods, such as vegetables, unrefined carbohydrates, fish, pulses, nuts, legumes, fruit, etc.
- adjust alcohol consumption, reducing intake if excessive or if associated with hypertension, hypertriglyceridaemia or central obesity
- achieve additional benefits with supplementary intake of foods containing lipid-lowering nutrients such as n-3 fatty acids, dietary fibre and plant sterols.

The response to diet is usually apparent within 3–4 weeks but dietary adjustment may need to be introduced gradually. Although hyperlipidaemia in general, and hypertriglyceridaemia in particular, can be very responsive to these measures, LDL-C reductions are often only modest in routine clinical practice. Explanation, encouragement and persistence are often required to induce patient compliance. Even minor weight loss can substantially reduce cardiovascular risk, especially in centrally obese patients (p. 116).

All other modifiable cardiovascular risk factors should be assessed and treated. If possible, intercurrent drug treatments that adversely affect the lipid profile should be replaced.

Pharmacological management

The main diagnostic categories provide a useful framework for management and the selection of first-line pharmacological treatment (Fig. 16.16).

Predominant hypercholesterolaemia

Predominant hypercholesterolaemia can be treated with one or more of the cholesterol-lowering drugs:

Statins. These reduce cholesterol synthesis by inhibiting the HMGCoA reductase enzyme. The reduction in cholesterol synthesis up-regulates activity of the LDL receptor, which increases clearance of LDL and its precursor, IDL, resulting in a secondary reduction in LDL synthesis. Statins reduce LDL-C by up to 60%, reduce TG by up to 40% and increase HDL-C by up to 10%. They also reduce the concentration of intermediate metabolites such as isoprenes, which may lead to other effects such as suppression of the inflammatory response. There is clear evidence of protection against total and coronary mortality, stroke and cardiovascular events across the spectrum of CVD risk (Box 16.29).

Statins are generally well tolerated and serious side-effects are rare (well below 2%). Liver function test abnormalities and muscle problems, such as myalgia, asymptomatic increase in creatine kinase (CK), myositis and, infrequently, rhabdomyolysis, are the most common. Side-effects are more likely in patients who are elderly, debilitated or receiving other drugs that interfere with statin degradation, which usually involves cytochrome P450 3A4 or glucuronidation.

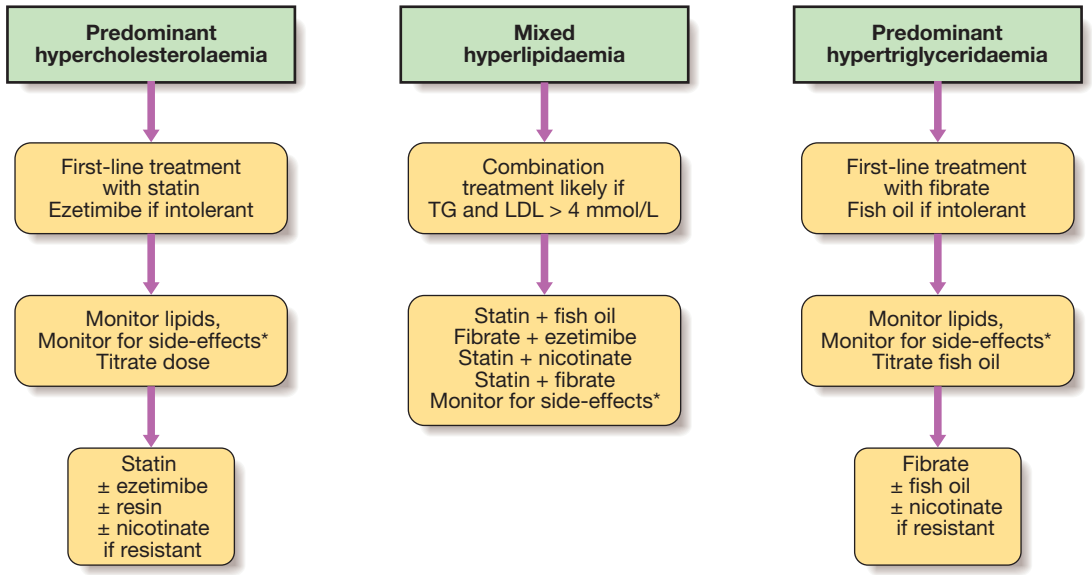

Fig. 16.16 Flow chart for the drug treatment of hyperlipidaemia. *Interrupt treatment if CK is more than 5–10 times the upper limit of normal, or if elevated with muscle symptoms, or if ALT is more than 2–3 times the upper limit. To convert TG in mmol/L to mg/dL, multiply by 88. To convert LDL-C in mmol/L to mg/dL, multiply by 38. (ALT = alanine aminotransferase; CK = creatine kinase)

EBM 16.29 Benefits of using statins to treat patients with hypercholesterolaemia

'Meta-analysis of major randomised controlled clinical trials involving over 130 000 subjects receiving statins for approximately 5 years showed a reduced risk of a major cardiovascular event of 21% (95% confidence interval 19–23%) per 1 mmol/L reduction in LDL-C, irrespective of age, gender, baseline LDL-C or intercurrent cardiovascular disease. Relative risk reduction was equally favourable in the subjects with the lowest risk.'

- Cholesterol Treatment Trialists Collaborators. Lancet 2012; 380:581–590.

Cholesterol absorption inhibitors. The only licensed drug in this class is ezetimibe, which inhibits activity of the intestinal mucosal transporter NPC1L1 that absorbs dietary and biliary cholesterol. Depletion of hepatic cholesterol up-regulates hepatic LDL receptor activity. This mechanism of action is synergistic with the effect of statins. Monotherapy with the standard 10 mg/day dose reduces LDL-C by 15–20%. Slightly greater (17–25%) incremental LDL-C reduction occurs when ezetimibe is added to statins. Ezetimibe is well tolerated, and evidence of a beneficial effect on cardiovascular disease endpoints may be inferred from a trial of combination therapy with simvastatin. Plant sterol-supplemented foods, which also reduce cholesterol absorption, lower LDL-C by 7–15%.

Bile acid sequestering resins. Drugs in this class include colestyramine, colestipol and colesevelam. These prevent the reabsorption of bile acids, thereby increasing de novo bile acid synthesis from hepatic cholesterol. As with ezetimibe, the resultant depletion of hepatic cholesterol up-regulates LDL receptor activity and reduces LDL-C in a manner that is synergistic with the action of statins. Resins reduce LDL-C and modestly increase HDL-C, but may increase TG. They are safe but may interfere with bioavailability of other drugs. Colesevelam has fewer gastrointestinal effects than older preparations that are less well tolerated. Development of specific inhibitors of the intestinal bile acid transporter may further improve tolerability of this class of agent.

Nicotinic acid. Pharmacological doses reduce peripheral fatty acid release with the result that VLDL and LDL decline whilst HDL-C increases. Randomised clinical trials have been inconsistent regarding effects on atherosclerosis and cardiovascular events. Side-effects include flushing, gastric irritation, liver function disturbances, and exacerbation of gout and hyperglycaemia. Slow-release formulations and low-dose aspirin may reduce flushing. Combination therapy with the prostaglandin D2 receptor inhibitor laropiprant to reduce flushing further is being evaluated.

Combination therapy. In many patients, treatment of predominant hypercholesterolaemia can be achieved by diet plus the use of a statin in sufficient doses to achieve target LDL-C levels. Patients who do not reach LDL targets on the highest tolerated statin dose, or who are intolerant of statins, may receive ezetimibe, plant sterols, nicotinic acid or resins. Ezetimibe and resins are safe and effective in combination with a statin, but nicotinic acid with a statin requires a greater level of caution because the risk of side-effects is slightly increased.

Predominant hypertriglyceridaemia

Predominant hypertriglyceridaemia can be treated with one of the TG-lowering drugs (see Fig. 16.16).

Fibrates. These stimulate peroxisome proliferator activated receptor (PPAR) alpha, which controls the expression of gene products that mediate the metabolism of TG and HDL. As a result, synthesis of fatty acids, TG and VLDL is reduced, whilst that of lipoprotein lipase, which catabolises TG, is enhanced. In addition, production of Apo A1 and ATP binding cassette A1 is up-regulated, leading to increased reverse cholesterol transport via HDL. Consequently, fibrates reduce TG by up to 50%

and increase HDL-C by up to 20%, but LDL-C changes are variable.

Fewer large-scale trials have been conducted with fibrates than with statins and the results are less conclusive, but reduced rates of cardiovascular disease have been reported with fibrate therapy in the subgroup of patients with low HDL-C levels and elevated TG (e.g. TG > 2.3 mmol/L (200 mg/dL)). Fibrates are usually well tolerated but share a similar side-effect profile to statins. In addition, they may increase the risk of cholelithiasis and prolong the action of anticoagulants. Accumulating evidence suggests that they may also have a protective effect against diabetic microvascular complications.

Highly polyunsaturated long-chain n-3 fatty acids. These include eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which comprise approximately 30% of the fatty acids in fish oil. EPA and DHA are potent inhibitors of VLDL TG formation. Intakes of greater than 2 g n-3 fatty acid (equivalent to 6 g of most forms of fish oil) per day lower TG in a dose-dependent fashion. Up to 50% reduction in TG may be achieved with 15 g fish oil per day. Changes in LDL-C and HDL-C are variable. Fish oil fatty acids have also been shown to inhibit platelet aggregation and improve cardiac arrhythmia in animal models. Dietary and pharmacological trials suggest that n-3 fatty acids may reduce mortality from coronary heart disease. Fish oils appear to be safe and well tolerated.

Patients with predominant hypertriglyceridaemia who do not respond to lifestyle intervention can be treated with fibrates, fish oil or nicotinic acid, depending on individual response and tolerance. If target levels are not achieved, the fibrates and fish oil or nicotinic acid can be combined. Massive hypertriglyceridaemia may require more aggressive limitation of dietary fat intake (< 10–20% energy as fat). Any degree of insulin deficiency should be corrected because insulin is required for optimal activity of lipoprotein lipase. The initial target for patients with massive hypertriglyceridaemia is TG < 10 mmol/L (880 mg/dL), to reduce the risk of acute pancreatitis.

Mixed hyperlipidaemia

Mixed hyperlipidaemia can be difficult to treat. Statins alone are less effective first-line therapy once fasting TG exceeds around 4 mmol/L (350 mg/dL). Fibrates are first-line therapy for dysbetalipoproteinaemia, but they may not control the cholesterol component in other forms of mixed hyperlipidaemia. Combination therapy is often required. Effective combinations include: statin plus fish oil when TG is not too high; fibrate plus ezetimibe; statin plus nicotinic acid; or statin plus fibrate. The risk of myopathy is increased with gemfibrozil, but fenofibrate is relatively safe in this regard.

Monitoring of therapy

The effect of drug therapy should be assessed after 6 weeks (12 weeks for fibrates). At this point, it is prudent to review side-effects, lipid response (see target levels above), CK and liver function tests. During longer-term follow-up, compliance with drug treatment, diet and exercise should be assessed, with monitoring of weight, blood pressure and lipid levels. The presence of cardiovascular symptoms or signs should be noted and absolute cardiovascular risk assessed periodically. It is not necessary to perform routine checks of CK and liver function unless symptoms occur, or if statins are used in combination with fibrates, nicotinic acid or other drugs that may interfere with their clearance. If myalgia or weakness occurs in association with CK elevation over 5–10 times the upper limit of normal, or if sustained alanine aminotransferase (ALT) elevation more than 2–3 times the upper limit of normal occurs that is not accounted for by fatty liver (p. 959), treatment should be discontinued and alternative therapy sought.

The principles of the management of dyslipidaemia can be applied broadly, but the objectives of treatment in the elderly (Box 16.30) and the safety of pharmacological therapy in pregnancy (Box 16.31) warrant special consideration.

16.30 Management of hyperlipidaemia in old age

- **Prevalence of atherosclerotic cardiovascular disease**: greatest in old age.
- **Associated cardiovascular risk**: lipid levels become less predictive, as do other risk factors apart from age itself.
- **Benefit of statin therapy**: maintained up to the age of 80 years but evidence is lacking beyond this.
- **Life expectancy and statin therapy**: lives saved by intervention are associated with shorter life expectancy than in younger patients, and so the impact of statins on quality-adjusted life years is smaller in old age.

16.31 Dyslipidaemia in pregnancy

- **Lipid metabolism**: lipid and lipoprotein levels increase during pregnancy. This includes an increase in LDL-C, which resolves post-partum. Remnant dyslipidaemia and hypertriglyceridaemia may be exacerbated during pregnancy.
- **Treatment**: dyslipidaemia is rarely thought to warrant urgent treatment so pharmacological therapy is usually contraindicated when conception or pregnancy is anticipated. Teratogenicity has been reported with systemically absorbed agents, and non-absorbed agents may interfere with nutrient bioavailability.
- **Monitoring**: cardiovascular disease is very unlikely amongst women of child-bearing age, but is possible in women with severe risk factor profiles or familial hypercholesterolaemia, when pre-conception cardiovascular review can be considered to ensure that the patient will be able to withstand the demands of pregnancy and labour.

DISORDERS OF HAEM SYNTHESIS – THE PORPHYRIAS

The porphyrias are a group of disorders caused by inherited abnormalities in the haem biosynthetic pathway (Fig. 16.17). Most of the described forms are due to partial enzyme deficiencies with a dominant mode of inheritance. They are commonly classified as either hepatic or erythropoietic, depending on whether the major site of excess porphyrin production is in the liver or in the red cell.

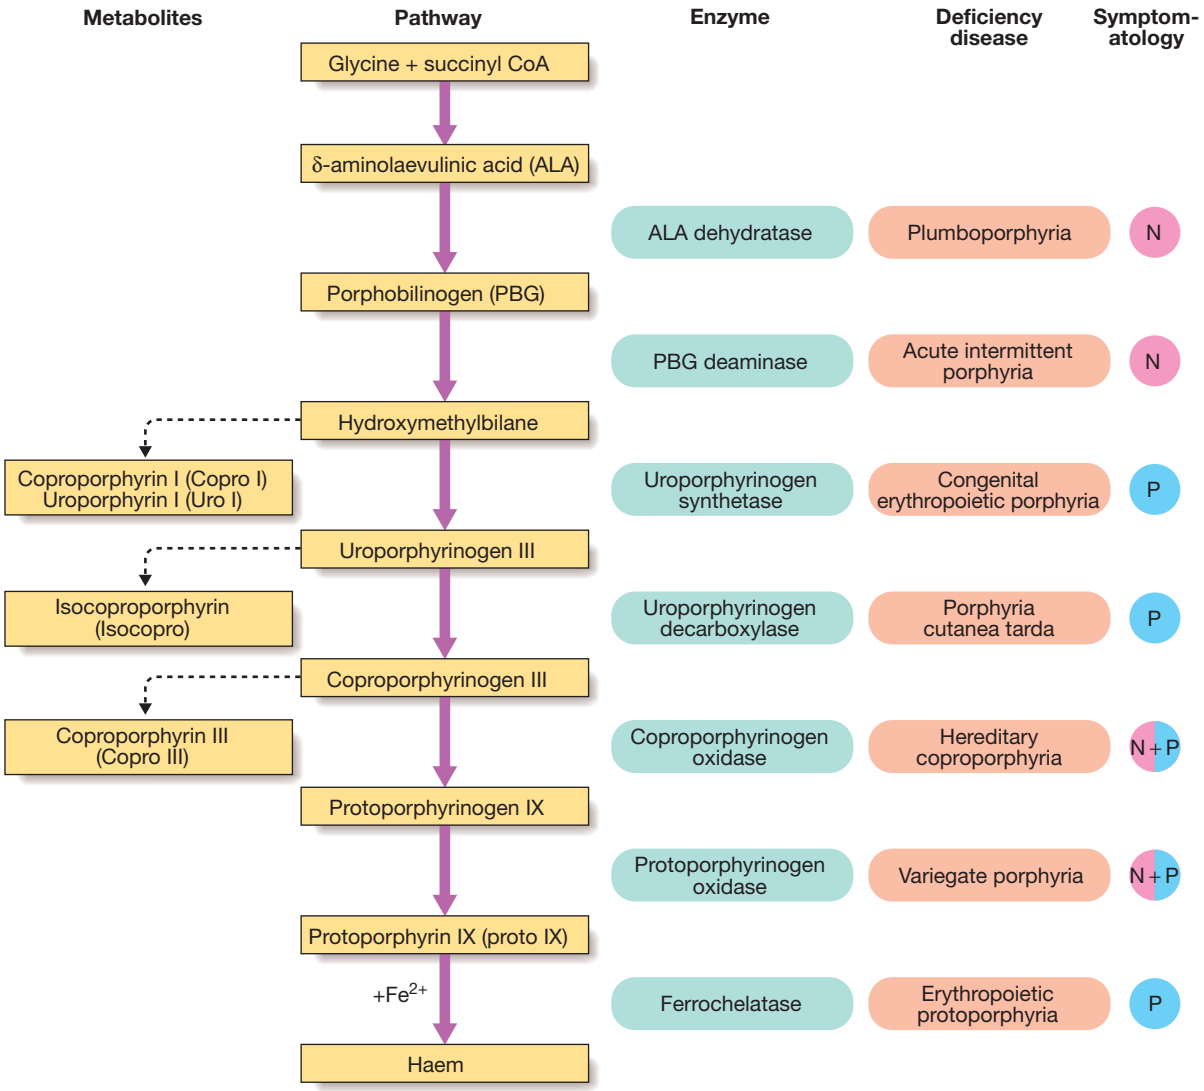

Fig. 16.17 Haem biosynthetic pathway and enzyme defects responsible for the porphyrias. (N = neurovisceral; P = photosensitive)

The porphyrias show a low penetrance in the order of 25%. Environmental factors are important in disease expression in some forms. In the most common of these conditions, porphyria cutanea tarda (PCT), these include alcohol, iron accumulation, exogenous oestrogens and exposure to various chemicals. Many cases are associated with hepatitis C infection and this should always be screened for on presentation.

Clinical features

The clinical features of porphyria fall into two broad categories, photosensitivity and acute neurovisceral syndrome. The enzyme defects responsible for the diseases are shown in Figure 16.17.

Photosensitive skin manifestations, attributable to excess production and accumulation of porphyrins in the skin, cause pain, erythema, bullae, skin erosions, hirsutism and hyperpigmentation, and occur predominantly on areas of the skin that are exposed to sunlight (p. 1260). The skin also becomes sensitive to damage from minimal trauma.

The other pattern of presentation is with an acute neurological syndrome. This presents with acute abdominal pain together with features of autonomic dysfunction such as tachycardia, hypertension and constipation. Neuropsychiatric manifestations, hyponatraemia due to inappropriate ADH release (p. 438), and an acute neuropathy may also occur (p. 1223). The neuropathy is usually motor and may, in severe cases, progress to respiratory failure.

There is no proven explanation for the episodic nature of the attacks in porphyria, which can relapse and remit or follow a prolonged and unremitting course. Sometimes, specific triggers can be identified, such as alcohol, fasting, or drugs such as anticonvulsants, sulphonamides, oestrogen and progesterone. The oral contraceptive pill is a common precipitating factor. In a significant number, no precipitant can be identified.

Diagnosis

The diagnosis of porphyria and classification into the various forms have traditionally relied on the pattern of

16.32 Diagnostic biochemical findings in the porphyrias

Condition	Elevated porphyrins and precursors		
	Blood	Urine	Faeces
ALA dehydratase deficiency (plumboporphyria)	Proto IX*	ALA, Copro III*	
Acute intermittent porphyria (AIP)		ALA, PBG	
Congenital erythropoietic porphyria (CEP)	Uro I	Uro I	Copro I
Porphyria cutanea tarda (PCT)		Uro I	Isocopro
Hereditary coproporphyria (HCP)		ALA, PBG, Copro III	Copro III
Variegate porphyria (VP)		ALA, PBG, Copro III	Proto IX
Erythropoietic protoporphyria (EPP)	Proto IX		Proto IX

*The paradoxical rise in coproporphyrin III (Copro III) and protoporphyrin (Proto) in this very rare condition is poorly understood.
Refer to Figure 16.17 for metabolic pathways.

the porphyrins and porphyrin precursors found in blood, urine and faeces (Box 16.32). This is a straightforward diagnosis at clinical presentation when the metabolites are significantly elevated, but this is not always the case in asymptomatic individuals.

More recently, measurement of the enzymes that are deficient in the various porphyrias has provided further diagnostic information (for example, PBG deaminase activity in red blood cells to diagnose acute intermittent porphyria). However, there is often considerable overlap between enzyme activities in affected and normal subjects. Furthermore, some of the enzymes occur in the mitochondria, for which it is more difficult to obtain suitable specimens for analysis. All the genes of the haem biosynthetic pathway have now been characterised. This has made it possible to identify affected individuals in families by genetic testing, a significant advance considering that penetrance of porphyria is low.

Metabolite excretory patterns are always grossly abnormal during an acute attack or in the presence of cutaneous manifestations of porphyria and are diagnostic of the particular porphyria. A normal metabolite profile under these circumstances effectively excludes porphyria. Metabolites usually remain abnormal for long periods after an acute attack, and in some individuals never return to normal. The diagnosis is not so straightforward in patients who are in remission, or in asymptomatic individuals with a positive family history. Neurological porphyria rarely manifests before puberty, nor can it be readily diagnosed from metabolite patterns after the menopause. In these circumstances, genetic testing for disease-specific mutations can now clarify the situation.

Management

For patients predisposed to neurovisceral attacks, general management includes avoidance of any agents known to precipitate acute porphyria. Specific management includes intravenous glucose, as provision of 5000 kilojoules per day can, in some cases, terminate acute attacks through a reduction in ALA synthetase activity, leading to reduced ALA synthesis. More recently, administration of haem (in various forms such as haematin or haem arginate) has been shown to reduce metabolite excretory rates, relieve pain and accelerate recovery. Cyclical acute attacks in women sometimes respond to suppression of the menstrual cycle using gonadotrophin-releasing hormone analogues. In rare cases with frequent prolonged attacks or attacks intractable to treatment, liver transplantation has been effective.

There are few specific or effective measures to treat the photosensitive manifestations. The primary goal is to avoid sun exposure and skin trauma. Barrier sun creams containing zinc or titanium oxide are the most effective products. New colourless creams containing nanoparticle formulations have improved patient acceptance. Beta-carotene is used in some patients with erythropoietic porphyria with some efficacy. Afamelanotide, a synthetic analogue of alpha-melanocyte stimulating hormone (α-MSH), has also been shown to provide protection in erythropoietic protoporphyria. In porphyria cutanea tarda, a course of venesections to remove iron can result in long-lasting clinical and biochemical remission, especially if exposure to identified precipitants, such as alcohol or oestrogens, is reduced. Alternatively, a prolonged course of low-dose chloroquine therapy is also effective.

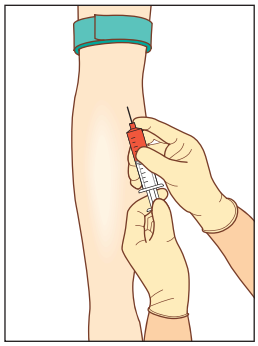
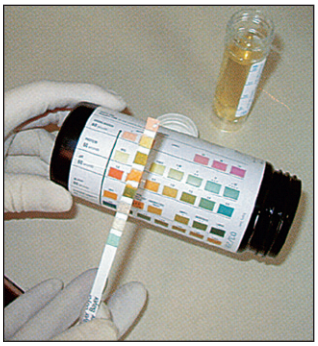
CLINICAL EXAMINATION OF THE KIDNEY AND URINARY TRACT

*Features of advanced chronic kidney disease (see also Fig. 17.13)



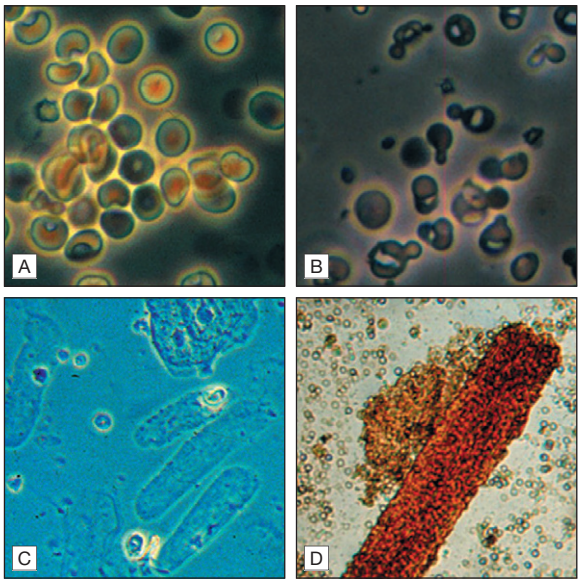
Many diseases of the kidney and urinary tract are clinically silent, at least in the early stages. Accordingly, it is common for these conditions to first be detected by routine blood tests or on dipstick testing of the urine. Several important abnormalities can also be picked up on physical examination, however, as summarised below.

1



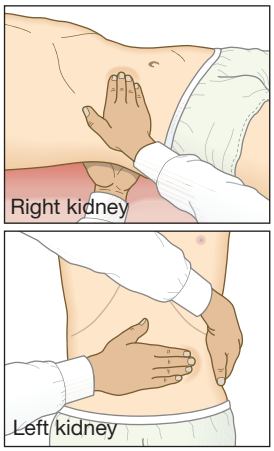
Blood pressure measurements

2



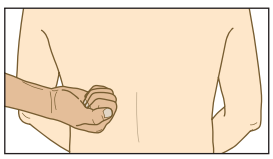
Blood tests for abnormal creatinine and electrolytes

3



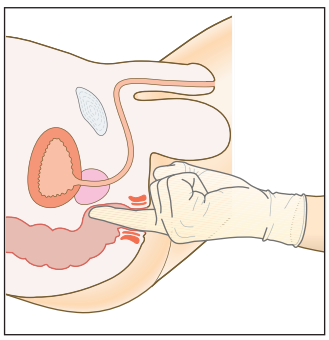
Dipstick testing for protein, blood, nitrate and leucocytes

4



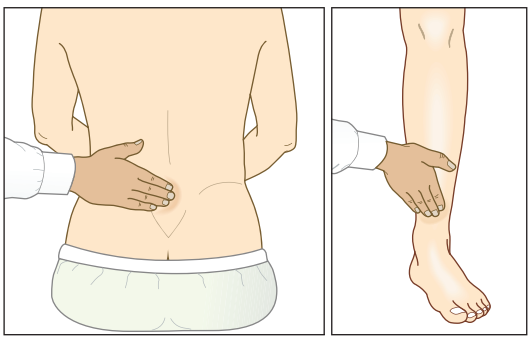
Urine microscopy. A Erythrocytes due to bleeding from lower in the urinary tract (x400). B Dysmorphic erythrocytes due to glomerular inflammation (x400). C Hyaline casts (arrows), in normal urine (×160). D Erythrocytes and a red cell cast (arrow) in glomerulonephritis (x100). Panels A–C are phase contrast images; D is a bright field image.

5



Abdominal examination for palpable kidneys

6



Percussing for tenderness in renal angle

7

Digital rectal examination for prostate enlargement

8

Checking sacrum and ankles for pitting oedema

Inset (Dipstick): From Pitkin J, et al. 2003 – see p. 523.

17

This chapter describes the disorders of the kidneys and urinary tract that are commonly encountered in routine practice, as well as giving an overview of the highly specialised field of renal replacement therapy. Disorders of renal tubular function, which may cause alterations in electrolyte and acid–base balance, are described in Chapter 16.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The kidneys

The kidneys play a central role in excretion of many metabolic breakdown products, including ammonia, urea and creatinine from protein, and uric acid from nucleic acids, drugs and toxins. They also regulate fluid and electrolyte balance. This is achieved by making large volumes of an ultrafiltrate of plasma (120 mL/min, 170 L/day) at the glomerulus, and selectively reabsorbing components of this ultrafiltrate at points along the nephron. The rates of filtration and reabsorption are controlled by many hormonal and haemodynamic signals.

The kidneys also regulate acid–base homeostasis, calcium and phosphate homeostasis, vitamin D metabolism and production of red blood cells. They are important in regulating blood pressure. Renin is secreted from the juxtaglomerular apparatus in response to reduced afferent arteriolar pressure, stimulation of sympathetic nerves, and changes in sodium content of fluid in the distal convoluted tubule at the macula densa, and is the first step in the generation of angiotensin II and aldosterone release, which in turn regulate systemic vasoconstriction and extracellular volume.

Each kidney is approximately 11–14 cm in length in healthy adults; they are located retroperitoneally on either side of the aorta and inferior vena cava between the 12th thoracic and 3rd lumbar vertebra (Fig. 17.1A). The right kidney is usually a few centimetres lower because the liver lies above it. Both kidneys rise and descend several centimetres with respiration.

The kidneys have a rich blood supply and receive approximately 20–25% of cardiac output through the renal arteries, which arise from the abdominal aorta. The renal arteries undergo various subdivisions within the kidney, eventually forming interlobular arteries that run through the renal cortex. These eventually give rise to afferent glomerular arterioles that supply individual nephrons, which are the functional units of the kidney. The efferent arteriole, leading from the glomerulus, supplies the distal nephron and medulla in a 'portal' circulation (Fig. 17.1B).

The nephron

Healthy kidneys contain approximately 1 million individual nephrons. Each nephron consists of a glomerulus, which is responsible for ultrafiltration of blood, a proximal renal tubule, a loop of Henle, a distal renal tubule and a collecting duct, which together are responsible for selective reabsorption of water and electrolytes that have been filtered at the glomerulus (see Fig. 16.2, p. 430). Under normal circumstances, more than 99% of the 170 litres of glomerular filtrate that is produced each day is reabsorbed in the tubules. The remainder passes through the collecting ducts of multiple nephrons and drains into the renal pelvis and ureters.

The glomerulus

The glomerulus comprises a tightly packed loop of capillaries supplied by an afferent arteriole and drained by an efferent arteriole. It is surrounded by a cup-shaped extension of the proximal tubule termed Bowman's capsule, which is comprised of epithelial cells. Blood that enters the glomerulus undergoes ultrafiltration across the glomerular basement membrane (GBM), which is formed by fusion of the basement membranes of tubular epithelial and vascular endothelial cells (Fig. 17.1C and D). The glomerular capillary endothelial cells contain pores (fenestrae), through which circulating molecules can pass to reach the underlying GBM. Glomerular epithelial cells (podocytes) have multiple long foot processes which interdigitate with those of the adjacent epithelial cells (Fig. 17.1E). As well as maintaining a selective barrier to filtration, podocytes are involved in regulating turnover of the GBM. Mesangial cells lie in the central region of the glomerulus. They have contractile properties similar to those of vascular smooth muscle cells but also have macrophage-like properties.

Under normal circumstances, the glomerulus is impermeable to proteins the size of albumin (67 kDa) or larger, while proteins of 20 kDa or smaller are filtered freely. The ability of molecules between 20 and 67 kDa to pass through the GBM is variable and depends on the size (smaller molecules are filtered more easily) and charge (positively charged molecules are filtered more easily). Very little lipid is filtered by the glomerulus.

Filtration pressure at the glomerulus is normally maintained at a constant level, in the face of wide variations in systemic blood pressure and cardiac output, by alterations in muscle tone within the afferent and efferent arterioles. This is known as autoregulation. When there is a reduction in renal perfusion pressure, renin is released by specialised smooth muscle cells in the juxtaglomerular apparatus. Renin cleaves angiotensinogen to release angiotensin I, which is further cleaved by angiotensin-converting enzyme (ACE) to produce angiotensin II (Fig. 17.1D). This restores glomerular perfusion pressure in the short term by causing vasoconstriction of the efferent arterioles within the kidney and by inducing systemic vasoconstriction to increase blood pressure and thus renal perfusion pressure. In the longer term, angiotensin II increases plasma volume by stimulating aldosterone release, which enhances sodium reabsorption by the renal tubules (see Fig. 20.17, p. 771).

Renal tubules, loop of Henle and collecting ducts

The proximal renal tubule, loop of Henle, distal renal tubule and collecting ducts are responsible for reabsorption of water, electrolytes and other solutes, as well as regulating acid–base balance, as described in detail on page 430 and in Figure 16.3. They also play a key role in regulating calcium homeostasis by converting 25-hydroxyvitamin D to the active metabolite 1,25-dihydroxyvitamin D (p. 1126). Failure of this process contributes to the pathogenesis of hypocalcaemia and bone disease which occurs in chronic kidney disease (CKD, p. 483). Fibroblast-like cells that lie in the interstitium of the renal cortex are responsible for production

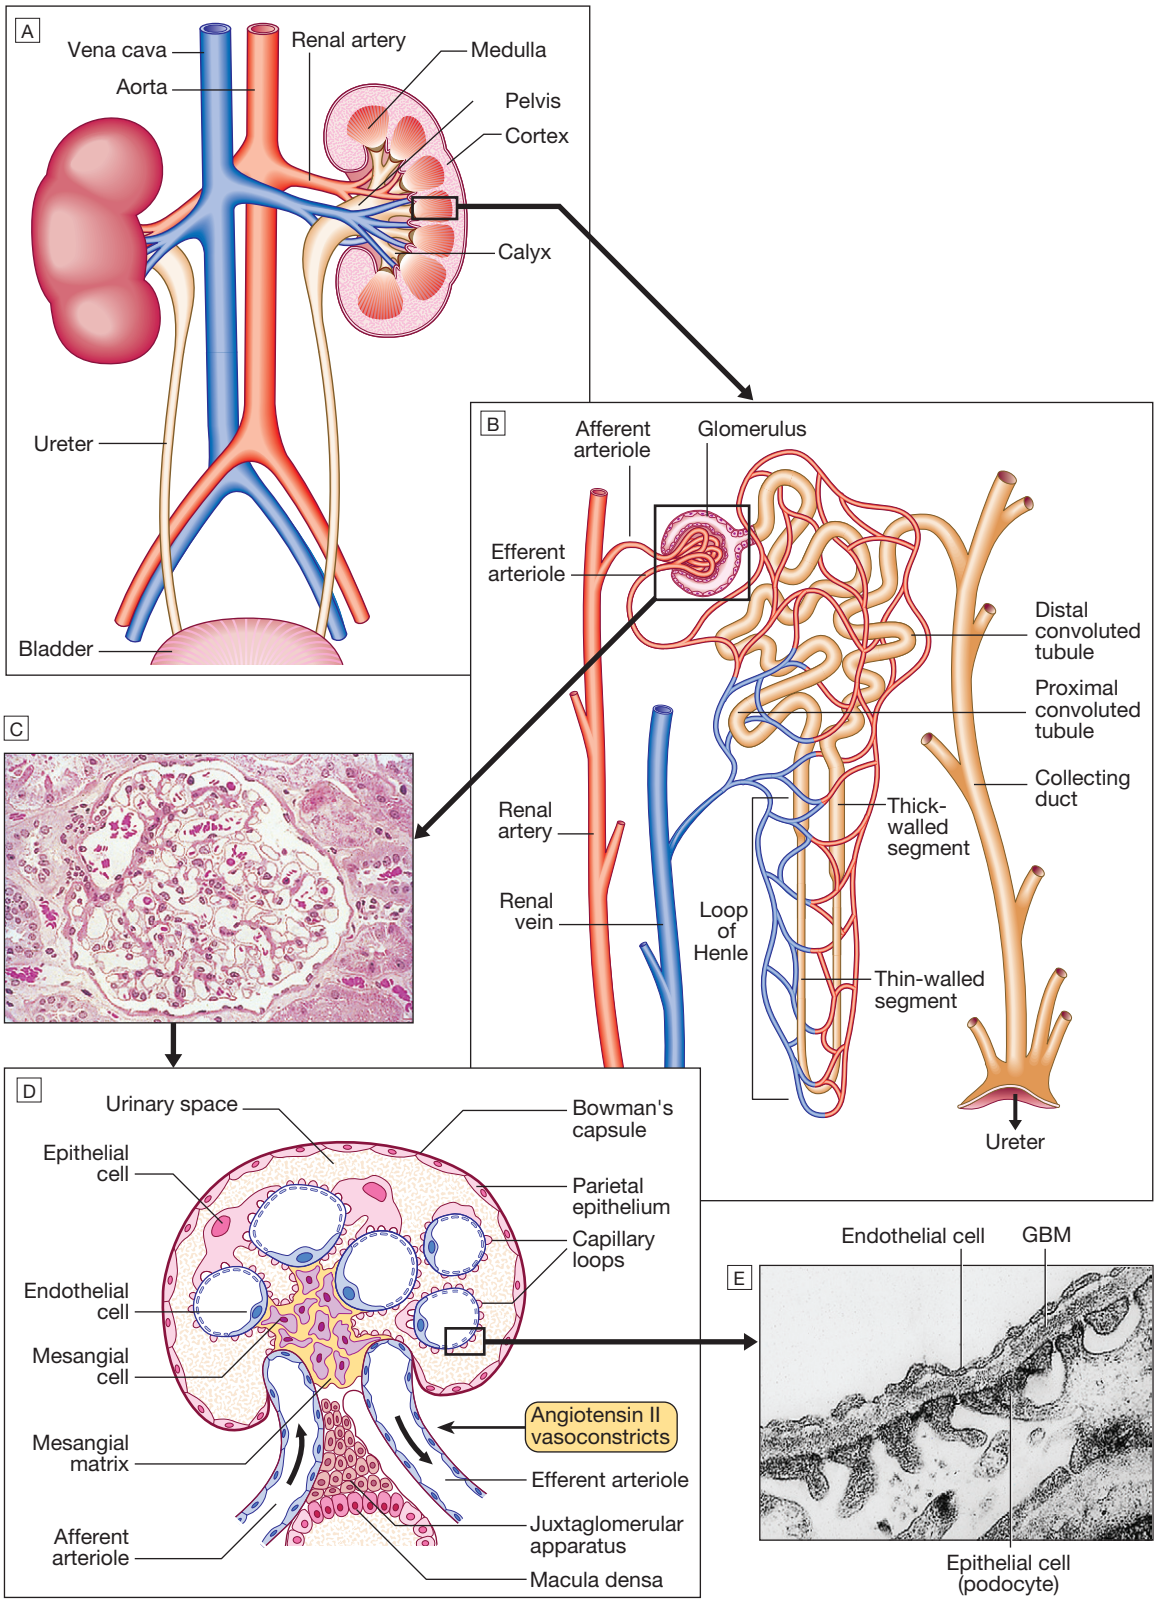


Fig. 17.1 Functional anatomy of the kidney. A Anatomical relationships of the kidney. B A single nephron. For the functions of different segments, see Figures 16.2 and 16.3 (pp. 430 and 431). C Histology of a normal glomerulus. D Schematic cross-section of a glomerulus, showing five capillary loops, to illustrate structure and show cell types. E Electron micrograph of the filtration barrier. (GBM = glomerular basement membrane)

of erythropoietin, which in turn is required for production of red blood cells. Erythropoietin synthesis is regulated by oxygen tension; anaemia and hypoxia increase production, whereas polycythaemia and hyperoxia inhibit it. Failure of erythropoietin production plays an important role in the pathogenesis of anaemia in CKD.

Ureters and bladder

The ureters drain urine from the renal pelvis (Fig. 17.1A) and deliver it to the bladder, a muscular organ that lies anteriorly in the lower part of the pelvis, just behind the pubic bone. The function of the bladder is to store and then release urine during micturition. The bladder is richly innervated. Sympathetic nerves arising from T10–L2 relay in the pelvic ganglia to cause relaxation of the detrusor muscle and contraction of the bladder neck (both via α-adrenoceptors), thereby preventing release of urine from the bladder. The distal sphincter mechanism is innervated by somatic motor fibres from sacral segments S2–4, which reach the sphincter either by the pelvic plexus or via the pudendal nerves. Afferent sensory impulses pass to the cerebral cortex, from where reflex-increased sphincter tone and suppression of detrusor contraction inhibit micturition until it is appropriate. Conversely, parasympathetic nerves arising from S2–4 stimulate detrusor contraction, promoting micturition.

The micturition cycle has a storage (filling) phase and a voiding (micturition) phase. During the filling phase, the high compliance of the detrusor muscle allows the bladder to fill steadily without a rise in intravesical pressure. As bladder volume increases, stretch receptors in its wall cause reflex bladder relaxation and increased sphincter tone. At approximately 75% bladder capacity, there is a desire to void. Voluntary control is now exerted over the desire to void, which disappears temporarily. Compliance of the detrusor allows further increase in capacity until the next desire to void. Just how often this desire needs to be inhibited depends on many factors, not the least of which is finding a suitable place in which to void.

The act of micturition is initiated first by voluntary and then by reflex relaxation of the pelvic floor and distal sphincter mechanism, followed by reflex detrusor contraction. These actions are coordinated by the pontine micturition centre. Intravesical pressure remains greater than urethral pressure until the bladder is empty.

The prostate gland

The prostate gland is situated at the base of the bladder, surrounding the proximal urethra. Exocrine glands within the prostate produce fluid, which comprises about 20% of the volume of ejaculated seminal fluid and is rich in zinc and proteolytic enzymes. The remainder of the ejaculate is formed in the seminal vesicles and bulbo-urethral glands, with spermatozoa arising from the testes.

Smooth muscle fibres within the prostate, which are under sympathetic control, play a role in controlling urine flow through the bulbar urethra, and also contract at orgasm to move seminal fluid through ejaculatory ducts into the bulbar urethra (emission). Contraction of the bulbocavernosus muscle (via a spinal muscle reflex) then ejaculates the semen out of the urethra.

The penis

Blood flow into the corpus cavernosum of the penis is controlled by sympathetic nerves from the thoracolumbar plexus, which maintain smooth muscle contraction. In response to afferent input from the glans penis and from higher centres, pelvic splanchnic parasympathetic nerves actively relax the cavernosal smooth muscle via neurotransmitters such as nitric oxide, acetylcholine, vasoactive intestinal polypeptide (VIP) and prostacyclin, with consequent dilatation of the lacunar space. At the same time, draining venules are compressed, trapping blood in the lacunar space with consequent elevation of pressure and erection (tumescence) of the penis.

INVESTIGATION OF RENAL AND URINARY TRACT DISEASE

Glomerular filtration rate

The glomerular filtration rate (GFR) is the rate at which fluid passes into nephrons after filtration and is a measure of renal function. It is proportionate to body

17.1 How to estimate glomerular filtration rate (GFR)

Measuring GFR

- Direct measurement using labelled EDTA or inulin
- Creatinine clearance (CrCl)
  - Minor tubular secretion of creatinine causes CrCl to exaggerate GFR when renal function is poor, and can be affected by drugs (e.g. trimethoprim, cimetidine)
  - Needs 24-hr urine collection (inconvenient and often unreliable)

$$\text{CrCl (mL/min)} = \frac{\text{urine creatinine concentration (μmol / L)} \times \text{volume (mL)}}{\text{plasma creatinine concentration (μmol/L)} \times \text{time (min)}}$$

Estimating GFR with equations

- Cockcroft and Gault equation
  - Reasonably accurate at normal to moderately impaired renal function
  - Estimates CrCl, not GFR
  - Requires patient weight

$$\text{CrCl} = \frac{(140 - \text{age in yrs}) \times \text{lean body weight (kg)} \times (1.22 \text{ males or } 1.04 \text{ females})}{\text{serum creatinine (μmol/L)}}$$

- The Modification of Diet in Renal Disease (MDRD) study equation (see www.renal.org/eGFR)
  - Performs better than Cockcroft and Gault at low GFR
  - Requires knowledge of age and sex only
  - Can be reported automatically by laboratories
  - For limitations, see Box 17.2

$$\text{eGFR} = 186^{*} \times (\text{creatinine in μmol/L}/88.4)^{-1.154} \times (\text{age in yrs})^{-0.203} \times (0.742 \text{ if female}) \times (1.21 \text{ if black})$$

- No equations perform well in unusual circumstances, such as extremes of body (and muscle) mass or in acutely unwell patients (see Box 17.2)

*A correction factor, either a value recommended by the laboratory/assay manufacturer or a default value of 186; see www.renal.org/ckd. To convert creatinine in mg/dL to μmol/L, multiply by 88.4.

size and the reference range is usually expressed after correction for body surface area as 120 ± 25 mL/min/1.73 m^2. The GFR may be measured directly by injecting and measuring the clearance of compounds such as inulin or radiolabelled ethylenediaminetetracetic acid, which are completely filtered at the glomerulus and are not secreted or reabsorbed by the renal tubules (Box 17.1). However, this is not performed routinely and is usually reserved for special circumstances, such as the assessment of renal function in potential live kidney donors. Instead, GFR is usually indirectly assessed in clinical practice by measuring serum levels of endogenously produced compounds that are excreted by the kidney. The most widely used is serum creatinine, which is produced by muscle at a constant rate, is almost completely filtered at the glomerulus, and is not reabsorbed. Although creatinine is secreted to a small degree by the proximal tubule, this is only usually significant in terms of GFR estimation in severe renal impairment, where it accounts for a larger proportion of the creatinine excreted. Accordingly, provided muscle mass remains constant, changes in serum creatinine concentrations closely reflect changes in GFR, although the reference range for creatinine is wide due to the fact that muscle mass varies widely between different individuals (Fig. 17.2). Several methods have been developed with which to estimate GFR from serum

17.2 Limitations of eGFR

- It is only an estimate, least reliable at extremes of body composition (malnourished, amputees) and in hospital inpatients (as it was derived from outpatients)
- Confidence intervals are wide (90% of patients will have eGFR within 30% of their measured GFR, and 98% within 50%)
- Values are consistent in individuals, so changes mean more than absolute values
- Creatinine level must be stable over days; eGFR is not valid in assessing acute kidney injury
- It tends to underestimate normal or near-normal function, so slightly low values should not be over-interpreted. Many laboratories report only up to > 60 mL/min/1.73 m^2 for this reason
- In the elderly, who constitute the majority of those with low eGFR, there is controversy about categorising people as having chronic kidney disease (CKD; Box 17.3) on the basis of eGFR alone, particularly at stage 3A, since there is little evidence of adverse outcomes when eGFR is > 50 unless there is also proteinuria
- eGFR is not valid in under-18s or during pregnancy
- The equation was originally validated in US patients and eGFR for any given creatinine was 21% higher in blacks. Performance in other racial groups is under investigation

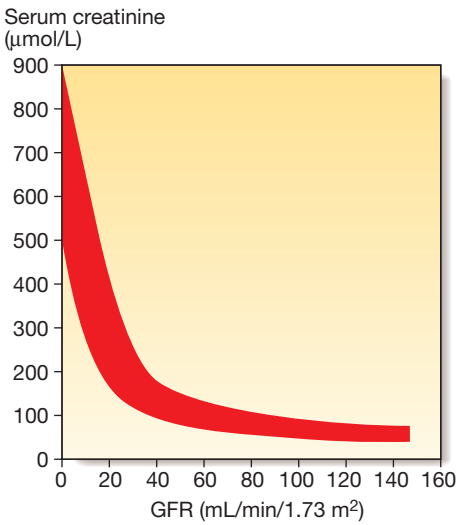

Fig. 17.2 Serum creatinine and the glomerular filtration rate (GFR). The inverse reciprocal relationship between GFR and serum creatinine is shown for a group of patients with renal disease. The red band indicates the range of values obtained. Note that some individuals have a GFR as low as 30–40 mL/min without serum creatinine rising out of the reference range.

17.3 Stages of chronic kidney disease (CKD)

Stage[1]	Definition[2]	Description	Prevalence[3]	Clinical presentation[4]
1	Kidney damage with normal or high GFR (> 90)	Mild CKD	6.5%	Asymptomatic
2	Kidney damage and GFR 60–89			Asymptomatic
3A[5]	GFR 45–59	Moderate CKD	4.5%	Usually asymptomatic
3B[5]	GFR 30–44			Anaemia in some patients at 3B Most are non-progressive or progress very slowly
4	GFR 15–29	Severe CKD	0.4%	First symptoms often at GFR < 20 Electrolyte problems likely as GFR falls
5	GFR < 15 or on dialysis	Kidney failure		Significant symptoms and complications usually present Dialysis initiation varies but usually at GFR < 10

[1]Stages of CKD 1–5 were originally defined by the US National Kidney Foundation Kidney Disease Quality Outcomes Initiative 2002.
[2]Kidney damage means pathological abnormalities or markers of damage, including abnormalities in urine tests or imaging studies. Two GFR values 3 mths apart are required to assign a stage. All GFR values are mL/min/1.73 m^2.
[3]From the NHANES III study of > 15 000 US adults (Am J Kid Dis 2003; 41:1–12).
[4]For further information, see page 483.
[5]3A/3B split recommended for UK in 2007/8, plus a suffix P, indicating presence of proteinuria (albumin:creatinine ratio (ACR) > 30 or protein:creatinine ratio (PCR) > 50 mg/mmol), e.g. 3 Ap, in view of the prognostic importance of proteinuria.

creatinine measurements (see Box. 17.1) but the most widely used is the MDRD equation, which is now the accepted standard for assessing estimated GFR (eGFR). Although the eGFR has several limitations (Box 17.2), its routine reporting by laboratories has increased recognition of moderate kidney damage and encouraged early deployment of protective therapies (Box 17.3).

A potentially more accurate assessment of GFR can be obtained by collection of a 24-hour urine sample and relating serum creatinine levels to urinary creatinine excretion (see Box 17.1).

Urinalysis

Screening for the presence of blood, protein, glucose, ketones, nitrates and leucocytes and to assess pH and osmolality of urine can be achieved by dipstick testing (p. 474). Urine microscopy (p. 463) or flow cytometry can detect erythrocytes, which are indicative of bleeding from the urogenital tract (anywhere from kidney to tip of penis); dysmorphic erythrocytes, which suggest the presence of nephritis; red cell casts, indicative of glomerular disease; and crystals, which may be observed in patients with renal stone disease. It should be noted that calcium oxalate and urate crystals can sometimes be found in normal urine that has been left to stand, due to crystal formation ex vivo. The presence of leucocytes and bacteria in urine is indicative of renal tract infection. White cell casts are strongly suggestive of pyelonephritis. Urine pH can provide diagnostic information in the assessment of renal tubular acidosis (p. 446). Urine collection over a 24-hour period can be performed to measure excretion of solutes, such as calcium, oxalate and urate, in patients with recurrent renal stone disease (p. 507). Proteinuria can also be measured on 24-hour collections but is usually now quantified by protein/creatinine ratio on spot urine samples.

Other dynamic tests of tubular function, including concentrating ability (p. 794), ability to excrete a water load (p. 438) and ability to excrete acid (p. 426), and calculation of fractional calcium, phosphate or sodium excretion, are valuable in some circumstances. The fractional excretion of these ions can be calculated by the general formula: (urine concentration of analyte × serum creatinine) / (serum concentration of analyte × urinary creatinine). For example, familial benign hypercalcaemia is characterised by a very low fractional excretion of calcium (p. 770), and hypophosphataemic rickets (p. 1128) by an increased fractional excretion of phosphate. Calculation of fractional excretion of sodium (FENa) can help differentiate volume depletion, when the tubules are avidly conserving sodium (FENa typically < 1.0), from acute tubular necrosis, when the tubules are damaged and are less able to conserve sodium (FENa typically > 1.0).

Blood tests

Haematology

A normochromic normocytic anaemia is common in CKD and is due in part to deficiency of erythropoietin and bone marrow suppression secondary to toxins retained in CKD. Other causes of anaemia include iron deficiency from urinary tract bleeding, and haemolytic anaemia secondary to disorders such as haemolytic uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Other abnormalities may be observed that reflect underlying disease processes, such as neutrophilia and raised erythrocyte sedimentation rate (ESR) in vasculitis or sepsis; lymphopenia and raised ESR in systemic lupus erythematosus (SLE); and fragmented red cells in HUS and TTP.

Biochemistry

Abnormalities of routine biochemistry are common in renal disease. Serum levels of creatinine may be raised, reflecting reduced GFR (see above), although serum creatinine values can remain within the reference range in patients with reduced muscle mass, even when the GFR has fallen by more than 50%. Serum levels of urea are often increased in kidney disease but this analyte has limited value as a measure of GFR since levels increase with protein intake, following gastrointestinal haemorrhage and in catabolic states. Conversely, urea levels may be reduced in patients with liver failure or anorexia and in malnourished patients, independently of changes in renal function. Serum calcium tends to be reduced and phosphate increased in CKD, in association with high parathyroid hormone (PTH) levels caused by reduced production of $1,25(OH)_2D$ by the kidney (secondary hyperparathyroidism). In some patients, this may be accompanied by raised serum alkaline phosphatase levels, which are indicative of renal osteodystrophy. Other biochemical abnormalities may be observed that reflect underlying disease processes, such as raised glucose and HbA_{1c} levels in diabetes mellitus (p. 807) and raised levels of C-reactive protein (CRP) in sepsis and vasculitis.

Immunology

Antinuclear antibodies, antibodies to extractable nuclear antigens and anti-double-stranded DNA antibodies may be detected in patients with renal disease secondary to SLE (p. 1109). Antineutrophil cytoplasmic antibodies (ANCA) may be detected in patients with glomerulonephritis secondary to systemic vasculitis (p. 1115), as may antibodies to GBM in patients with Goodpasture's syndrome (p. 497) and low levels of complement in SLE, systemic vasculitis and HUS.

Imaging

Ultrasound

Renal ultrasound is a valuable non-invasive technique that is indicated to assess renal size and to investigate patients who are suspected of having obstruction of the urinary tract (Fig. 17.3) or renal tumours, cysts or stones. It is often the only method required for renal imaging and has the advantage of showing other abdominal, pelvic and retroperitoneal pathology. Ultrasound can also be used to provide images of the prostate gland and bladder, and to estimate the completeness of emptying in patients with suspected bladder outflow obstruction. Ultrasonography may show increased density of the renal cortex with loss of distinction between cortex and medulla, which is characteristic of CKD. Doppler

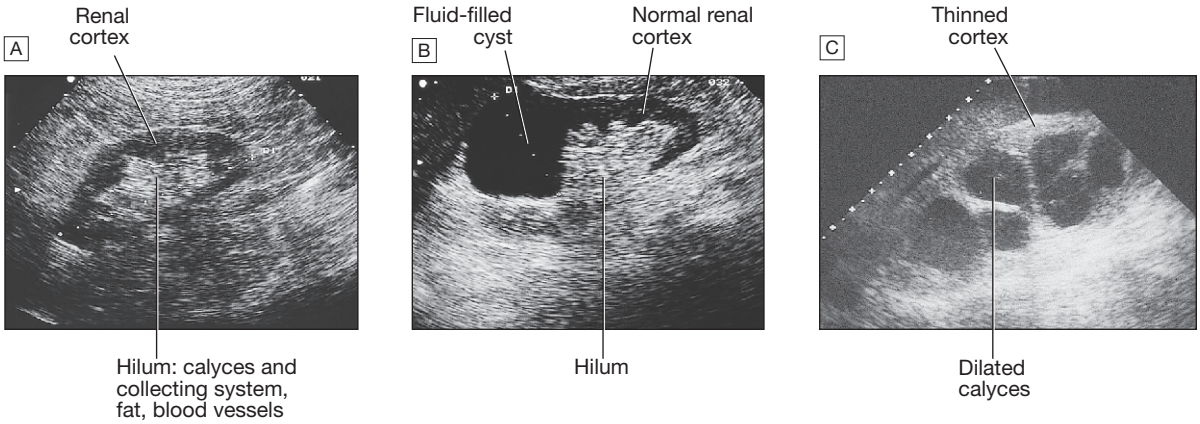

Fig. 17.3 Renal ultrasound. A Normal kidney. The normal cortex is less echo-dense (blacker) than the adjacent liver. B A simple cyst occupies the upper pole of an otherwise normal kidney. C The renal pelvis and calyces are dilated by a chronic obstruction to urinary outflow. The thinness and increased density of the remaining renal cortex indicate chronic changes.

imaging can be used to study blood flow in extrarenal and larger intrarenal vessels and can assess the resistivity index, which is the ratio of peak systolic and diastolic velocity. This is influenced by the resistance to flow through small intrarenal arteries and may be elevated in various diseases, including acute glomerulonephritis and rejection of a renal transplant. High peak velocities can also occur in severe renal artery stenosis. However, renal ultrasound is operator-dependent, the stored images convey only a fraction of the dynamic information gained during the investigation, and the results are often less clear in obese patients.

Computed tomography

Computed tomography urography (CTU) is used to evaluate cysts and mass lesions in the kidney or filling defects within the collecting systems. It usually entails an initial scan without contrast medium, and subsequent scans following injection of contrast to obtain a nephrogram image and images during the excretory phases. This technique gives more information than intravenous urography (IVU) but entails a substantially larger radiation dose. Contrast enhancement is particularly useful for characterising mass lesions within the kidney and differentiating benign from malignant lesions (see Fig. 17.32A, p. 516). Computed tomography without contrast (CT) gives clear definition of retroperitoneal anatomy regardless of obesity and is superior to ultrasound in this respect. Non-contrast CT of kidneys, ureters and bladder (CTKUB) is the method of choice for demonstrating stones within the kidney or ureter.

Computed tomography and angiography

This technique (CT-angiography) involves performing computed tomography, following an intravenous injection of contrast medium, to obtain images of the renal vasculature. It produces high-quality images of the main renal vessels and is of value in patients who have suffered renal trauma and those with haemorrhage from the renal tract, and in the investigation of renal artery stenosis. Other vascular structures, such as angiomyolipomas and aneurysms, can also be detected. Drawbacks include the fact that relatively large doses of contrast medium are required, which can cause renal dysfunction, and that the radiation dose is significant (Box 17.4).

17.4 Renal complications of radiological investigations

Contrast nephrotoxicity

- Acute deterioration in renal function, sometimes life-threatening, commencing < 48 hrs after administration of IV radiographic contrast media

Risk factors

- Pre-existing renal impairment
- Use of high-osmolality, ionic contrast media and repetitive dosing in short time periods
- Diabetes mellitus
- Myeloma

Prevention

- Provide hydration with free oral fluids plus IV isotonic saline 500 mL, then 250 mL/hr during procedure
- Avoid nephrotoxic drugs; withhold non-steroidal anti-inflammatory drugs (NSAIDs). Omit metformin for 48 hrs after the procedure, in case renal impairment occurs
- *N*-acetylcysteine may provide some protection but data are conflicting
- If the risks are high, consider alternative methods of imaging

Cholesterol atheroembolism

- Typically follows days to weeks after intra-arterial investigations or interventions (p. 496)

Nephrogenic sclerosing fibrosis after MRI contrast agents

- Chronic progressive sclerosis of skin, deeper tissues and other organs, associated with gadolinium-based contrast agents
- Only reported in patients with renal impairment, typically on dialysis or with GFR < 15 mL/min/1.73 m^2, but caution is advised in patients with GFR < 30 mL/min/1.73 m^2

Magnetic resonance imaging

Magnetic resonance imaging (MRI) offers excellent resolution and gives good distinction between different tissue types (see Fig. 17.26, p. 506). It is very useful for local staging of prostate, bladder and penile cancers. Magnetic resonance angiography (MRA) provides an alternative to CT-angiography for imaging renal vessels

but involves administration of gadolinium-based contrast media, which may carry risks for patients with impaired renal function (see Box 17.4). Whilst MRA gives good images of the main renal vessels, stenosis of small branch arteries may be missed.

Renal arteriography

Renal arteriography involves taking X-rays following an injection of contrast medium directly into the renal artery. The main indication is to investigate renal artery stenosis (p. 494) or haemorrhage. Renal angiography can often be combined with therapeutic balloon dilatation or stenting of the renal artery and can be used to occlude bleeding vessels and arteriovenous fistulae by the insertion of thin platinum wires (coils). These curl up within the vessel and promote thrombosis, thereby securing haemostasis.

Intravenous urography

Intravenous urography (IVU) involves taking serial plain X-rays immediately before and after an intravenous injection of contrast medium. It has largely been replaced by ultrasound, CTKUB and CTU for most renal imaging purposes but remains a useful method of viewing the renal papillae, stones and urothelial malignancies (Fig. 17.4). The initial X-rays may show the renal outlines (if perinephric fat and bowel gas shadows allow), as well as radio-opaque calculi and calcification within the renal tract. Early films taken 1 minute after injection can be used to assess renal perfusion, whereas films at later time points provide images of the collecting system, ureters and bladder. The disadvantages of this technique are the need for an injection, dependence on adequate renal function, and exposure to irradiation and contrast medium (see Box 17.4).

Pyelography

Pyelography involves direct injection of contrast medium into the collecting system from above or below. It offers the best views of the collecting system and upper tract, and is sometimes used to identify the cause of urinary tract obstruction (p. 472). Antegrade pyelography requires the insertion of a fine needle into the pelvicalyceal system under ultrasound or radiographic control. This approach is much more difficult and hazardous in a non-obstructed kidney. In the presence of obstruction, percutaneous nephrostomy drainage can be established, and often stents can be passed through any obstruction. Retrograde pyelography can be performed by inserting catheters into the ureteric orifices at cystoscopy (Fig. 17.5).

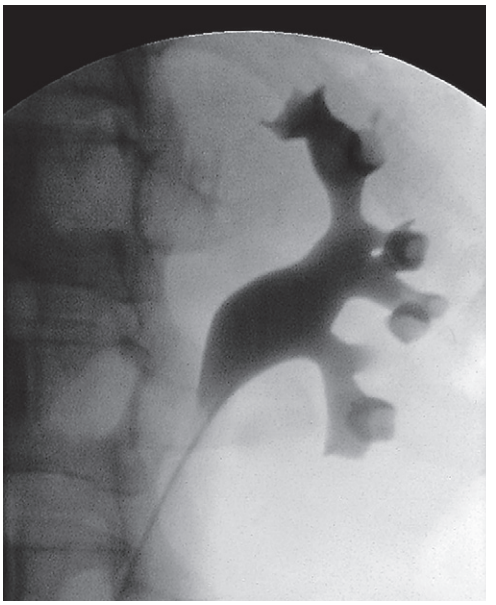

Fig. 17.5 Retrograde pyelography. The best views of the normal collecting system are shown by pyelography. A catheter has been passed into the left renal pelvis at cystoscopy. The anemone-like calyces are sharp-edged and normal.

Radionuclide studies

These are functional studies requiring the injection of gamma ray-emitting radiopharmaceuticals that are taken up and excreted by the kidney, a process that can be monitored by an external gamma camera.

Dynamic radionucleotide studies are performed with mercaptoacetyltriglycine labelled with technetium (^{99m}Tc-MAG3), which is filtered by the glomerulus and excreted into the urine. Imaging following ^{99m}Tc-MAG3 injection can provide valuable information about the perfusion of each kidney but is not a reliable method for identifying renal artery stenosis. In patients with significant obstruction of the outflow tract, ^{99m}Tc-MAG3

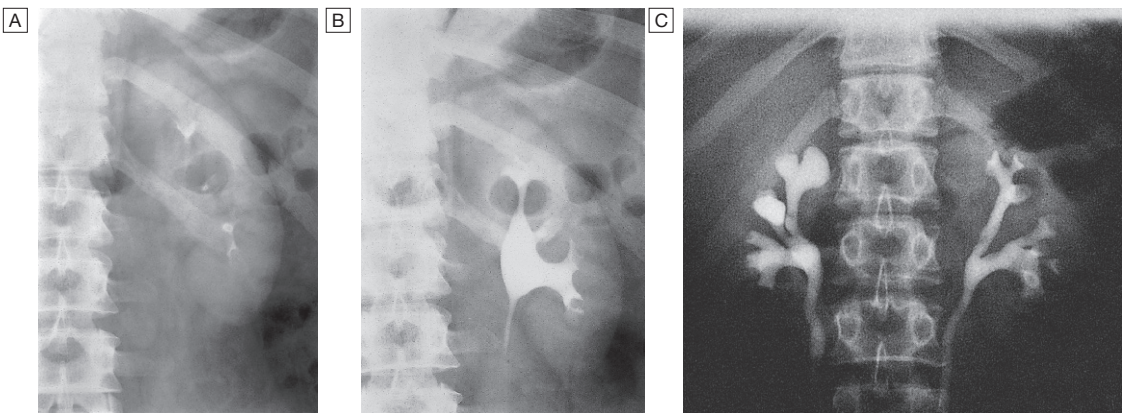

Fig. 17.4 Intravenous urography (IVU). A Normal nephrogram phase at 1 minute. B Normal collecting system at 5 minutes. C Bilateral reflux nephropathy (and chronic pyelonephritis), showing clubbing of the calyces that is particularly marked in the upper right pole.

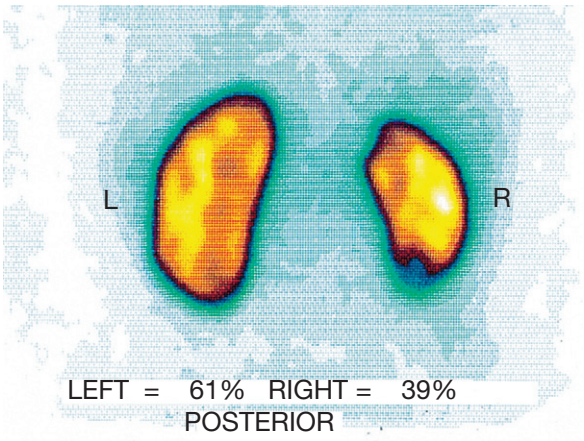

Fig. 17.6 DMSA isotope renogram. A posterior view is shown of a normal left kidney and a small right kidney (with evidence of cortical scarring at upper and lower poles) that contributes only 39% of total renal function.

persists in the renal pelvis and a loop diuretic fails to accelerate its disappearance. This can be useful in determining the functional significance of a 'baggy' or equivocally obstructed collecting system without undertaking pyelography.

Formal measurements of GFR can be made by radionuclide studies following the injection of diethylenetriamine pentacetic acid (^{99m}Tc-DPTA).

Static radionucleotide studies are performed with dimercaptosuccinic acid labelled with technetium (^{99m}Tc-DMSA), which is taken up by proximal tubular cells. Following intravenous injection, images of the renal cortex are obtained that show the shape, size and relative function of each kidney (Fig. 17.6). This is a sensitive method for demonstrating cortical scarring in reflux nephropathy and a way of assessing the individual function of each kidney.

Radionuclide bone scanning following the injection of methylene diphosphonate (^{99m}Tc-MDP) is indicated to assess the presence and extent of bone metastases in men with advanced prostate cancer (p. 517).

Renal biopsy

Renal biopsy is used to establish the nature and extent of renal disease in order to judge the prognosis and need for treatment (Box 17.5). The procedure is performed transcutaneously with ultrasound or contrast radiography guidance to ensure accurate needle placement into a renal pole. Light microscopy, electron microscopy and immunohistological assessment of the specimen may all be required.

17.5 Renal biopsy

Indications

- Acute kidney injury that is not adequately explained
- CKD with normal-sized kidneys
- Nephrotic syndrome or glomerular proteinuria in adults
- Nephrotic syndrome in children that has atypical features or is not responding to treatment
- Isolated haematuria or proteinuria with renal characteristics or associated abnormalities

Contraindications

- Disordered coagulation or thrombocytopenia. Aspirin and other antiplatelet agents increase bleeding risk
- Uncontrolled hypertension
- Kidneys < 60% predicted size
- Solitary kidney* (except transplants)

Complications

- Pain, usually mild
- Bleeding into urine, usually minor but may produce clot colic and obstruction
- Bleeding around the kidney, occasionally massive and requiring angiography with intervention, or surgery
- Arteriovenous fistula, rarely significant clinically

*Relative contraindication.

PRESENTING PROBLEMS IN RENAL AND URINARY TRACT DISEASE

Dysuria

Dysuria refers to painful urination, often described as burning, scalding or stinging, and commonly accompanied by suprapubic pain. It is often associated with frequency of micturition and a feeling of incomplete emptying of the bladder. By far the most common cause is urinary tract infection, as described on page 511. Other diagnoses that need to be considered in patients with dysuria include sexually transmitted infections (p. 411) and bladder stones (p. 507).

Loin pain

Loin pain is often caused by musculoskeletal disease but can be a manifestation of renal tract disease; in the latter case, it may arise from renal stones, ureteric stones, renal tumours, acute pyelonephritis and urinary tract obstruction. Acute loin pain radiating anteriorly and often to the groin is termed renal colic. When combined with haematuria, this is typical of ureteric obstruction due to calculi (p. 507). When loin pain is precipitated by a large fluid intake (Dietl's crisis), upper urinary tract obstruction caused by a congenital abnormality of the pelviureteric junction (PUJ, p. 510) is often responsible.

Oliguria/anuria

Oliguria is defined as being present when less than 300 mL urine is passed per day, whereas anuria is deemed to exist when less than 50 mL urine is passed per day.

The volume of urine produced represents a balance between the amount of fluid that is filtered at the glomerulus and that reabsorbed by the renal tubules. When GFR is low, urine volumes may still be normal if tubular reabsorption is also reduced; hence urine volume alone is a poor indicator of kidney disease. Oliguria and anuria may be caused by a reduction in urine production, as in pre-renal acute kidney injury, when GFR is reduced but tubular homeostatic mechanisms increase

reabsorption to conserve salt and water. A high solute load or associated tubular dysfunction may, however, produce normal or high urine volumes in such cases until the pre-renal insult becomes severe and GFR is markedly reduced, such as occurs in diabetic ketoacidosis with marked glycosuria. Urine volumes are variable in acute kidney injury due to intrinsic renal disease, but a rapid decline in urine volume may be observed in patients with bilateral renal infarction, in those with a single functioning kidney, and in those with rapidly progressive glomerulonephritis.

Obstruction of the renal tract can also produce oliguria and anuria, but to do so, obstruction must be complete and occur distal to the bladder neck, be bilateral, or be unilateral on the side of a single functioning kidney. If an obstruction is not relieved, the pressure will be transmitted back to the nephrons, causing GFR to fall.

Patients with oliguria and anuria should be assessed clinically to look for evidence of hypotension or volume depletion; of bladder enlargement; and of phimosis or meatal stenosis.

The presence of pain that is exacerbated by a fluid load suggests an acute obstruction of the renal tract, and its characteristics may be of value in reaching a diagnosis. Obstruction at the bladder neck is associated with lower midline abdominal discomfort due to bladder dilatation, whereas ureteric obstruction typically presents as loin pain radiating to the groin. Obstructions at the level of the renal pelvis may present as flank pain. Chronic obstruction rarely produces pain but may give rise to a dull ache. Unilateral ureteric obstruction may not lead to any noticeable reduction in urine output, whereas bilateral ureteric obstruction will result in oliguria or anuria. Urethral strictures should be considered as a possible cause, especially in patients with a history of instrumentation of the renal tract. Urethral valves should also be considered, especially in the paediatric population.

The presence of bladder enlargement in a middle-aged or elderly man suggests benign or malignant enlargement of the prostate gland as a potential cause of oliguria or anuria (pp. 515 and 517). It is important to note that about 50% of cases of acute urinary retention are seen after general anaesthesia, particularly in patients with pre-existing prostatic enlargement. Partial obstruction can be associated with a normal or even high urine volume due to chronic tubular injury, which causes loss of tubular concentrating ability. This chronic tubular injury can also produce a type 1 renal tubular acidosis (p. 446). Over time, even partial obstruction can cause tubular atrophy and irreversible renal failure.

All patients with oliguria or anuria should have routine biochemistry and haematology checked. Catheterisation should be performed so that urine volumes can be accurately monitored and the urine analysed for evidence of proteinuria and red cell casts, which may be found in patients with glomerulonephritis and systemic diseases such as vasculitis or SLE. Isolated haematuria may be indicative of an obstructive uropathy secondary to urinary calculi (p. 507) or tumours affecting the renal tract. If oliguria persists without any other clear explanation, ultrasound examination should be undertaken promptly to look for evidence of obstruction. Rarely, however, the urinary tract may not be particularly dilated in patients with acute kidney injury due to obstruction because of lack of urine production.

Management of oliguria and anuria should be directed at the underlying cause. While relief of obstruction is usually accompanied by a rapid return of renal function, tubular function may be impaired, resulting in polyuria and failure to conserve electrolytes.

Polyuria

Polyuria is defined as a urine volume in excess of 3 L/day. Various underlying conditions, both renal and extrarenal, may be responsible, as outlined in Box 17.6.

Investigation of polyuria includes measurement of urea, creatinine and electrolytes, glucose, calcium and albumin. A 24-hour urine collection may be helpful to confirm the severity of polyuria and the presence of nocturnal polyuria. Investigation and management of suspected diabetes insipidus are described on page 794.

17.6 Causes of polyuria

- Excess fluid intake
- Hyperglycaemia
- Cranial diabetes insipidus
- Nephrogenic diabetes insipidus
  - Lithium
  - Diuretics
  - Interstitial nephritis
  - Hypokalaemia
  - Hypercalcaemia

Nocturia

Nocturia is defined as waking up at night to void urine. It may be a consequence of polyuria but may also result from increased fluid intake or diuretic use in the late evening. Nocturia also occurs in CKD, and in prostatic enlargement when it is associated with poor stream, hesitancy, incomplete bladder emptying, terminal dribbling and urinary frequency due to partial urethral obstruction (p. 515). Nocturia may also occur in sleep disturbance without functional abnormalities of the urinary tract.

Frequency

Frequency describes micturition more often than a patient's expectations. It may be a consequence of polyuria, when urine volume is normal or high, but is also found in patients with dysuria and prostatic diseases, when the urine volume is low.

Urinary incontinence

Urinary incontinence is defined as any involuntary leakage of urine. It may occur in patients with a normal urinary tract, as the result of dementia or poor mobility, or transiently during an acute illness or hospitalisation,

17.7 Incontinence in old age

- **Prevalence**: urinary incontinence affects 15% of women and 10% of men aged over 65 years.
- **Cause**: incontinence may be transient and due to an acute confusional state, urinary infection, medication (such as diuretics), faecal impaction or restricted mobility, and these should be treated before embarking on further specific investigation.
- **Detrusor over-activity**: established incontinence in old age is most commonly due to detrusor over-activity, which may be caused by damage to central inhibitory centres or local detrusor muscle abnormalities.
- **Catheterisation**: poor manual dexterity or cognitive impairment may necessitate the help of a carer to assist with intermittent catheterisation.

especially in older people (Box 17.7). Diuretics, alcohol and caffeine may worsen incontinence.

Pathophysiology

As urine accumulates in the bladder during the storage phase, the sphincter tone gradually increases, but there are no significant changes in vesical pressure, detrusor pressure or intra-abdominal pressure. During voiding, intravesical pressure increases, due to detrusor contraction, and the sphincter relaxes, allowing urine to flow from the bladder until it is empty. Clinical disorders associated with incontinence are connected with various abnormalities in this cycle and these are discussed in more detail below.

Stress incontinence

This occurs because passive bladder pressure exceeds the urethral pressure, due to either poor pelvic floor support or a weak urethral sphincter. Most often, there is an element of both. Stress incontinence is very common in women and seen most frequently following childbirth. It is rare in men and usually follows surgery to the prostate. The presentation is with incontinence during coughing, sneezing or exertion. In women, perineal inspection may reveal leakage of urine when the patient coughs.

Urge incontinence

This usually occurs because of detrusor overactivity, which produces an increased bladder pressure that overcomes the urethral sphincter. Urgency with or without incontinence may also be driven by a hypersensitive bladder resulting from urinary tract infection or a bladder stone. Detrusor overactivity is usually idiopathic, other than in patients with neurological conditions such as spina bifida or multiple sclerosis, in which case it is neurogenic (p. 1174). The incidence of urge incontinence increases with age, occurring in 10-15% of the population aged over 65 years and around 50% of patients requiring nursing home care. It is also seen in men with lower urinary tract obstruction and most often remits after the obstruction is relieved.

Continual incontinence

This is suggestive of a fistula, usually between the bladder and vagina (vesicovaginal), or the ureter and vagina (ureterovaginal). It is most common following gynaecological surgery but is also seen in patients with gynaecological malignancy or post-radiotherapy. In parts of the world where obstetric services are scarce, prolonged obstructed labour can be a common cause of vesicovaginal fistulae. Continual incontinence may also be seen in infants with congenital ectopic ureters. Occasionally, stress incontinence is so severe that the patient leaks continuously.

Overflow incontinence

This occurs when the bladder becomes chronically overdistended and may be associated with acute kidney injury (high-pressure chronic urinary retention). It is most commonly seen in men with benign prostatic enlargement or bladder neck obstruction (p. 514), but may arise in either sex as a result of failure of the detrusor muscle (atonic bladder). The latter may be idiopathic but more commonly is the result of damage to the pelvic nerves, either from surgery (commonly, hysterectomy or rectal excision), trauma or infection, or from compression of the cauda equina by disc prolapse, trauma or tumour. Incontinence due to prostatic enlargement can be regarded as a type of overflow incontinence.

Post-micturition dribble

This is very common in men, even in the relatively young. It is due to a small amount of urine becoming trapped in the U-bend of the bulbar urethra, which leaks out when the patient moves. It is more pronounced if associated with a urethral diverticulum or urethral stricture. It may occur in females with a urethral diverticulum and may mimic stress incontinence.

Clinical assessment

Patients should be encouraged to keep a voiding diary, including the measured volume voided, frequency of voiding, precipitating factors and associated features, such as urgency, since this can be of diagnostic value. The patient should be assessed for evidence of cognitive impairment and mobility. A neurological assessment should be performed to detect disorders such as multiple sclerosis that may affect the nervous supply of the bladder, and the lumbar spine should be inspected for features of spina bifida occulta. Perineal sensation and anal sphincter tone should be assessed. Rectal examination is needed to assess the prostate in men and to exclude faecal impaction as a cause of incontinence. Genital examination should be done to identify phimosis and paraphimosis in men, and vaginal mucosal atrophy, cystoceles or rectoceles in women.

Investigations

Urinalysis and culture should be performed in all patients. Ultrasound examination can be helpful in identifying patients with overflow incontinence who have incomplete bladder emptying, as they may reveal a significant amount of fluid in the bladder (> 100 mL) post-micturition. Urine flow rates and full urodynamic assessment by cystometrography may be required to diagnose the type of incontinence and are indicated in selected cases when the diagnosis is unclear on clinical grounds. An IVU should be performed in patients with continual incontinence who are suspected of having a

fistula. Imaging with MRI is indicated when a urethral diverticulum is suspected.

Management

Females with stress incontinence respond well to physiotherapy. The mainstay of treatment for urge incontinence is bladder retraining, which involves teaching patients to hold more urine voluntarily in their bladder, assisted by anticholinergic medication. Surgery may be required in patients who have severe daytime incontinence despite conservative treatment. The treatment of incontinence secondary to fistula formation is surgical. Patients with overflow incontinence due to bladder obstruction should be treated surgically or with long-term catheterisation (intermittent or continuous). Incontinence secondary to neurological diseases can be treated by intermittent self-catheterisation.

Erectile dysfunction

Causes of erectile failure are shown in Box 17.8. Vascular, neuropathic and psychological causes are most common. With the exception of diabetes mellitus, endocrine causes are relatively uncommon and are characterised by loss of libido, as well as erectile dysfunction. Erectile dysfunction and reduced libido occur in over 50% of men with advanced CKD or on dialysis. Erectile dysfunction is a markedly under-diagnosed problem. It is important to discuss matters frankly with the patient, and to establish whether there are associated features of hypogonadism (p. 760) and if erections occur at any other time. If the patient has erections on wakening, vascular and neuropathic causes are much less likely and a psychological cause should be suspected.

Investigations

Blood should be taken for glucose, prolactin, testosterone, luteinising hormone (LH) and follicle-stimulating hormone (FSH). A number of further tests are available but are rarely employed because they do not usually influence management. These include nocturnal tumescence monitoring (using a plethysmograph placed around the shaft of the penis overnight) to establish whether blood supply and nerve function are sufficient to allow erections to occur during sleep; intracavernosal injection of prostaglandin E1 to test the adequacy of blood supply; internal pudendal artery angiography; and tests of autonomic and peripheral sensory nerve conduction.

17.8 Causes of erectile dysfunction

With reduced libido

- Hypogonadism
- Depression

With intact libido

- Psychological problems, including anxiety
- Vascular insufficiency (atheroma)
- Neuropathic causes (diabetes mellitus, alcohol excess, multiple sclerosis)
- Drugs (β-blockers, thiazide diuretics)

Management

First-line therapy is usually with oral phosphodiesterase type 5 inhibitors, such as sildenafil, which elevate cyclic guanosine monophosphate (cGMP) levels in vascular smooth muscle cells of the corpus cavernosum, causing vasodilatation and penile erection. Co-administration of these drugs with nitric oxide donors, such as glycerol trinitrate, is contraindicated because of the risk of severe hypotension. Other treatments for impotence include self-administered intracavernosal injection or urethral administration of prostaglandin E1; vacuum devices which achieve an erection that is maintained by a tourniquet around the base of the penis; and prosthetic implants, either of a fixed rod or an inflatable reservoir. Psychotherapy involving the patient and sexual partner may be helpful for psychological problems. Erectile dysfunction associated with peripheral neuropathy and vascular disease is difficult to treat. If hypogonadism is detected, it should be managed as described on page 760.

Haematuria

Healthy individuals may have occasional red blood cells in the urine (up to 12500 cells/mL), but the presence of macroscopic haematuria (visible to the naked eye) or non-visible haematuria on dipstick testing (15000–20000 cells/mL or more) is indicative of significant bleeding from somewhere in the urinary tract (Fig. 17.7) and demands further assessment. First, it is important to confirm the presence of blood cells in the urine by microscopy (p. 463), since dipstick tests can also be positive in the presence of free haemoglobin or myoglobin. Microscopy not only confirms the diagnosis but may also be helpful in establishing the cause of bleeding (Box 17.9). Other causes of red or dark urine may sometimes be confused with haematuria but produce negative dipstick tests and microscopy (Box 17.10). Positive tests may also occur during menstruation, infection or strenuous exercise. Investigation

17.9 Interpretation of dipstick-positive haematuria

Dipstick test positive	Urine microscopy	Suggested cause
Haematuria	White blood cells	Infection
	Abnormal epithelial cells	Tumour
	Red cell casts	Glomerular bleeding*
	Dysmorphic erythrocytes (phase contrast microscopy)	Glomerular bleeding*
Haemoglobinuria	No red cells	Intravascular haemolysis
Myoglobinuria (brown urine)	No red cells	Rhabdomyolysis

*Glomerular bleeding implies that the GBM is ruptured. It can occur physiologically following very strenuous exertion but usually indicates intrinsic renal disease and is an important feature of the nephritic syndrome (see Box 17.12).

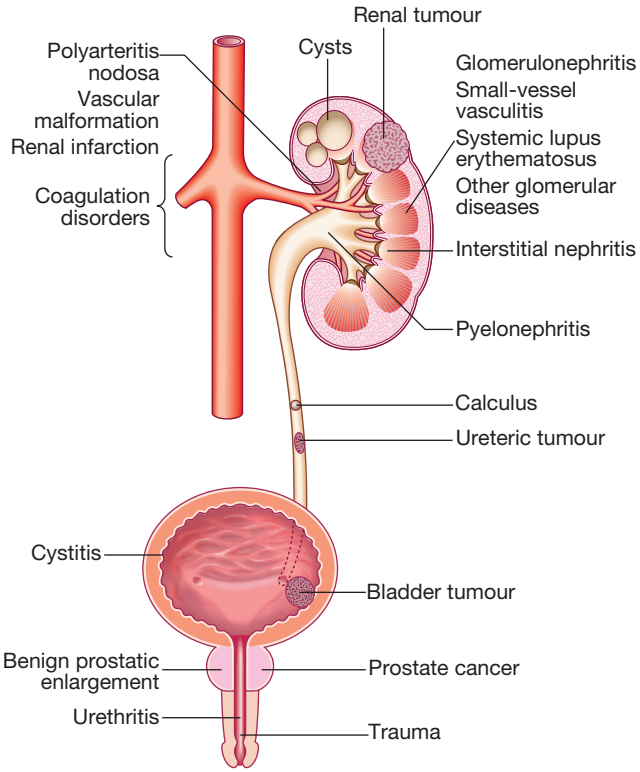

Fig. 17.7 Causes of haematuria.

17.10 Dipstick-negative dark urine

Cause	Urine colour
Food dyes	
Acanthocyanins	Red
Drugs	
Phenolphthalein	Pink when alkaline
Senna/other anthaquinones	Orange
Rifampicin	Orange
Levodopa	Darkens on standing
Porphyria	Darkens on standing
Alkaptonuria	Darkens on standing
Bilirubinuria	
Obstructive jaundice	Dark Dipstick-positive for bilirubin, negative for haemoglobin

17.11 Nephritic and nephrotic syndromes

Nephritic syndrome[1]

- Haematuria (red or brown urine)
- Oedema and generalised fluid retention
- Hypertension
- Oliguria

Nephrotic syndrome[2]

- Overt proteinuria: usually > 3.5 g/24 hrs (urine may be frothy)
- Hypoalbuminaemia (< 30 g/L)
- Oedema and generalised fluid retention
- Intravascular volume depletion with hypotension, or intravascular expansion with hypertension, may occur

[1]The complete form is classically seen in post-infectious glomerulonephritis, may occur in acute IgA nephropathy, and occasionally occurs in other types of glomerulonephritis. The presence of one or more features is common to many types of glomerular disease.
[2]Classically seen in non-inflammatory and subacute inflammatory/proliferative glomerular disorders (see Fig. 17.21, p. 497).

EBM 17.12 Haematuria and urothelial malignancy

'Macroscopic haematuria has a positive predictive value of 83% for bladder cancer and 22% for all urothelial tumours, rising to 41% in patients over the age of 40.'

- Buntinx F, et al. Fam Pract 1997; 14(1):63–68.

of haematuria is always required, as even non-visible haematuria can be caused by malignancy.

Glomerular bleeding is characteristic of inflammatory, destructive or degenerative processes that disrupt the GBM and may cause microscopic or macroscopic haematuria. In glomerulonephritis, one or more other features of the 'nephritic syndrome' (Box 17.11) may be present but the full syndrome is rare (p. 497). Other benign causes include thin basement membrane disease (p. 502) and vascular malformations.

Visible haematuria is most likely to be caused by tumour, which can affect any part of the urogenital tract (p. 515 and Box 17.12). Other common causes of visible haematuria are urine infection and stones. Investigation of haematuria (Fig. 17.8), whether non-visible or visible, should be directed first at the exclusion of an anatomical bleeding lesion, such as malignancy (see Box 17.12). If haematuria occurs with proteinuria and other clinical features of kidney disease (see Box 17.11), inflammatory

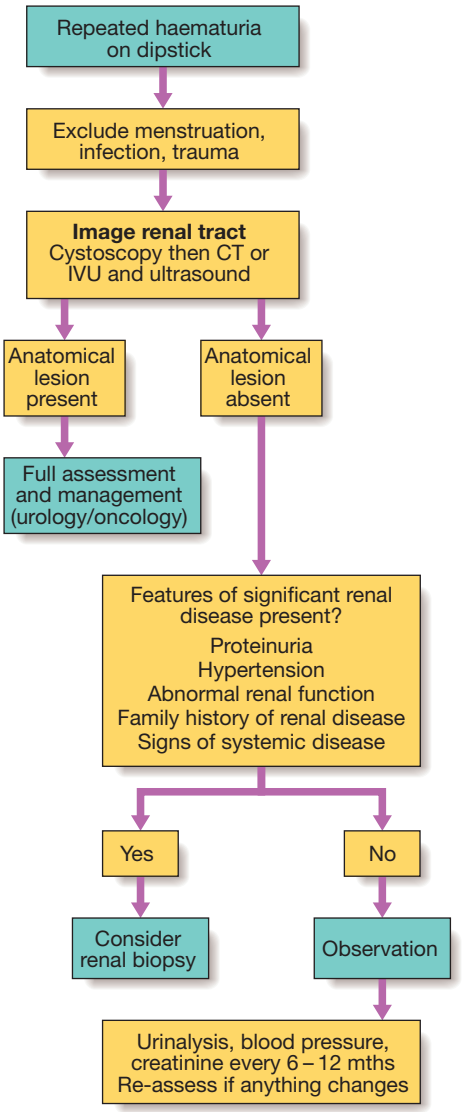

Fig. 17.8 Investigation of haematuria.

renal disease (p. 497) should be considered and a renal biopsy may be indicated. Where there are no features of significant kidney disease, and malignancy and renal stones have been excluded, it may be appropriate to manage the patient by observation with periodic review, although occasionally these individuals develop significant overt renal disease during follow-up. Management of haematuria should be directed at the underlying cause.

Proteinuria and nephrotic syndrome

Whilst moderate amounts of low-molecular-weight protein pass through the healthy GBM, these proteins are normally reabsorbed by receptors on tubular cells. In healthy individuals, less than 150 mg of protein is excreted in the urine each day. A proportion of this is Tamm–Horsfall protein, secreted by the renal tubules. The presence of larger amounts of protein is usually indicative of significant renal disease (Box 17.13).

17.13 Quantifying proteinuria in random urine samples

ACR[1]	PCR[2]	Typical dipstick results[3]	Significance
< 3.5 (female) < 2.5 (male)		–	Normal
~3.5–15		–	Microalbuminuria
~15–50	~15–50	+ to ++	Dipsticks positive; equivalent to 24-hr protein excretion < 0.5 g
50–200	> 250	++ to +++	Glomerular disease more likely
> 200	> 300	+++ to ++++	Nephrotic range: always glomerular disease, equivalent to 24-hr protein excretion > 3 g

[1]Urinary albumin (mg/L)/urine creatinine (mmol/L). [2]Urine protein (mg/L)/urine creatinine (mmol/L). (If urine creatinine is measured in mg/dL, reference values for PCR and ACR can be derived by dividing by 11.31.)
[3]Dipstick results are affected by urine concentration and are occasionally weakly positive on normal samples.

Clinical assessment

Proteinuria is usually asymptomatic and is often picked up by urinalysis. Transient proteinuria can occur after vigorous exercise, during fever, in heart failure and in patients with urinary tract infection. Patients should be assessed for the presence of these conditions and urine testing repeated once the potential trigger has been treated or resolved. So-called orthostatic proteinuria may arise in the absence of renal disease. This occurs only during the day, in association with an upright posture, and the first morning sample is negative. Typically, less than 1 g protein per day is excreted. Orthostatic proteinuria is regarded as a benign disorder which does not require treatment. Large amounts of protein make urine froth easily and this may be noticed by the patient. Very large amounts can cause nephrotic syndrome, which presents with oedema (Boxes 17.11 and 17.14). In adults, this predominantly affects the lower limbs but extends to the genitalia and lower abdomen as it becomes more severe. The upper limbs and face may be more affected on waking in the morning. In children, ascites occurs early and oedema is often seen only in the face. Blood volume may be normal, reduced or increased. Renal sodium retention is an early and universal feature; the mechanisms of this are shown in Figure 16.5 (p. 435).

Microalbuminuria refers to the urinary excretion of small amounts of albumin. The consistent presence of albumin in the urine is abnormal and is clinically important in identifying the very early stages of glomerular disease, as occurs in conditions like diabetic nephropathy (p. 830). Because significant renal damage has already taken place before standard dipstick tests become positive, patients with diabetes mellitus should be screened regularly for microalbuminuria. Persistent microalbuminuria has also been associated with an increased risk of atherosclerosis and cardiovascular

17.14 Consequences of the nephrotic syndrome and their management

Feature	Mechanism	Consequence	Management
Hypoalbuminaemia	Urinary protein losses exceed synthetic capacity of liver	Reduced oncotic pressure Oedema	Treat underlying cause
Avid sodium retention	Secondary hyper-aldosteronism Additional poorly characterised intrarenal mechanisms	Oedema	Diuretics and a low-sodium diet*
Hypercholesterolaemia	Non-specific increase in lipoprotein synthesis by liver in response to low oncotic pressure	High rate of atherosclerosis	Statins, ezetimibe
Hypercoagulability	Relative loss of inhibitors of coagulation (antithrombin III, protein C and S) and increase in liver synthesis of procoagulant factors	Venous thromboembolism	Consider prophylaxis in chronic or severe nephrotic syndrome
Infection	Hypogammaglobulinaemia due to urinary loss of immunoglobulins	Pneumococcal and meningococcal infection	Consider vaccination

*Severe nephrotic syndrome may need very large doses of combinations of diuretics acting on different parts of the nephron (e.g. loop diuretic plus thiazide plus amiloride). In occasional patients with hypovolaemia, intravenous salt-poor albumin infusions may help to establish a diuresis, although efficacy is controversial. Over-diuresis risks secondary impairment of renal function through hypovolaemia.

mortality but neither the mechanism of proteinuria nor an explanation for this association has been established.

Investigations

All patients with persistent proteinuria should have the amount of protein quantified to guide further investigations (Fig. 17.9). Since quantification by 24-hour urine collection is often inaccurate, the protein : creatinine ratio (PCR) in a spot sample of urine is preferred. This makes an allowance for the variable degree of urinary dilution and can be used to extrapolate to 24-hour values (see Box 17.13). Changes in PCR also give valuable information about the progression of renal disease in CKD. It is possible to measure 24-hour albumin excretion or albumin : creatinine ratio (ACR), but this requires a more expensive immunoassay and is usually reserved for detection of the early stages of diabetic nephropathy (p. 830). When assessing protein excretion by analysis of spot urine samples, greater consistency can be achieved by using first morning urine samples but this is not essential for routine clinical use.

It is sometimes helpful to identify the type of protein in the urine. Low-molecular-weight proteins may appear in the urine in quantities greater than 150 mg/day. This is usually assessed by measurement of specific low-molecular-weight proteins, such as β_2-microglobulin (molecular weight 12 kDa). Large amounts of small proteins in the urine suggest renal tubular damage and are referred to as tubular proteinuria. This rarely exceeds 1.5–2 g/24 hours (maximum PCR 150–200 mg/mmol). When more than 2 g protein per day is being excreted, glomerular disease is likely and this is an indication for renal biopsy. The diseases that cause nephrotic syndrome all affect the glomerulus (see Fig. 17.21, p. 497), either directly, by damaging podocytes, or indirectly, by causing scarring or by depositing exogenous material such as amyloid into the glomerulus. A notable exception is in children, when heavy proteinuria and nephrotic syndrome are most commonly caused by minimal change glomerulonephritis. In this case, renal biopsy is not usually required unless the patient fails to respond to high-dose corticosteroid therapy.

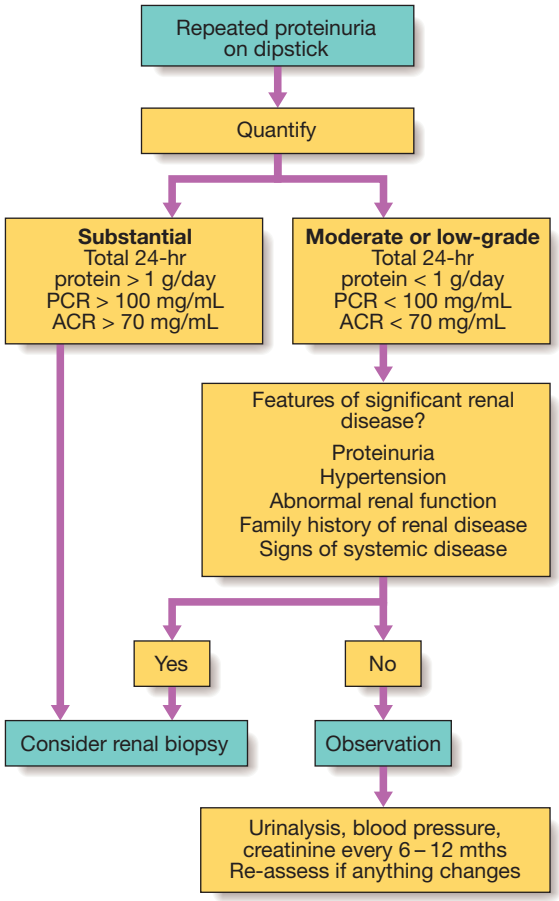

Fig. 17.9 Investigation of proteinuria. (ACR = albumin : creatinine ratio; PCR = protein : creatinine ratio.)

Free immunoglobulin light chains (molecular weight 25 kDa) are filtered freely at the glomerulus and can be identified as 'Bence Jones protein' in fresh urine samples. Bence Jones protein is poorly identified by dipstick tests and so specific immunodetection methods are required. This may occur in AL amyloidosis (p. 86) and in B-cell

disorders, but is particularly important as a marker for myeloma (p. 1046).

Management

Management of proteinuria should be directed at the underlying cause. This may involve immunosuppressive therapy in glomerulonephritis and supportive management for nephrotic syndrome (Box 17.14).

Oedema

Oedema is caused by an excessive accumulation of fluid within the interstitial space. Clinically, this can be detected by persistence of an indentation in tissue following pressure on the affected area (pitting oedema). Non-pitting oedema is typical of lymphatic obstruction and may also occur as the result of excessive matrix deposition in tissues – for example, in hypothyroidism (p. 743) or scleroderma (p. 1112). There are various possible causes (Box 17.15). Pitting oedema tends to accumulate in the ankles during the day and improves overnight as the interstitial fluid is reabsorbed. In developed countries, the most common causes of oedema are local venous problems and heart failure (p. 546), but it is important to identify other causes.

Clinical assessment

The ankles and lower parts of the leg are typically affected first but oedema can be restricted to the sacrum in bed-bound patients. With increasing severity, oedema spreads to affect the upper parts of the legs, the genitalia and abdomen. Ascites is common and often an earlier feature in children or young adults, and in liver disease. Pleural effusions are common and can be a feature of any cause of generalised oedema. Facial oedema on waking is common. Features of intravascular volume depletion (tachycardia, postural hypotension) may occur when oedema is due to decreased oncotic pressure or increased capillary permeability. If oedema is localised – for example, to one ankle but not the other, then venous thrombosis, inflammation or lymphatic disease should be suspected.

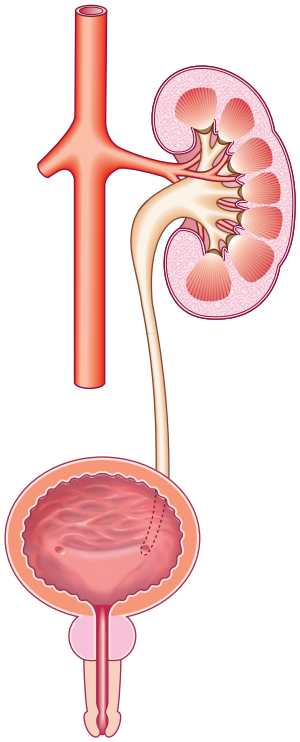
17.15 Causes of oedema

Increased total extracellular fluid	
• Congestive heart failure • Renal failure	• Liver disease
High local venous pressure	
• Deep venous thrombosis or venous insufficiency	• Pregnancy • Pelvic tumour
Low plasma oncotic pressure/serum albumin	
• Nephrotic syndrome • Liver failure	• Malnutrition/malabsorption
Increased capillary permeability	
• Leakage of proteins into the interstitium, reducing the osmotic pressure gradient which draws fluid into the lymphatics and blood • Infection/inflammation • Severe sepsis • Calcium channel blockers	
Lymphatic obstruction	
• Infection: filariasis, lymphogranuloma venereum (pp. 372 and 424)	• Malignancy • Radiation injury • Congenital abnormality

Investigations

The cause of oedema is usually apparent from the history and examination of the cardiovascular system and abdomen. Blood should be taken for measurement of urea and electrolytes and serum albumin, and the urine tested for protein. Further imaging of the liver, heart or kidneys may be indicated, based on history and clinical examination. Where ascites or pleural effusions occur in isolation, aspiration of fluid with measurement of protein and glucose, and microscopy for cells, will usually help to clarify the diagnosis in differentiating a transudate (typical of oedema) from an exudate (more suggestive of local pathology, p. 662).

Management



Mild oedema usually responds to a thiazide or a low dose of a loop diuretic, such as furosemide or bumetanide. In nephrotic syndrome, renal failure and severe cardiac failure, very large doses of diuretics, sometimes in combination, may be required to achieve a negative sodium and fluid balance. In resistant cases, restriction of sodium intake and fluid intake may be required. Diuretics are not helpful in the treatment of oedema caused by venous or lymphatic obstruction or by increased capillary permeability. Specific causes of oedema, such as venous thrombosis, should be treated.

Hypertension

Hypertension is a very common feature of renal disease. Additionally, the presence of hypertension identifies a population at risk of developing CKD and current recommendations are that patients on antihypertensive medication should have renal function checked annually. Control of hypertension is very important in patients with renal impairment because of its close relationship with further decline of renal function (p. 486) and because of the exaggerated cardiovascular risk associated with CKD. Pathophysiology and management are discussed on pages 606–613.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI), also referred to as acute renal failure, describes the situation where there is a sudden and often reversible loss of renal function, which develops over days or weeks and is usually accompanied by a reduction in urine volume. Approximately 7% of all hospitalised patients and 20% of acutely ill patients develop signs of AKI. In uncomplicated AKI, such as that due to haemorrhage or drugs, mortality is low, even when renal replacement therapy is required. In AKI associated with serious infection and multiple organ failure, mortality is 50–70% and the outcome is usually determined by the severity of the underlying disorder and other complications, rather than by renal failure itself.

PRE-RENAL

Impaired perfusion:
- Cardiac failure
- Sepsis
- Blood loss
- Dehydration
- Vascular occlusion

RENAL

Glomerulonephritis
Small-vessel vasculitis
Acute tubular necrosis
- Drugs
- Toxins
- Prolonged hypotension

Interstitial nephritis
- Drugs
- Toxins
- Inflammatory disease
- Infection

POST-RENAL

Urinary calculi
Retroperitoneal fibrosis
Benign prostatic enlargement
Prostate cancer
Cervical cancer
Urethral stricture/valves
Meatal stenosis/phimosis

Fig. 17.10 Causes of acute kidney injury.

Pathophysiology

There are many causes of AKI and it is frequently multifactorial. It is often classified into three subtypes: 'pre-renal', when perfusion to the kidney is reduced; 'renal', when the primary insult affects the kidney itself; and 'post-renal', when there is obstruction to urine flow at any point from the tubule to the urethra (Fig. 17.10). In pre-renal AKI, the kidney becomes damaged as the result of hypoperfusion, leading to acute tubular necrosis. Histologically, the kidney shows inflammatory changes, focal breaks in the tubular basement membrane and interstitial oedema. Dead tubular cells may also be shed into the tubular lumen, leading to tubular obstruction. Although tubular cell damage is the dominant feature under the microscope, there may also be profound alterations in the renal microcirculation. Renal AKI may be caused by nephrotoxic drugs (p. 522), which can cause acute tubular necrosis and a similar histological picture to pre-renal AKI or interstitial nephritis. The other common cause is glomerulonephritis, in which there is direct inflammatory damage to the glomeruli (p. 498). Post-renal AKI occurs as the result of obstruction to the renal tract, with kidney damage arising as the result of back pressure. Anaemia is common in AKI and may occur as the result of blood loss, haemolysis or decreased erythropoiesis. In established AKI, there is an increased risk of bleeding and spontaneous gastrointestinal haemorrhage due to the uraemia.

Clinical features

Early recognition and intervention is important in AKI; all emergency admissions to hospital should have renal function, blood pressure, temperature and pulse checked on arrival and should undergo a risk assessment for the likelihood of developing AKI. This includes looking at coexisting diseases such as diabetes, vascular disease and liver disease, which make AKI more likely, as well as gathering information on drug treatments such as ACE inhibitors and NSAIDs, which may be associated with renal dysfunction. If a patient is found to have a high serum creatinine, it is important to establish whether this is an acute or acute-on-chronic phenomenon, or a sign of chronic kidney disease. Previous measurements of renal function can be of great value in differentiating these possibilities. Patients with AKI need to be assessed quickly to determine the likely underlying cause. Investigations that are required in all cases are shown in Box 17.16. Additional investigations that are required in some cases, depending on the clinical picture are shown in Box 17.17. The diagnosis of pre-renal AKI is usually obvious clinically (see below). Various criteria have been proposed to classify AKI and to help identify high-risk patients, guide treatment and provide information regarding prognosis. The most commonly used are the KDIGO and RIFLE criteria (Box 17.18), which use serum creatinine and urine output as biomarkers of kidney function.

Pre-renal AKI

Patients with pre-renal AKI are typically hypotensive and tachycardic with signs of poor peripheral perfusion, such as delayed capillary return. Tachycardia and postural hypotension (a fall in blood pressure of > 20/10 mmHg from lying to standing) are valuable signs of early hypovolaemia. Many patients with sepsis initially present with poor peripheral perfusion, as mentioned above, but then show evidence of peripheral vasodilatation once they have undergone initial resuscitation with intravenous fluids. However, this is accompanied by relative underfilling of the arterial tree and the kidney responds as it would to absolute hypovolaemia, with renal vasoconstriction leading to AKI with acute tubular necrosis. Biochemical assessment in pre-renal AKI usually reveals evidence of a metabolic acidosis and hyperkalaemia. It is important to note that pre-renal AKI may also occur without systemic hypotension, particularly in patients taking NSAIDs or ACE inhibitors. The cause of the hypotension is usually obvious clinically, but concealed blood loss can occur into the gastrointestinal tract, following trauma (particularly where there are fractures of the pelvis or femur), and into the pregnant uterus. Large volumes of intravascular fluid may also be lost into tissues after crush injuries or burns, and in severe inflammatory skin diseases or sepsis.

Renal AKI

Factors that can help differentiate the various causes of renal and post-renal AKI are summarised in Box 17.19. Patients with glomerulonephritis usually demonstrate significant haematuria and proteinuria and may have clinical manifestations of an underlying disease, such as SLE or systemic vasculitis. Although blood tests, including an immunological screen, should be performed to clarify the diagnosis in glomerulonephritis, a renal biopsy is usually required. Drug-induced acute interstitial nephritis is harder to spot but should be suspected in a previously well patient if there is an acute

17.16 Investigation of patients with established acute kidney injury

Initial test	Interpretation and further tests
Urea and creatinine	Compare to previous results. Chronically abnormal in CKD (see Box 17.26)
Electrolytes	If potassium > 6 mmol/L, treat urgently (p. 442)
Calcium and phosphate	Low calcium and high phosphate may indicate CKD (see Box 17.26) Calcium low in rhabdomyolysis: measure creatine kinase Hypercalcaemia in myeloma
Albumin	Low albumin in nephrotic syndrome (see urinalysis below) Low albumin in sepsis: take blood cultures
Full blood count **Clotting screen**	Anaemia may indicate CKD (see Box 17.26) or myeloma (see Box 17.17) Anaemia and fragmented RBC on blood film with raised LDH in thrombotic microangiopathy Low platelets and abnormal coagulation in DIC, including in sepsis: take blood cultures
C-reactive protein	ESR is misleading in renal failure High CRP may indicate sepsis or inflammatory disease
Urinalysis	Less reliable in an oliguric catheterised patient Seek earlier results if possible Marked haematuria suggests glomerulonephritis, tumour of renal tract or bleeding disorder Heavy proteinuria suggests glomerular disease: measure PCR or ACR
Urine microscopy	Casts or dysmorphic red cells suggest glomerulonephritis Leucocytes suggest infection/interstitial nephritis Crystals may be observed in drug-induced or uric acid nephropathy
Renal ultrasound	Hydronephrosis ± enlarged bladder in urinary tract obstruction: consider PSA and further imaging of urinary tract Small kidneys suggest CKD (see Box 17.26) Asymmetric kidneys suggest renovascular or developmental disease: consider renal artery imaging
Cultures	Culture blood, urine, sputum, wounds as appropriate Treat all infections
Chest X-ray	Pulmonary oedema in fluid overload Globular heart in pericardial (uraemic) effusion: perform echocardiogram 'Bat wing' appearance with normal heart size (± low Hb) may suggest pulmonary haemorrhage: measure CO transfer factor Fibrotic change in systemic inflammatory disease with lung and kidney involvement: request pulmonary function and high-resolution CT
Serology	HIV and hepatitis serology is urgent if dialysis is needed
ECG	If patient is > 40 yrs or has electrolyte abnormalities or risk of cardiac disease

(ACR = albumin:creatinine ratio; CKD = chronic kidney disease; CRP = C-reactive protein; DIC = disseminated intravascular coagulation; ESR = erythrocyte sedimentation rate; Hb = haemoglobin; LDH = lactate dehydrogenase; PCR = protein:creatinine ratio; PSA = prostate-specific antigen; RBC = red blood cells)

17.17 Clinical features and investigations of specific causes of acute kidney injury

Possibility	Consider
Vascular occlusion Aorta, or renal artery to single kidney; pointers include newly missing pulses, complete anuria	Urgent arteriography Doppler ultrasound
Malignant hypertension BP very high; RBC fragments on blood film and haemolysis	Examine optic fundi for typical features Check previous BP readings
Scleroderma Sclerodactyly, other features of scleroderma, severe hypertension	Autoantibodies to extractable nuclear antigens Imaging for involvement of other organs (p. 1112)
Systemic inflammatory disease Multi-organ involvement, rash and evidence of glomerular disease Differential diagnosis includes infection, especially endocarditis or tuberculosis	Complement (see Box 17.40), ANCA, ANF, anti-GBM antibodies, cryoglobulins and tissue biopsy Cultures, echocardiogram

Continued

17.17 Clinical features and investigations of specific causes of acute kidney injury – cont'd

Possibility	Consider
Glomerular disease Heavy proteinuria and/or haematuria	Screen for systemic inflammatory disease as above *Plus* urgent renal biopsy, unless cause already known
Interstitial nephritis Consider if urinary abnormalities minor but leucocytes present. Usually non-oliguric in early stages. Take detailed history of exposure to drugs and other possible causes	Eosinophilia and urinary eosinophils Renal biopsy Uric acid if tumour lysis possible
Myeloma Extra renal features may be present, including bone pain and hypercalcaemia. Renal disease can occur without overt myeloma. Often presents with interstitial nephritis but cast formation can be acute, so patients frequently oliguric	FBC, calcium, skeletal survey, bone marrow aspirate Serum immunoglobulins and protein electrophoresis Check urinary light chains Consider renal biopsy
Infections Leptospirosis, hantavirus, syphilis, post-streptococcal glomerulonephritis	ASO titre and other serological tests for infection

(ANCA = antineutrophil cytoplasmic antibodies; ANF = antinuclear factor; ASO = anti-streptolysin O; BP = blood pressure; FBC = full blood count; GBM = glomerular basement membrane; RBC = red blood cells)

17.18 Criteria for acute kidney injury

KDIGO (Kidney disease: improving global outcomes)	RIFLE (Risk, injury, failure, loss, end-stage)
Stage 1: serum creatinine increase > 1.5–1.9-fold, urine production of < 0.5 mL/kg/hr for 6–12 hrs	= Risk
Stage 2: serum creatinine increase > 2.0–2.9-fold, urine production of < 0.5 mL/kg/hr for ≥ 12 hrs	= Injury
Stage 3: serum creatinine increase > 3.0-fold, urine production of < 0.3 mL/kg/hr for ≥ 24 hrs or absolute anuria for ≥ 12 hrs, or absolute serum creatinine > 354 μmol/L with an acute rise of > 44 μmol/L	= Failure
	Loss: persistent AKI, or complete loss of kidney function for > 4 wks
	End-stage renal disease: need for renal replacement therapy for > 3 mths

17.19 Acute kidney injury in a haemodynamically stable, non-septic patient

Urinary tract obstruction

- Suggested by a history of loin pain, haematuria, renal colic or difficulty in micturition but often clinically silent
- Can usually be excluded by renal ultrasound: essential in any patient with unexplained AKI
- Prompt relief of the obstruction restores renal function

Drugs and toxins

- Poisoning, paraphenylenediamine hair dye, snake bite, paraquat, paracetamol, herbal medicines, *Cortinarius* mushrooms
- Therapeutic agents: direct toxicity (aminoglycosides, amphotericin, tenofovir); or haemodynamic effects (NSAIDs, ACE inhibitors), often with other factors. Phosphate crystallisation after IV administration or from bowel preparation
- Sometimes associated with systemic vasculitis, systemic lupus erythematosus (SLE) and Goodpasture's (anti-GBM) disease
- Useful blood tests include: antineutrophil cytoplasmic antibodies (ANCA), antinuclear antibodies (ANA), anti-GBM antibodies, complement, immunoglobulins
- Renal biopsy shows aggressive glomerular inflammation, usually with crescent formation

Acute interstitial nephritis

- Usually caused by an adverse drug reaction
- Characterised by small amounts of blood and protein in urine, often with leucocyturia
- Kidneys are normal size
- Requires cessation of drug and often prednisolone treatment

deterioration of renal function coinciding with introduction of a new drug treatment. Drugs that are commonly implicated include gentamicin, omeprazole, cisplatin and amphotericin B.

Post-renal AKI

Patients should be examined clinically to look for evidence of bladder enlargement and should also undergo imaging with ultrasound to detect evidence of obstruction above the level of the bladder. Post-renal AKI is usually accompanied by hydronephrosis, but this can be absent if the ureters are affected by fibrosis or malignancy, or if obstruction of the renal tract occurs in combination with a renal disorder such as acute tubular necrosis that causes reduced urinary flow.

Management

Management options common to all forms of AKI are discussed in more detail below and summarised in Box 17.20.

17.20 Management of acute kidney injury

- Correct hypovolaemia and optimise systemic haemodynamic status with inotropic drugs if necessary
- Administer glucose and insulin to correct hyperkalaemia if K^+ > 6.5 mmol/L
- Consider administering sodium bicarbonate (100 mmol) to correct acidosis if pH < 7.0 (> 100 nmol/L)
- Discontinue potentially nephrotoxic drugs and reduce doses of therapeutic drugs according to level of renal function
- Match fluid intake to urine output plus an additional 500 mL to cover insensible losses once patient is euvolaemic
- Measure body weight on a regular basis as a guide to fluid requirements
- Ensure adequate nutritional support
- Administer proton pump antagonists to reduce the risk of upper gastrointestinal bleeding
- Screen for intercurrent infections and treat promptly if present

EBM 17.21 Colloid resuscitation fluids in the critically ill

'A systematic review and meta-analysis of randomised controlled trials comparing hydroxyethyl starch (HES) with crystalloid or albumin solutions in the resuscitation of critically ill patients with sepsis revealed that, in trials with a low risk of bias, HES was associated with increased mortality (relative risk 1.11. 95% confidence interval 1.0–1.23), a greater requirement for renal replacement therapy (1.36 [1.03–1.80]) and more serious adverse events (1.30 [1.02–1.67]).'

- Haase N, et al. BMJ 2103; 346:f839.

EBM 17.22 Low-dose dopamine in acute kidney injury

'Dopamine at low, "renal" doses has been used in the belief that it may increase renal blood flow in critically ill patients (as it does in normal individuals) and prevent AKI. However, meta-analysis of clinical trials does not support its use in patients with, or at risk of, acute kidney injury.'

- Friedrich JO, et al. Ann Intern Med 2005; 142(7):510–524.

Haemodynamic status

If hypovolaemia is present, it should be corrected by replacement of intravenous fluid or blood; excessive administration of fluid should be avoided, since this can worsen outcome in AKI due to the development of pulmonary oedema. Monitoring of the central venous pressure may be of value in determining the rate of administration of fluid in these circumstances. Balanced salt solutions, such as Hartmann's or Ringer's lactate, may be preferable to isotonic (0.9%) saline when large volumes of fluid resuscitation are required, in order to avoid hyperchloraemic acidosis, but whether this substantially influences outcome remains unclear. Administration of hydroxyethyl starch solutions should be avoided, since they have been associated with higher rates of established AKI (Box 17.21). Critically ill patients may require inotropic drugs to restore an effective blood pressure but clinical trials do not support a specific role for low-dose dopamine (Box 17.22).

Hyperkalaemia and acidosis

Hyperkalaemia is common, particularly in patients with sepsis, burns, haemolysis or metabolic acidosis (p. 442). If serum K^+ concentration is > 6.5 mmol/L, this should be treated immediately, as described in Box 16.17 (p. 443), to prevent life-threatening cardiac arrhythmias. Metabolic acidosis develops unless prevented by loss of hydrogen ions through vomiting or aspiration of gastric contents. Severe acidosis can be ameliorated with sodium bicarbonate if volume status allows. Restoration of blood volume will correct acidosis by restoring kidney function. Infusions of sodium bicarbonate (50 mL of 8.4%) may also be used, if acidosis is severe, to reduce life-threatening hyperkalaemia.

Cardiopulmonary complications

Pulmonary oedema (Fig. 17.11) may result from the administration of excessive amounts of fluids relative to urine output and because of increased pulmonary capillary permeability. If pulmonary oedema is present and urine output cannot be rapidly restored, treatment with dialysis may be required to remove excess fluid. Temporary respiratory support may also be necessary with continuous positive airways pressure (CPAP) or intermittent positive pressure ventilation (IPPV). Once initial resuscitation has been performed, fluid intake should be matched to urine output plus 500 mL to cover insensible losses, unless diarrhoea is present, in which case additional fluids might be required.

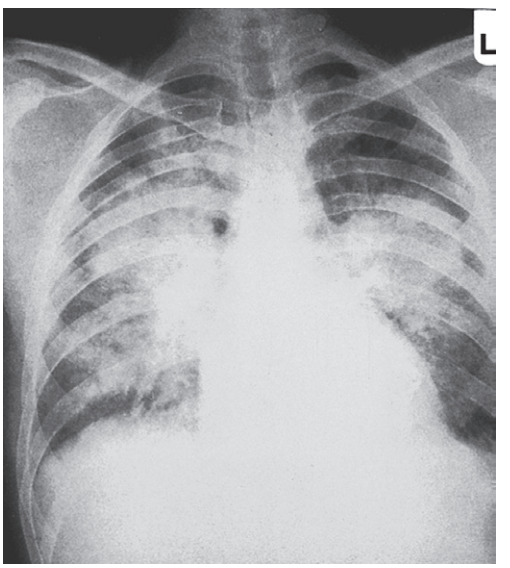


Fig. 17.11 Pulmonary oedema in acute kidney injury. The appearances are indistinguishable from left ventricular failure but the heart size is usually normal. Blood pressure is often high.

Electrolyte disturbances

Electrolyte disturbances, such as dilutional hyponatraemia, may occur if the patient has continued to drink freely despite oliguria or has received inappropriate amounts of intravenous dextrose. They can be avoided by paying careful attention to fluid balance and by giving intravenous fluids slowly. Modest hypocalcaemia is common but rarely requires treatment. Serum phosphate levels are usually high but may fall to

dangerously low levels in patients on daily or continuous dialysis or haemofiltration, necessitating phosphate replacement.

Dietary measures

Adequate nutritional support should be ensured and it is important to give sufficient amounts of energy and adequate amounts of protein; high protein intake should be avoided. This is particularly important in patients with sepsis and burns who are hypercatabolic. Enteral or parenteral nutrition may be required (p. 123).

Infection

Patients with AKI are at substantial risk of intercurrent infection because humoral and cellular immune mechanisms are depressed. Regular clinical examination, supplemented by microbiological investigation where appropriate, is required to diagnose infection. If infection is discovered, it should be treated promptly according to standard principles (Ch. 6).

Medications

Patients with drug-induced acute tubular necrosis (see Fig. 17.24B, p. 503) or drug-induced acute interstitial nephritis should have the offending drug withdrawn. Additionally, vasoactive drugs, such as NSAIDs and ACE inhibitors, should be discontinued, as they may prolong AKI. H_2-receptor antagonists should be given to prevent gastrointestinal bleeding. Other drug treatments should be reviewed and the doses adjusted if necessary, to take account of renal function. Non-essential drug treatments should be stopped.

Immunosuppression

Patients with glomerulonephritis may require immunosuppressive drugs (p. 498), plasma infusion and plasma exchange (p. 501).

Renal tract obstruction

In post-renal AKI, the obstruction should be relieved as soon as possible. This may involve catheterisation in urethral obstruction, or correction of ureteric obstruction with a ureteric stent or percutaneous nephrostomy.

Renal replacement therapy

Conservative management can be successful in AKI with meticulous attention to fluid balance, electrolytes and nutrition, but renal replacement therapy (RRT) may be required in patients who are not showing signs of recovery with these measures. Typically, the decision to start RRT is driven by hyperkalaemia, fluid overload or acidosis. Severe uraemia with pericarditis and neurological signs (uraemic encephalopathy) is uncommon in AKI but, when present, is a strong indication for RRT. No specific cut-off values for serum urea or creatinine have been identified at which RRT should be commenced, and clinical trials of earlier versus later RRT in unselected patients with AKI have not shown differences in outcome. Furthermore, RRT can be a risky intervention in patients with comorbidity, since it requires the placement of large intravenous catheters that may become infected and can also represent a major haemodynamic challenge in unstable patients. Accordingly, the decision to institute RRT should be made on an individual basis, taking account of the potential risks and benefits, comorbidity and other aspects of the patient's care, including an assessment of whether early or delayed recovery is likely. The two main options for RRT in AKI are haemodialysis and high-volume haemofiltration, or the hybrid approach of haemodiafiltration. Peritoneal dialysis is also an option if haemodialysis is not available (p. 490).

Recovery from AKI

This is usually heralded by a gradual return of urine output and a steady improvement in plasma biochemistry. During recovery, there is often a diuretic phase in which urine output increases rapidly and remains excessive for several days before returning to normal. This may be due in part to tubular damage and to temporary loss of the medullary concentration gradient. This gradient plays a key role in concentrating urine in the collecting duct, and depends on continued delivery of filtrate to the ascending limb of the loop of Henle and active tubular transport. After a few days, urine volume falls to normal as the concentrating mechanism and tubular reabsorption are restored. During the recovery phase of AKI, it may be necessary to provide supplements of sodium chloride, sodium bicarbonate, potassium chloride and sometimes phosphate temporarily, to compensate for increased urinary losses.

17.23 Acute kidney injury in old age

- **Physiological change**: nephrons decline in number with age and average GFR falls progressively.
- **Creatinine**: as muscle mass falls with age, less creatinine is produced each day. Serum creatinine can be misleading as a guide to renal function.
- **Renal tubular function**: declines with age, leading to loss of urinary concentrating ability.
- **Drugs**: increased drug prescription in older people (diuretics, ACE inhibitors and NSAIDs) may contribute to risk of AKI.
- **Causes**: infection, renal vascular disease, prostatic obstruction, hypovolaemia and severe cardiac dysfunction are common.
- **Mortality**: rises with age, primarily because of comorbid conditions.

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD), previously termed chronic renal failure, refers to an irreversible deterioration in renal function which usually develops over a period of years (see Box 17.3, p. 467). Initially, it is manifest only as a biochemical abnormality but, eventually, loss of the excretory, metabolic and endocrine functions of the kidney leads to the clinical symptoms and signs of renal failure, collectively referred to as uraemia. When death is likely without RRT (CKD stage 5), it is called end-stage renal disease or failure (ESRD or ESRF).

Epidemiology

The social and economic consequences of CKD are considerable. In most countries, estimates of the prevalence of CKD stage 3–5 (eGFR < 60) are around 5-7%, mostly affecting people aged 65 years and above. The

prevalence of CKD in hypertension, diabetes and vascular disease is substantially higher, and targeted screening for CKD should be considered in these and other high-risk groups. The great majority of patients with earlier CKD (stages 1–3) never develop ESRD, which is fortunate, given the numbers (see Box 17.3).

Pathophysiology

Common causes of CKD are shown in Box 17.24. In many cases, the underlying diagnosis is unclear, especially among the large number of elderly patients with moderate GFR reductions (stage 3 CKD; see Box 17.3), in whom the additional information gained from a biopsy would not alter treatment. Many patients diagnosed at a late stage have bilateral small kidneys; renal biopsy is rarely undertaken in this group since it is more risky, less likely to provide a histological diagnosis because of the severity of damage, and unlikely to alter management.

17.24 Common causes of end-stage renal failure

Disease	Proportion	Comments
Congenital and inherited	5%	Polycystic kidney disease, Alport's syndrome
Renovascular disease	5%	Mostly atheromatous, may be more common
Hypertension	5–20%	Causality controversial, much may be renal disease
Glomerular diseases	10–20%	IgA nephropathy is most common
Interstitial diseases	20–30%	Often drug-induced
Systemic inflammatory diseases	5–10%	Systemic lupus erythematosus, vasculitis
Diabetes mellitus	20–40%	Large racial and geographical differences
Unknown	5–20%	

Clinical features

The typical presentation is with a raised urea and creatinine found during routine blood tests, frequently accompanied by hypertension, proteinuria or anaemia. The rate of change in renal function varies between patients but is relatively constant for an individual and provides useful prognostic information. A plot of GFR, or of the reciprocal of the plasma creatinine concentration against time (Fig. 17.12), can demonstrate whether a patient has a stable GFR over time, predict when ESRF will be reached if decline is progressive, and can detect any unexpected worsening of kidney disease. It can also be used to monitor the success of interventions.

General symptoms

Most patients with slowly progressive disease are asymptomatic until GFR falls below 30 mL/min/1.73 m^2 (stage 4 or 5) and some can remain asymptomatic with much lower GFR values than this. An early symptom is nocturia, due to the loss of concentrating ability and increased osmotic load per nephron, but this is non-specific. When GFR falls below 15–20 mL/min/1.73 m^2, symptoms and signs are common and can affect almost all body systems (Fig. 17.13). They typically include tiredness or breathlessness, which may, in part, be related to renal anaemia, pruritus, anorexia, weight loss, nausea and vomiting. With further deterioration in renal function, patients may suffer hiccups, experience unusually deep respiration related to metabolic acidosis (Kussmaul's respiration), and develop muscular twitching, fits, drowsiness and coma.

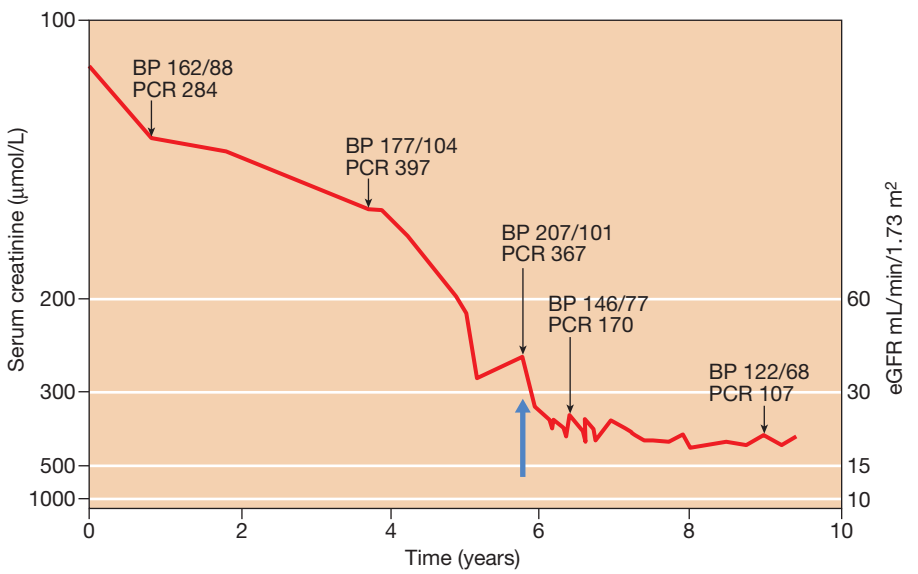

Fig. 17.12 Plot of the reciprocal of serum creatinine concentration against time in a patient with type 1 diabetes mellitus. After approximately 6 years of monitoring (blue arrow), he entered an aggressive treatment programme aimed at optimising blood pressure (BP) and glycaemic control. The reduction in blood pressure was accompanied by a fall in proteinuria (protein : creatinine ratio, PCR; mg/mmol) and a stabilisation in renal function.

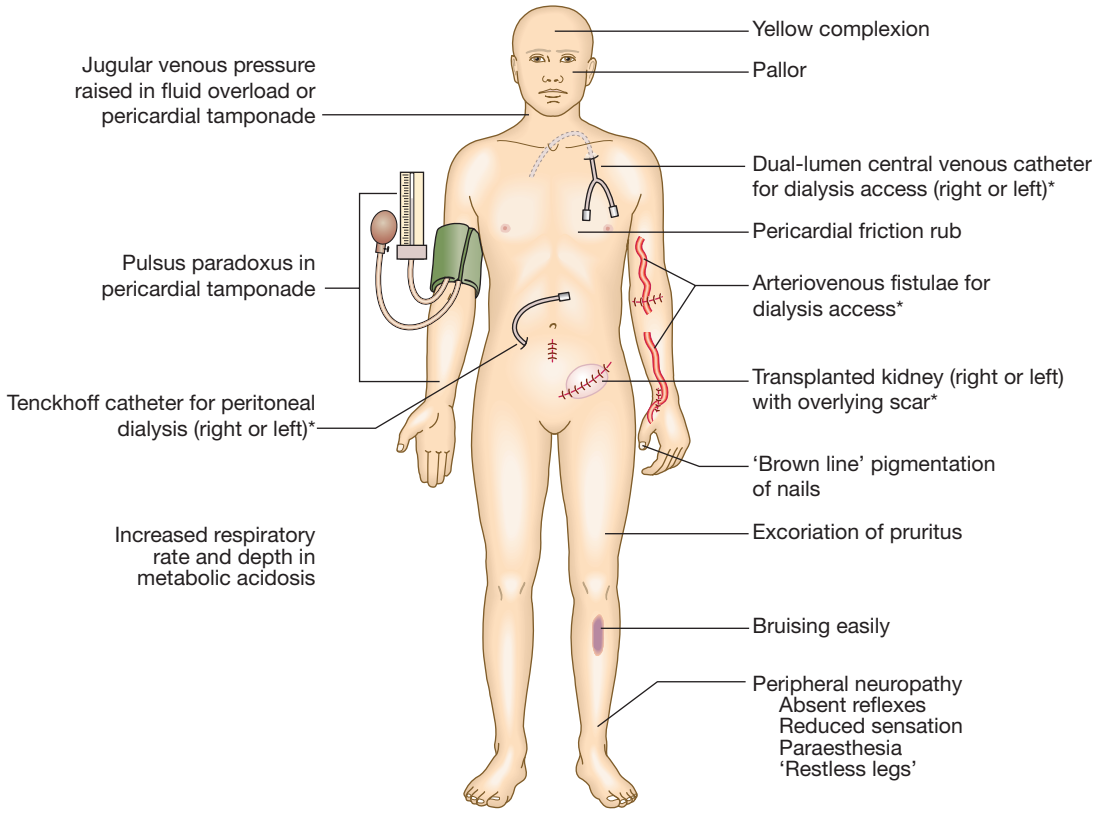

Fig. 17.13 Physical signs in advanced chronic kidney disease. (*Features of renal replacement therapy)

Immune dysfunction

Cellular and humoral immunity is impaired in advanced CKD and there is increased susceptibility to infections, the second most common cause of death in dialysis patients, after cardiovascular disease. Many infections are associated with access devices but some are common infections, such as pneumonia.

Haematological

There is an increased bleeding tendency in advanced CKD, which manifests as cutaneous ecchymoses and mucosal bleeds. Platelet function is impaired and bleeding time prolonged. Adequate dialysis partially corrects the bleeding tendency in those with severe uraemia, but these patients are at significantly increased risk of complications from all anticoagulants, including those that are required during dialysis. Anaemia is common and is due in part to reduced erythropoietin production. Haemoglobin can be as low as 50–70 g/L in CKD stage 5, although it is often less severe or absent in patients with polycystic kidney disease. Several mechanisms are implicated, as summarised in Box 17.25.

Electrolyte abnormalities

Patients with CKD often develop electrolyte abnormalities and metabolic acidosis (p. 445). Fluid retention is common in advanced CKD and disproportionate fluid retention may occur in milder disease, sometimes leading to episodic pulmonary oedema. This is particularly associated with renal artery stenosis. Conversely, some patients with tubulo-interstitial disease can develop 'salt-wasting' disease and may require a high sodium and water intake, including supplements of sodium salts, to prevent fluid depletion and worsening of renal function. Acidosis is common. Although it is usually asymptomatic, it may be associated with increased tissue catabolism and decreased protein synthesis, and may exacerbate bone disease and the rate of decline in renal function.

17.25 Causes of anaemia in chronic kidney disease

- Deficiency of erythropoietin
- Toxic effects of uraemia on marrow precursor cells
- Reduced red cell survival
- Increased blood loss due to capillary fragility and poor platelet function
- Reduced intake, absorption and utilisation of dietary iron

Endocrine function

A number of hormonal abnormalities may also be observed. In both genders, there is loss of libido related, at least in part, to hypogonadism as a consequence of hyperprolactinaemia (p. 790). The half-life of insulin is prolonged in CKD due to reduced tubular metabolism of insulin but there is also insulin resistance and reduced appetite. Because of this, insulin requirements are unpredictable in diabetic patients in advanced CKD.

Neurological and muscle function

Generalised myopathy may occur due to a combination of poor nutrition, hyperparathyroidism, vitamin D deficiency and disorders of electrolyte metabolism. Muscle cramps are common. The 'restless leg syndrome', in which the patient's legs are jumpy during the night, may

be troublesome. Both sensory and motor neuropathy can arise, presenting as paraesthesia and foot drop, respectively, but appear late during the course of CKD. They are now unusual, given the widespread availability of RRT; if present, they can often improve once dialysis is established.

Cardiovascular disease

The risk of cardiovascular disease is substantially increased in patients with CKD stage 3 or worse (GFR < 60 mL/min/1.73 m^2) and those with proteinuria or microalbuminuria. Left ventricular hypertrophy may occur, secondary to hypertension, and may account for the increased risk of sudden death (presumed to be caused by dysrhythmias) in this patient group. Pericarditis may complicate untreated or inadequately treated ESRD and cause pericardial tamponade or constrictive pericarditis. Medial vascular calcification is common and may be due, in part, to the high serum phosphate levels which are present in stage 3b CKD and above. Hyperphosphataemia may also contribute to the itching that arises in advanced CKD and probably contributes in an important way to the increased risk of cardiovascular disease. Reflecting this fact, serum fibroblast growth factor 23 (FGF23) levels (which increase in response to serum phosphate – see below) are an independent predictor of mortality in CKD.

Metabolic bone disease

Disturbances of calcium and phosphate metabolism are almost universal in advanced CKD, and various types of metabolic bone disease may also occur, including osteitis fibrosa cystica, osteomalacia and osteoporosis (Fig. 17.14). The sequence of events that leads to renal bone disease is complex. There is impaired conversion of 25-hydroxyvitamin D to its active metabolite, 1,25-dihydroxyvitamin D, due in part to renal tubular cell damage and elevated FGF23 levels. The reduced 1,25-dihydroxyvitamin D levels impair intestinal absorption of calcium, thereby causing hypocalcaemia, which leads in turn to increased PTH production by the parathyroid glands. Serum phosphate levels also start to rise because of the reduction in GFR. This leads to increased production of the hormone FGF23 from osteocytes (p. 1061). The FGF23 promotes phosphate excretion, thereby compensating in part for the reduced glomerular filtration of phosphate. This homeostatic response eventually fails, however, as renal failure progresses and hyperphosphataemia develops. The raised levels of serum phosphate complex with calcium in the extracellular space, causing ectopic calcification in blood vessels and other tissues. Patients with CKD commonly develop parathyroid gland hypertrophy and secondary hyperparathyroidism. In some cases, tertiary hyperparathyroidism supervenes, due to autonomous production of PTH by the enlarged parathyroid glands; this presents with hypercalcaemia. The histological picture in renal bone disease is complex. In osteitis fibrosa cystica, there is increased bone turnover due to the high levels of PTH, whereas low bone turnover (adynamic bone disease) may be observed in patients who have been over-treated with vitamin D metabolites.

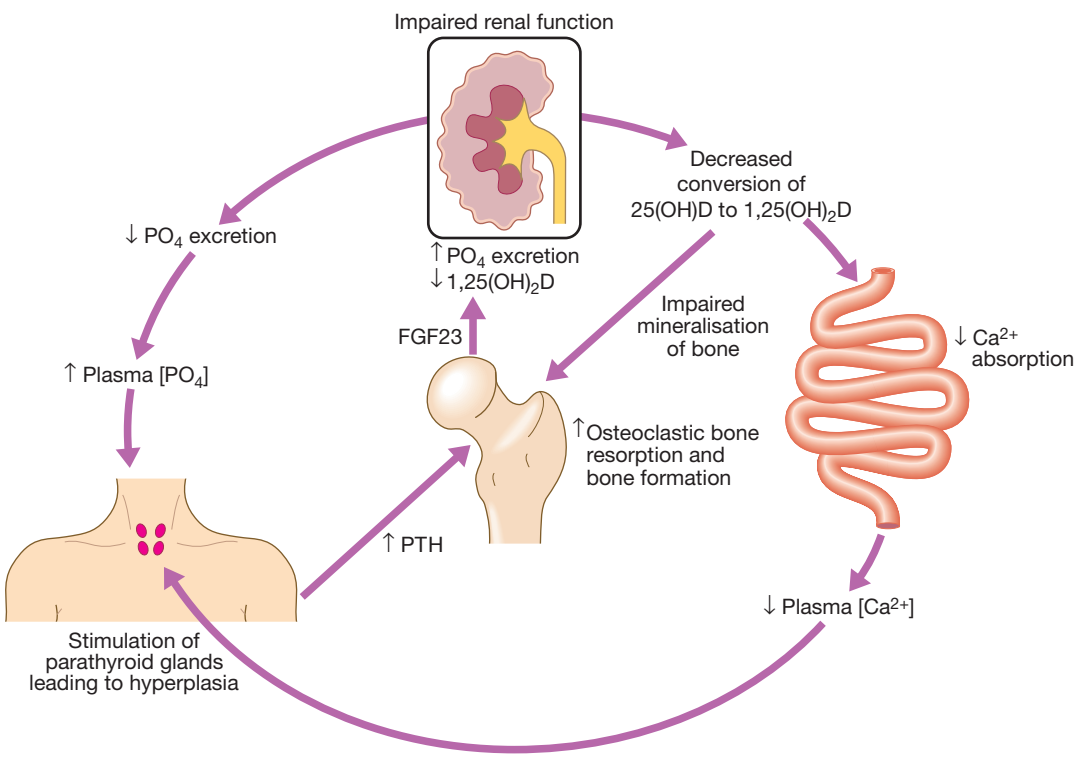

Fig. 17.14 Pathogenesis of renal osteodystrophy. Low $1,25(OH)_2D$ levels cause calcium malabsorption and this, combined with high phosphate levels, causes hypocalcaemia, which increases PTH production by the parathyroid glands. The raised level of PTH increases osteoclastic bone resorption and bone formation. Although production of FGF23 from osteocytes also increases, promoting phosphate excretion, this is insufficient to prevent hyperphosphataemia in advanced CKD.

17.26 Suggested investigations in chronic kidney disease

Initial tests	Interpretation
Urea and creatinine	To assess stability/progression: compare to previous results
Urinalysis and quantification of proteinuria	Haematuria and proteinuria may indicate cause. Proteinuria indicates risk of progressive CKD requiring preventive ACE inhibitor or ARB therapy
Electrolytes	To identify hyperkalaemia and acidosis
Calcium, phosphate, parathyroid hormone and 25(OH)D	Assessment of renal osteodystrophy
Albumin	Low albumin: consider malnutrition, inflammation
Full blood count (± Fe, ferritin, folate, B_{12})	If anaemic, exclude common non-renal explanations then manage as renal anaemia
Lipids, glucose ± HbA_{1c}	Cardiovascular risk high in CKD: treat risk factors aggressively
Renal ultrasound	Only if there are urinary symptoms (to exclude obstruction) or progressive CKD. Small kidneys suggest chronicity. Asymmetric renal size suggests renovascular or developmental disease
Hepatitis and HIV serology	If dialysis or transplant is planned. Hepatitis B vaccination recommended if seronegative
ECG	If patient is > 40 yrs or hyperkalaemic, or there are risk factors for cardiac disease
Other tests	Consider relevant tests from Boxes 17.16 and 17.17 (p. 480), especially if the cause of CKD is unknown

(ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker)

Osteomalacia can occur with over-treatment of hyperphosphataemia (p. 449).

Investigations

The recommended investigations in patients with CKD are shown in Box 17.26. Their main aims are:

- to identify the underlying cause where possible, since this may influence the treatment
- to identify reversible factors that may worsen renal function, such as hypertension, urinary tract obstruction, nephrotoxic drugs, and salt and water depletion
- to screen for complications of CKD, such as anaemia and renal osteodystrophy
- to screen for cardiovascular risk factors.

Referral to a nephrologist is appropriate for patients with potentially treatable underlying disease and those who are likely to progress to ESRD. Suggested referral criteria are listed in Box 17.27.

17.27 Criteria for referral of chronic kidney disease patients to a nephrologist

- Age < 40 years
- Stage 4 CKD or worse (eGFR < 30 mL/min/1.73 m^2)
- Rapid deterioration in renal function[1]
- Significant proteinuria (PCR > 100 mg/mmol or ACR > 70 mg/mmol)
- Significant haematuria[2]

[1]Fall in eGFR > 5 mL/min/1.73 m2/yr or > 10 mL/min/1.73 m2 over 5 yrs.
[2]After exclusion of urinary tract infection and urological abnormalities such as stones and tumours.

Management

The aims of management in CKD are to prevent or slow further renal damage; to limit the adverse physiological effects of renal impairment on the skeleton and on haematopoiesis; to treat risk factors for cardiovascular disease; and to prepare for RRT, if appropriate (p. 489).

Antihypertensive therapy

Lowering of blood pressure slows the rate at which renal function declines in CKD, independently of the agent used (Box 17.28), and has additional benefits in lowering the risk of hypertensive heart failure, stroke and peripheral vascular disease, as well as reducing proteinuria (see below). No threshold for beneficial effects has been identified and any reduction of blood pressure appears to be beneficial. Various targets have been suggested, such as 130/80 mmHg for uncomplicated CKD, and 125/75 mmHg for CKD complicated by significant proteinuria of more than 1 g/day (PCR > 100 mg/mmol or ACR > 70 mg/mmol). Achieving these blood pressure targets often requires multiple drugs, and therapeutic success may be limited by adverse effects and poor compliance.

Reduction of proteinuria

There is a clear relationship between the degree of proteinuria and the rate of progression of renal disease, and strong evidence that reducing proteinuria reduces the risk of progression. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) reduce proteinuria and retard the progression of CKD (Box 17.28). These effects are partly due to the reduction in blood pressure but there is evidence for a specific beneficial effect in patients with proteinuria (PCR > 50 mg/mmol or ACR > 30 mg/mmol) and those with incipient or overt diabetic nephropathy. In addition, ACE inhibitors have been shown to reduce the risk of cardiovascular events and all-cause mortality in CKD. Treatment with ACE inhibitors and ARBs may be accompanied by an immediate reduction in GFR when treatment is initiated, due to a reduction in glomerular perfusion pressure. Treatment can be continued so long

EBM 17.28 Lowering blood pressure in chronic kidney disease

'A meta-analysis of randomised controlled trials, including over 50 000 patients, showed that the risk of progression to end-stage renal disease (ESRD) was reduced as blood pressure was lowered. Patients with the greatest reduction in blood pressure (–6.9 mmHg; 95% confidence interval –9.1 to –4.8) had a relative risk of ESRD of 0.74 (0.59–0.92).'

'Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers reduce proteinuria and slow the progression of CKD in hypertensive patients to a greater extent than can be explained by the reduction in blood pressure alone.'

- Casas JP, et al. Lancet 2005; 366:2026–2033.
- Scottish Intercollegiate Guidelines Network 103. Diagnosis and management of chronic kidney disease.

For further information: www.sign.ed.ac.uk

as the reduction in GFR is less than 20% and is not progressive. Accordingly ACE inhibitors and/or ARBs should be prescribed to all patients with diabetic nephropathy and those with proteinuria, irrespective of whether or not hypertension is present, providing that hyperkalaemia does not occur.

Dietary and lifestyle interventions

There is experimental evidence that restricting dietary protein can reduce progression of CKD in animal models but the results are less clear-cut in humans. All patients with stage 4 and 5 CKD should be given dietetic advice aimed at preventing excessive consumption of protein, ensuring adequate calorific intake and limiting potassium and phosphate intake. Severe protein restriction is not recommended. All patients should be advised to stop smoking, since there is evidence that this slows the decline in renal function in addition to reducing cardiovascular risk. Exercise and weight loss may also reduce proteinuria and have beneficial effects on cardiovascular risk profile.

Lipid-lowering therapy

Hypercholesterolaemia is almost universal in patients with significant proteinuria, and increased triglyceride levels are also common in patients with CKD. Lipid lowering has been shown to reduce vascular events in non-dialysis CKD patients (Box 17.29). There is some evidence that control of dyslipidaemia with statins may slow the rate of progression of renal disease.

Treatment of anaemia

Anaemia is common in patients with a GFR below 30 mL/min/1.73 m^2 and contributes to many of the non-specific symptoms of CKD. Recombinant human erythropoietin is effective in correcting the anaemia of CKD and improving the associated morbidity. Erythropoietin treatment does not influence mortality, however, and correcting haemoglobin to normal levels may carry some extra risk, including hypertension and thrombosis (including thrombosis of the arteriovenous fistulae used for haemodialysis). The target haemoglobin is usually between 100 and 120 g/L (10–20 g/dL). Erythropoietin is less effective in the presence of iron deficiency, active inflammation or malignancy, and in patients with aluminium overload, which may occur in dialysis.

EBM 17.29 Effects of lipid-lowering therapy in chronic kidney disease

'The SHARP trial of lipid-lowering in patients with CKD studied approximately 9500 patients aged 40 years or more, with a median follow-up of 4.9 years. The combination of ezetimibe 10 mg and simvastatin 20 mg reduced major atherosclerotic events by 17%, compared to placebo in patients not on dialysis (approximately 6000) ($p < 0.01$) and by 10% in patients on dialysis (not significant), although there was no overall benefit for mortality.'

- Baigent C, et al. Lancet 2011; 377:2181–2192.

Maintaining fluid and electrolyte balance

Patients with evidence of fluid retention should have dietary sodium intake limited to about 100 mmol/day, but often loop diuretics may also be required to treat fluid overload. If hyperkalaemia occurs, drug therapy should be reviewed, to reduce or stop potassium-sparing diuretics, ACE inhibitors and ARBs. Correction of acidosis may be helpful, and limiting potassium intake to about 70 mmol/day may be necessary in late CKD. Potassium-binding resins, such as calcium resonium, may be useful in the short term but should not be used chronically. The plasma bicarbonate should be maintained above 22 mmol/L by giving sodium bicarbonate supplements (starting dose of 1 g 3 times daily, increasing as required). If the increased sodium intake induces hypertension or oedema, calcium carbonate (up to 3 g daily) may be used as an alternative, since this has the advantage of also binding dietary phosphate.

Renal bone disease

Treatment should be initiated with active vitamin D metabolites (either 1-α-hydroxyvitamin D or 1,25-dihydroxyvitamin D) in patients who are found to have hypocalcaemia or serum PTH levels more than twice the upper limit of normal. The dose should be adjusted to try to reduce PTH levels to between 2 and 4 times the upper limit of normal to avoid over-suppression of bone turnover and adynamic bone disease, but care must be exercised in order to avoid hypercalcaemia. Hyperphosphataemia should be treated by dietary restriction of foods with high phosphate content (milk, cheese, eggs and protein-rich foods) and by the use of phosphate-binding drugs. Various drugs are available, including calcium carbonate, aluminium hydroxide, lanthanum carbonate and polymer-based phosphate binders such as sevelamer. The aim is to maintain serum phosphate values at 1.8 mmol/L (5.6 mg/dL) or below if possible, but many of these drugs are difficult to take and compliance may be a problem.

Parathyroidectomy may be required for the treatment of tertiary hyperparathyroidism. An alternative is to employ calcimimetic agents, such as cinacalcet, which bind to the calcium-sensing receptor and reduce PTH secretion. They have a place if parathyroidectomy is unsuccessful or not possible.

RENAL REPLACEMENT THERAPY

Renal replacement therapy (RRT) may be required on a temporary basis in patients with AKI or on a permanent

basis for those with CKD secondary to the many different types of renal disease discussed in this chapter.

Since the advent of long-term RRT in the 1960s, the numbers of patients with ESRD who are kept alive by dialysis and transplantation have increased considerably. For example, in the UK, there was a 3.3% increase per year between 2005 and 2010. By the end of 2010, over 51 000 patients (832 per million) were on RRT, and the incidence of new patients starting RRT was 107 per million of the adult population. Whilst these numbers have been relatively steady over the last few years in the UK, they are still rising in the USA. The median age of patients starting RRT in the UK is now 65 years and 24% have a primary renal diagnosis of diabetic nephropathy. There are variations in the numbers of patients receiving RRT in different countries due to differences in the incidence of predisposing disease, as well as differences in medical practice. For example, in the USA, incidence rates for RRT in 2010 were about three times higher than in the UK at 348 per million population, and prevalence rates more than twice as high at 1752 per million population. Nearly half of these patients had a primary diagnosis of diabetes mellitus.

At the present time, RRT is commenced in about 1 in 10 000 of the general population in the UK each year. Of patients starting dialysis in 2010, about 68% were still being treated with haemodialysis 3 months later – 18% by peritoneal dialysis, 8% by renal transplant (often before dialysis has been initiated) – and 6% had died or stopped treatment. Of prevalent patients established on RRT, about 48% had been transplanted, 44% were maintained on haemodialysis (approximately 1.5% on home haemodialysis) and 8% were on peritoneal dialysis.

Following initiation of dialysis in the UK, the survival is 84% at 1 year and 50% after 5 years. Mortality is strongly influenced by age; patients over 65 have a 76% survival at 1 year and 29% survival at 5 years, whereas corresponding figures for patients aged less than 65 are 91% and 71%, respectively. Although many young patients without extrarenal disease lead normal and active lives on RRT, those aged 30–34 have a mortality rate 25 times higher than age-matched controls. Comorbid conditions, such as diabetes mellitus (47% 5-year survival versus 66% for non-diabetics starting at age 45–64 years) and generalised vascular disease, also have a strong influence on mortality.

The aim of RRT is to replace the excretory functions of the kidney, and to maintain normal electrolyte concentrations and fluid balance. Various options are available, including haemodialysis, haemofiltration, haemodiafiltration, peritoneal dialysis and renal transplantation, and each of these is discussed in more detail below.

Preparing for renal replacement therapy

It is crucial that patients who are known to have progressive CKD are prepared well in advance for the institution of RRT. This involves ensuring that they are referred to a nephrologist in a timely manner, as those who are referred late, when they are either at the stage of or very close to requiring dialysis (about 20% of referrals in the UK), tend to have poorer outcomes. It is often possible to predict when RRT will be required from serial measurements of serum creatinine in patients with progressive CKD (see Box 17.3, p. 467). In such patients, preparations for the initiation of RRT should be started at least 12 months before the predicted start date.

At the present time, the average eGFR at the time of initiating RRT in the UK is about 8 mL/min/1.73 m^2 but there is wide variation. Since there is no evidence that early initiation of RRT improves outcome, the overall aim is to commence RRT by the time symptoms of CKD have started to appear but before serious complications have occurred. Preparation for RRT involves providing the patient with psychological and social support, assessing home circumstances and discussing the various choices of treatment (Fig. 17.15). Depression is common in patients who are on or approaching RRT, and support from the renal multidisciplinary team should be provided for both them and their relatives, to explain and help them adapt to the changes to lifestyle that may be necessary once RRT starts; this may help to reduce their anxieties about these changes.

Several decisions need to be taken in discussion with the patient and their family. The first is to decide whether RRT is an appropriate choice or whether conservative treatment might be preferable (p. 490). This is especially relevant in older people with significant comorbidity. For those that decide to go ahead with RRT, there are further choices between haemodialysis and peritoneal dialysis (Box 17.30), between hospital and home treatment, and on referral for renal transplantation.

17.30 Comparison of haemodialysis and peritoneal dialysis

Haemodialysis	Peritoneal dialysis
Efficient; 4 hrs three times per wk is usually adequate	Less efficient; 4 exchanges per day are usually required, each taking 30–60 mins (continuous ambulatory peritoneal dialysis) or 8–10 hrs each night (automated peritoneal dialysis)
2–3 days between treatments	A few hours between treatments
Requires visits to hospital (although home treatment is possible for some patients)	Performed at home
Requires adequate venous circulation for vascular access	Requires an intact peritoneal cavity without major scarring from previous surgery
Careful compliance with diet and fluid restrictions required between treatments	Diet and fluid less restricted
Fluid removal compressed into treatment periods; may cause symptoms and haemodynamic instability	Slow continuous fluid removal, usually asymptomatic
Infections related to vascular access may occur	Peritonitis and catheter-related infections may occur
Patients are usually dependent on others	Patients can take full responsibility for their treatment

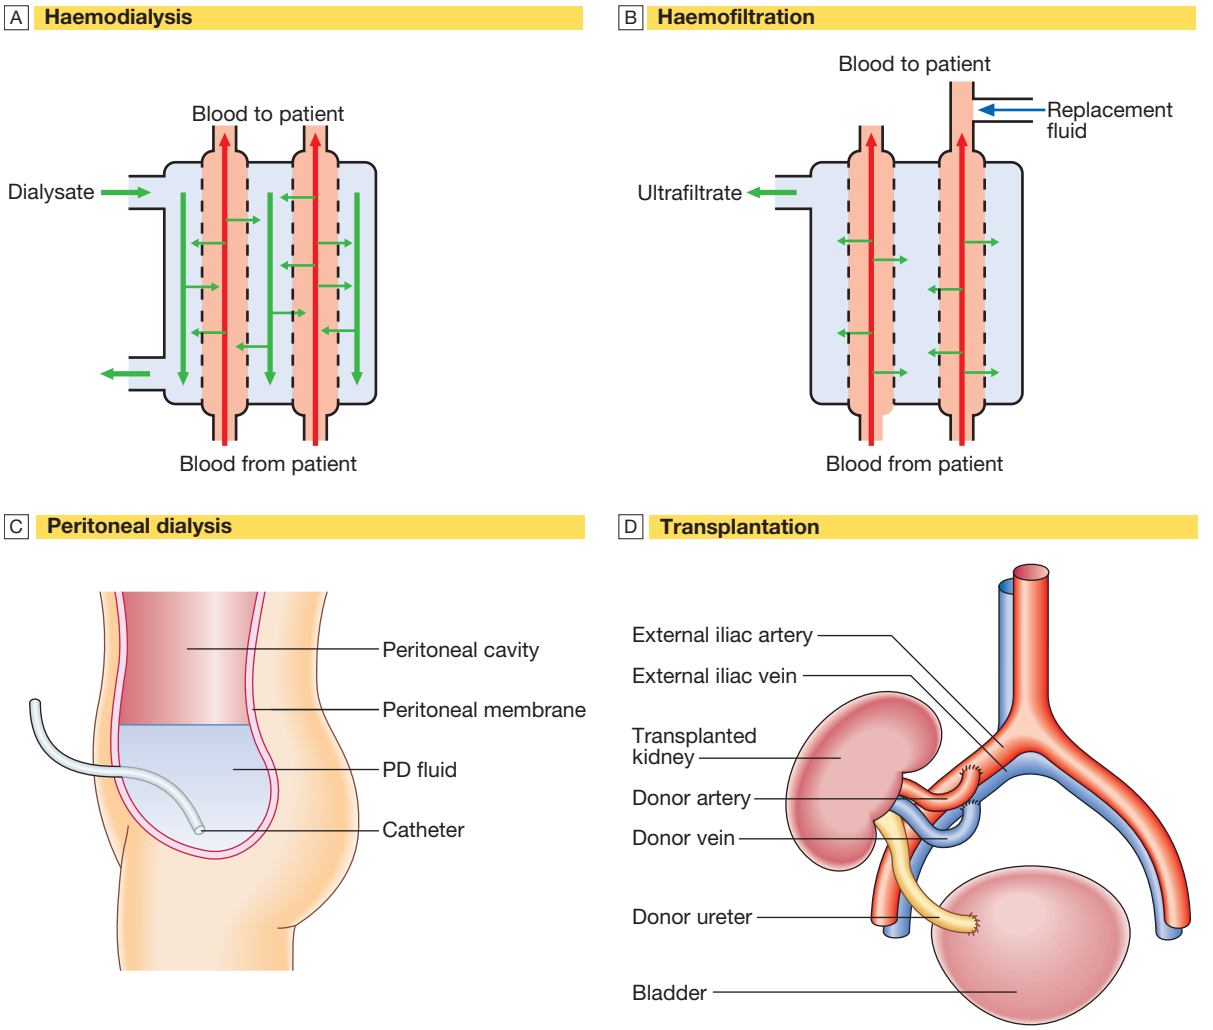

Fig. 17.15 Options for renal replacement therapy. A In haemodialysis, there is diffusion of solutes from blood to dialysate across a semipermeable membrane down a concentration gradient. B In haemofiltration, both water and solutes are filtered across a porous semipermeable membrane by a pressure gradient. Replacement fluid is added to the filtered blood before it is returned to the patient. C In peritoneal dialysis (PD), fluid is introduced into the abdominal cavity using a catheter. Solutes diffuse from blood across the peritoneal membrane to PD fluid down a concentration gradient and water diffuses through osmosis (see text for details). D In transplantation, the blood supply of the transplanted kidney is anastomosed to the internal iliac vessels and the ureter to the bladder. The transplanted kidney replaces all functions of the failed kidney.

Conservative treatment

In older patients with multiple comorbidities, conservative treatment of stage 5 CKD, aimed at limiting the adverse symptomatic effects of ESRD without commencing RRT, is increasingly viewed as a positive choice (Box 17.31). Current evidence suggests that survival of these patients without dialysis can be similar or only slightly shorter than that of patients who undergo RRT, but they avoid the hospitalisation and interventions associated with dialysis. Patients are offered full medical, psychological and social support to optimise and sustain their existing renal function and to treat complications, such as anaemia, for as long as possible, with appropriate palliative care in the terminal phase of their disease. Many of these patients enjoy a good quality of life for several years. It is also appropriate to discontinue dialysis treatment, with the consent of the patient, and to offer conservative therapy and palliative care when quality of life on dialysis is inadequate.

Haemodialysis

Haemodialysis is the most common form of RRT in ESRD and is also used in AKI. Haemodialysis involves gaining access to the circulation, either through an arteriovenous fistula, a central venous catheter or an arteriovenous shunt, such as a Scribner shunt. The patient's blood is pumped through a haemodialyser, which allows bidirectional diffusion of solutes between blood and the dialysate across a semipermeable membrane down a concentration gradient (Fig. 17.15A). The composition of the dialysate can be varied to achieve the desired gradient and fluid can be removed by applying negative pressure to the dialysate side.

17.31 Renal replacement therapy in old age

- **Quality of life**: age itself is not a barrier to good quality of life on RRT.
- **Coexisting cardiovascular disease**: older people are more sensitive to fluid balance changes, predisposing to hypotension during dialysis with rebound hypertension between dialyses. A failing heart cannot cope with fluid overload, and pulmonary oedema develops easily.
- **Provision of treatment**: often only hospital-provided haemodialysis is suitable and older patients require more medical and nursing time.
- **Survival on dialysis**: difficult to predict for an individual patient, but old age plus substantial comorbidity are associated with poor median survival.
- **Withdrawal from dialysis**: a common cause of death in older patients with comorbid disease.
- **Transplantation**: relative risks of surgery and immunosuppression, and limited organ availability exclude most older people from transplantation.
- **Conservative therapy**: without dialysis but with adequate support; is an appropriate option for patients at high risk of complications from dialysis, who have a limited prognosis and little hope of functional recovery.

Haemodialysis in AKI

Haemodialysis offers the best rate of small solute clearance in AKI, as compared with other techniques such as haemofiltration, but should be started gradually because of the risk of confusion and convulsions due to cerebral oedema (dialysis disequilibrium). Typically, 1–2 hours of dialysis is prescribed initially but, subsequently, patients with AKI who are haemodynamically stable can be treated by 4–5 hours of haemodialysis on alternate days, or 2–3 hours every day. During dialysis, it is standard practice to anticoagulate patients with heparin but the dose may be reduced if there is a bleeding risk. Epoprostenol can be used as an alternative but carries a risk of hypotension. For short dialyses and in patients with abnormal clotting, it may be possible to avoid anticoagulation altogether. In AKI, dialysis is performed through a large-bore, dual-lumen catheter inserted into the femoral or internal jugular vein. Subclavian lines are avoided where possible, as thromboses or stenoses here will compromise the ability to form a functioning fistula in the arm if the patient fails to recover renal function and needs chronic dialysis.

Haemodialysis in CKD

In CKD, vascular access for haemodialysis is gained by formation of an arteriovenous fistula, usually in the forearm, up to a year before dialysis is contemplated. After 4–6 weeks, increased pressure transmitted from the artery to the vein leading from the fistula causes distension and thickening of the vessel wall (arterialisation). Large-bore needles can then be inserted into the vein to provide access for each haemodialysis treatment. Figure 17.16 shows a patient undergoing haemodialysis through such a fistula. Preservation of arm veins is thus very important in patients with progressive renal disease who may require haemodialysis in the future. If this access is not possible, venous or Gortex grafts may be fashioned or plastic catheters in central veins can be used for short-term access. These may be tunnelled under the skin to reduce infection risk. All patients must be screened in advance for hepatitis B, hepatitis C and human immunodeficiency virus (HIV), and vaccinated against hepatitis B if they are not immune. All dialysis units should have segregation facilities for hepatitis B-positive patients, given its easy transmissibility. Patients with hepatitis C and HIV are less infectious and can be treated satisfactorily using machine segregation and standard infection control measures.

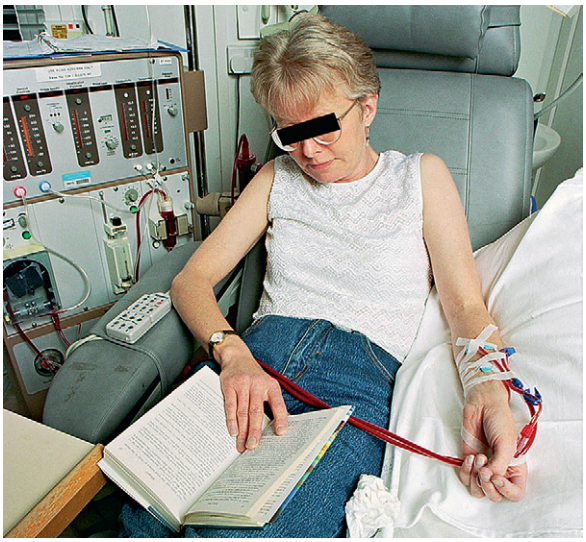

Fig. 17.16 Haemodialysis. A patient receiving haemodialysis through a forearm subcutaneous (Brescia–Cimino) fistula. She subsequently received a live related transplant.

Haemodialysis is usually carried out for 3–5 hours three times weekly, either at home or in an outpatient dialysis unit. The intensity and frequency of dialysis should be adjusted to achieve a reduction in urea during dialysis (urea reduction ratio) of over 65%. Most patients notice an improvement in symptoms during the first 6 weeks of treatment. Plasma urea and creatinine are lowered by each treatment but do not return to normal. The intensity of dialysis can be increased by escalating the number of standard sessions to four or more per week; by performing short, frequent dialysis sessions of 2–3 hours 5–7 times per week; or by performing nocturnal haemodialysis, when low blood-pump speeds and single-needle dialysis are used for approximately 8 hours overnight 5–6 times per week.

More frequent dialysis and nocturnal dialysis can achieve better fluid balance and electrolyte control than standard dialysis and, in particular, better control of serum phosphate levels. Studies are currently in progress to determine whether these different modes of dialysis improve clinical outcome. Box 17.32 summarises some of the problems related to haemodialysis.

Haemofiltration

This technique is principally used in the treatment of AKI. Water and solutes are filtered from blood across a porous semipermeable membrane under a pressure gradient. Replacement fluid of a suitable electrolyte composition is added to the blood after it exits from the haemofilter. If removal of fluid is required, then less

17.32 Problems with haemodialysis

Problem	Clinical features	Cause	Treatment
Hypotension during dialysis	Sudden ↓BP; often leg cramps; sometimes chest pain	Fluid removal and hypovolaemia	Saline infusion; exclude cardiac ischaemia; quinine may help cramp
Cardiac arrhythmias	Hypotension, sometimes chest pain	Potassium and acid–base shifts	Check K^+ and arterial blood gases; review dialysis prescription; stop dialysis
Haemorrhage	Blood loss (overt or occult); hypotension	Anticoagulation Venous needle disconnection	Stop dialysis; seek source; consider heparin-free treatment
Air embolism	Circulatory collapse; cardiac arrest	Disconnected or faulty lines and equipment malfunction	Stop dialysis
Dialyser hypersensitivity	Acute circulatory collapse	Allergic reaction to dialysis membrane or sterilisant	Stop dialysis; change to different artificial kidney
Between treatments			
Pulmonary oedema	Breathlessness	Fluid overload	Ultrafiltration ± dialysis
Systemic sepsis	Rigors; fever; ↓BP	Usually involves vascular access devices (catheter or fistula)	Blood cultures; antibiotics

fluid is added back than is removed (Fig. 17.15B). Haemofiltration may be either intermittent or continuous, and typically 1–2 litres of filtrate is replaced per hour (equivalent to a GFR of 15–30 mL/min); higher rates of filtration may be of benefit in patients with sepsis and multi-organ failure. In continuous arteriovenous haemofiltration (CAVH), the extracorporeal blood circuit is driven by the arteriovenous pressure difference, but poor filtration rates and clotting of the filter are common and this treatment has fallen out of favour. Continuous venovenous haemofiltration (CVVH) is pump-driven, providing a reliable extracorporeal circulation. Issues concerning anticoagulation are similar to those for haemodialysis, but may be more problematic because longer or continuous anticoagulation is necessary.

Haemodiafiltration

This technique combines haemodialysis with approximately 20–30 litres of ultrafiltration (with replacement of filtrate) over a 3–5-hour treatment. It uses a large-pore membrane and combines the improved middle-molecule clearance of haemofiltration with the higher small-solute clearance of haemodialysis. It is sometimes used in the treatment of AKI but is increasingly favoured in the treatment of CKD. It is more expensive than haemodialysis, however, and the long-term benefits are not yet established.

Peritoneal dialysis

Peritoneal dialysis is principally used in the treatment of CKD. It requires the insertion of a permanent Silastic catheter into the peritoneal cavity (Fig. 17.15C). Two types are in common use. In continuous ambulatory peritoneal dialysis (CAPD), about 2 litres of sterile, isotonic dialysis fluid are introduced and left in place for approximately 4–6 hours. Metabolic waste products diffuse from peritoneal capillaries into the dialysis fluid down a concentration gradient. The fluid is then drained and fresh dialysis fluid introduced, in a continuous four-times-daily cycle. The inflow fluid is rendered hyperosmolar by the addition of glucose or glucose polymer; this results in net removal of fluid from the patient during each cycle, due to diffusion of water from the blood through the peritoneal membrane down an osmotic gradient (ultrafiltration). The patient is mobile and able to undertake normal daily activities. Automated peritoneal dialysis (APD) is similar to CAPD but uses a mechanical device to perform the fluid exchanges during the night, leaving the patient free, or with only a single exchange to perform, during the day.

CAPD is particularly useful in children, as a first treatment in adults with residual renal function, and as a treatment for elderly patients with cardiovascular instability. The long-term use of peritoneal dialysis may be limited by episodes of bacterial peritonitis and damage to the peritoneal membrane, including sclerosing peritonitis, but some patients have been treated successfully for more than 10 years. Box 17.33 summarises some of the problems related to CAPD treatment.

Renal transplantation

Renal transplantation offers the best chance of long-term survival in ESRD, and is the most cost-effective treatment. Transplantation can restore normal kidney function and correct all the metabolic abnormalities of CKD but requires long-term immunosuppression with its attendant risks (see below). All patients with ESRD should be considered for transplantation, unless there are contraindications (Box 17.34).

Kidney grafts may be taken from a cadaver in the UK after brain death (51%) or circulatory death (11%), or from a living donor (38%). As described on page 94, matching of a donor to a specific recipient is strongly influenced by immunological factors, since graft rejection is the major cause of transplant failure. Compatibility of ABO blood group between donor and recipient is usually required and the degree of matching for major histocompatibility (MHC) antigens, particularly HLA-DR, influences the incidence of rejection. Immediately prior to transplantation, tests should be performed for

17.33 Problems with continuous ambulatory peritoneal dialysis

Problem	Clinical features	Cause	Treatment
Peritonitis	Cloudy drainage fluid; abdominal pain and systemic sepsis are variable	Usually entry of skin contaminants via catheter; bowel organisms less common	Culture of peritoneal dialysis fluid Intraperitoneal antibiotics, tobramycin, vancomycin Catheter removal sometimes required
Catheter exit site infection	Erythema and pus around exit site	Usually skin organisms	Antibiotics; sometimes surgical drainage
Ultrafiltration failure	Fluid overload	Damage to peritoneal membrane, leading to rapid transport of glucose and loss of osmotic gradient	Replace glucose with synthetic, poorly absorbed polymers for some exchanges (icodextrin)
Peritoneal membrane failure	Inadequate clearance of urea etc.	Scarring/damage to peritoneal membrane	Increase exchange volumes; consider automated peritoneal dialysis or switch to haemodialysis
Sclerosing peritonitis	Intermittent bowel obstruction Malnutrition	Unknown; typically occurs after many years	Switch to haemodialysis (may still progress) Surgery and tamoxifen may be used

17.34 Contraindications to renal transplantation

Absolute

- Active malignancy: a period of at least 2 yrs of complete remission recommended for most tumours
- Active vasculitis or recent anti-GBM disease
- Severe heart disease
- Severe occlusive aorto-iliac vascular disease

Relative

- Age: while practice varies, transplants are not routinely offered to very young children (< 1 yr) or older people (> 75 yrs)
- High risk of disease recurrence in the transplant kidney
- Disease of the lower urinary tract: in patients with impaired bladder function, an ileal conduit may be considered
- Significant comorbidity

antibodies against HLA antigens and for antibodies that can bind to lymphocytes of the donor (p. 95). Positive tests predict early rejection. Although some ABO- and HLA-incompatible transplants are now possible, this involves appropriate preparation with pre-transplant plasma exchange and/or immunosuppression, so that recipient antibodies to the donor's tissue are reduced to acceptably low levels. This option is generally only available for living donor transplants because of the preparation required. Paired exchanges, in which a donor–recipient pair which has compatibility issues, either blood group or HLA, is computer-matched with another pair to overcome the mismatch, are also used to help increase the number of successful transplants that can be performed.

During the transplant operation, the kidney is placed in the pelvis; the donor vessels are usually anastomosed to the recipient's internal iliac artery and vein, and the donor ureter anastomosed to the bladder (Fig. 17.15D). The failed kidneys are usually left in place. Peri-operative problems include:

- *Fluid balance.* Careful matching of input to output is required. Patients can be very polyuric in the initial period after transplantation.
- *Primary graft non-function.* Causes include hypovolaemia, preservation injury/acute tubular necrosis during storage and transfer, other pre-existing renal damage, hyperacute rejection, vascular occlusion and urinary tract obstruction.
- *Sepsis.* In addition to risks of sepsis associated with any operation, there is an increased risk due to the uraemia and immunosuppression.

Once the graft begins to function, near-normal biochemistry is usually achieved within days to weeks. The median eGFR of patients in the UK receiving a deceased donor transplant at 1 year is 51 mL/min/1.73 m^2.

All transplant patients require regular life-long follow-up to monitor renal function and immunosuppression. Life-long immunosuppressive therapy (see Box 4.25, p. 96) is required to prevent rejection but needs to be more intensive in the early post-transplantation period, when the risk is highest. A common regimen is triple therapy with prednisolone; ciclosporin or tacrolimus; and azathioprine or mycophenolate mofetil. Sirolimus (rapamycin) is an alternative that can be introduced later. Antibodies to deplete or modulate specific lymphocyte populations are increasingly used; targeting the lymphocyte interleukin (IL)-2 receptor is particularly effective for preventing rejection. Acute rejection is usually treated, in the first instance, by short courses of high-dose corticosteroids, such as methylprednisolone 500 mg IV on 3 consecutive days. Other therapies, such as antilymphocyte antibodies, intravenous immunoglobulin and plasma exchange, can be used for episodes of acute rejection that do not respond to high-dose corticosteroids.

Complications of immunosuppression include infections and malignancy (p. 95). Approximately 50% of white patients develop skin malignancy by 15 years after transplantation.

The prognosis after kidney transplantation is good. Recent UK statistics for transplants from cadaver donors indicate 96% patient survival and 93% graft survival at 1 year, and 88% patient survival and 84% graft survival at 5 years. Even better figures are obtained with living donor transplantation (91% graft survival at 5 years).

Advances in immunosuppression have greatly improved results from using genetically unrelated donors, such as spouses.

RENAL VASCULAR DISEASES

Diseases which affect renal blood vessels may cause renal ischaemia, leading to acute or chronic kidney disease or secondary hypertension. The rising prevalence of atherosclerosis and diabetes mellitus in ageing populations has made renovascular disease an important cause of ESRD.

Renal artery stenosis

Renal artery stenosis is a relatively uncommon disorder, which presents clinically with hypertension. It has been estimated to occur in about 2% of unselected patients with hypertension but may affect up to 4% of older patients with hypertension who have evidence of atherosclerotic disease elsewhere. Most cases of renal artery stenosis are caused by atherosclerosis but fibromuscular dysplasia involving the vessel wall may be responsible in younger patients. Rare causes include vasculitis, thromboembolism and aneurysms of the renal artery.

Pathophysiology

Renal artery stenosis results in a reduction in renal perfusion pressure, which activates the renin–angiotensin system, leading to increased circulating levels of angiotensin II. This provokes vasoconstriction and increases aldosterone production by the adrenal, causing sodium retention by the renal tubules. Significant reduction of renal blood flow occurs when there is greater than 70% narrowing of the artery, and this is commonly associated with a dilated region more distally (post-stenotic dilatation). Atherosclerosis is the most common cause. The characteristic lesion is an ostial stenosis that is associated with atherosclerosis within the aorta and affects other major branches, particularly the iliac vessels. The picture is often complicated by small-vessel disease in affected kidneys, which may be related to subclinical atheroemboli or other vascular disease. As the stenosis becomes more severe, global renal ischaemia leads to shrinkage of the affected kidney and may cause renal failure (ischaemic nephropathy). However, the progression of stenosis is not easily predictable, and many patients die from coronary, cerebral or other vascular disease rather than renal failure.

In younger patients, fibromuscular dysplasia is a more likely cause of renal artery stenosis. This is an uncommon disorder of unknown cause. It is characterised by hypertrophy of the media (medial fibroplasia), which narrows the artery but rarely leads to total occlusion. It may be associated with disease in other arteries; for example, those who have carotid artery dissections are more likely to have renal arteries with this appearance. It most commonly presents with hypertension in patients aged 15–30 years, and women are affected more frequently than men. Irregular narrowing (beading) may occur in the distal renal artery and this sometimes extends into the intrarenal branches of the vessel. Rarely, renal artery stenosis may occur as a complication of large-vessel vasculitis, such as Takayasu's arteritis and polyarteritis nodosa (pp. 1116 and 1117). Untreated, atheromatous renal artery stenosis is thought to progress to complete arterial occlusion in about 15% of cases. This figure increases with more severe degrees of stenosis. If the progression is gradual, collateral vessels may develop and some function may be preserved, preventing infarction and loss of kidney structure. Conversely, at least 85% of patients with renal artery stenosis will not develop progressive renal impairment, and indeed, in many patients, the stenosis may be haemodynamically insignificant and not responsible for coexisting essential hypertension. Unfortunately, methods of predicting which patients are at risk of progression or who will respond to treatment are still imperfect.

Clinical features

Renal artery stenosis can present in various ways (Box 17.35), including hypertension, renal failure (with bilateral disease), a deterioration in renal function when ACE inhibitors or ARBs are used, or acute pulmonary oedema. Although many patients experience a slight drop in GFR when commencing these drugs, an increase in serum creatinine of 25% or more raises the possibility of renal artery stenosis. Acute pulmonary oedema is particularly characteristic of bilateral renovascular disease. It is associated with severe hypertension, occurring without other obvious cause in patients with normal or only mildly impaired renal function. Clinical evidence of generalised vascular disease may be observed, particularly in the legs, in older patients with atherosclerotic renal artery stenosis. Clinical features associated with an increased risk of renal artery stenosis in hypertensive patients are summarised in Box 17.35. The presence of one or more of these features should prompt investigation for possible renal artery stenosis, as described below, provided that intervention is being contemplated to improve renal perfusion.

Investigations

When appropriate, imaging of the renal vasculature with either CT angiography or MR angiography should be performed to confirm the diagnosis (Fig. 17.17). Both give good views of the main renal arteries, the vessels predominantly involved and the most amenable to intervention. Biochemical testing may reveal impaired renal function and an elevated plasma renin activity, sometimes with hypokalaemia due to hyperaldosteronism. Ultrasound may also reveal a discrepancy in size between the two kidneys. While these investigations

17.35 Presentation and clinical features of renal artery stenosis

Renal artery stenosis is more likely if:

- hypertension is severe, of recent onset or difficult to control
- kidneys are asymmetrical in size
- flash pulmonary oedema occurs repeatedly*
- there is peripheral vascular disease of the lower limbs
- there is renal impairment*
- renal function has deteriorated on ACE inhibitors or angiotensin II receptor blockers

*Particularly with bilateral disease.

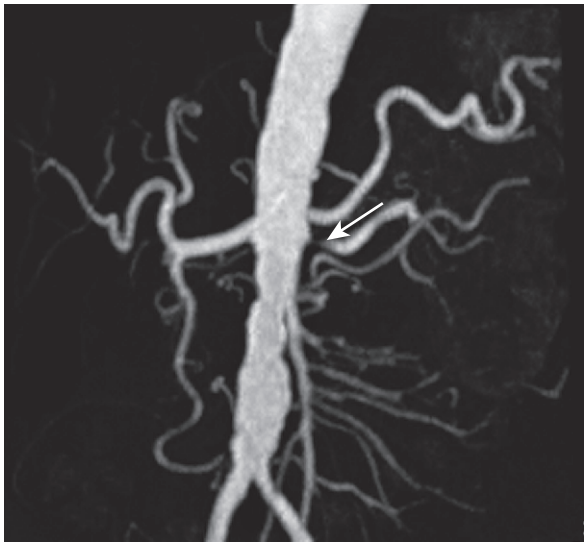

Fig. 17.17 Renal artery stenosis. A magnetic resonance angiogram following injection of contrast. The abdominal aorta is severely irregular and atheromatous. The left renal artery is stenosed (arrow).

provide supportive information, they are insufficiently sensitive or specific to be of value in diagnosis of renovascular disease in hypertensive patients.

Management

The first-line management in patients with renal artery stenosis is medical therapy with antihypertensive drugs, supplemented, where appropriate, by statins and low-dose aspirin in those with atherosclerotic disease. Interventions to correct the vessel narrowing should be considered in young patients (age below 40) suspected of having renal artery stenosis; those in whom blood pressure cannot easily be controlled with antihypertensive agents; those who have a history of 'flash' pulmonary oedema or accelerated phase (malignant) hypertension; and those in whom renal function is deteriorating. The most commonly used technique is angioplasty. The best results are obtained in non-atheromatous fibromuscular dysplasia, where correction of the stenosis has a high chance of success in improving blood pressure and protecting renal function. Angioplasty and stenting can sometimes be successful in atherosclerotic disease but randomised trials have produced no convincing evidence for overall benefit in terms of renal function or blood pressure control (Box 17.36). The risks of angioplasty and stenting include renal artery occlusion, renal infarction, and atheroemboli (p. 496) from manipulations in a severely diseased aorta. Small-vessel disease distal to the stenosis may preclude substantial functional recovery.

EBM 17.36 Stenting for renal artery stenosis

'The ASTRAL trial compared medical therapy to revascularisation in 806 patients with atherosclerotic renal disease and found substantial risks but no evidence of a worthwhile clinical benefit from revascularisation over 5 years of follow-up. Specifically, there was no statistical difference in blood pressure or rate of change of renal function between the groups, but serious complications associated with revascularisation occurred in 23 patients, including 2 deaths and 3 amputations of toes or limbs.'

- ASTRAL Investigators. N Engl J Med 2009; 361:1953–1962.

Acute renal infarction

This is an uncommon condition that occurs as the result of sudden occlusion of the renal arteries. The presentation is typically with loin pain of acute onset, usually in association with haematuria detected on dipstick testing or urine microscopy, but pain may be absent in some cases. Severe hypertension is common but not universal, presumably because some residual renal perfusion is required to generate renin release. Blood levels of lactate dehydrogenase (LDH) and CRP are commonly raised. The condition may be caused by local atherosclerosis (atheroembolic) or by thromboemboli from a distant source, where occlusion may occur in branch arteries distal to the main renal artery. This can cause multiple infarcts within the renal parenchyma of both kidneys, which may be visualised by CT scanning. If occlusion of the main renal arteries is bilateral or if there is occlusion of a single functioning kidney, the presentation is with AKI and the patient is typically anuric. Patients with bilateral occlusion usually have evidence of widespread vascular disease and may show evidence of aortic occlusion, with absent femoral pulses and reduced lower limb perfusion. Management is largely supportive, and includes anticoagulation if a source of thromboembolism is an identified source. It is sometimes possible to carry out stenting of an acutely blocked main renal artery to try to restore renal blood flow and kidney function.

Diseases of small intrarenal vessels

A number of conditions are associated with acute damage and occlusion of small blood vessels (arterioles and capillaries) in the kidney (Box 17.37). They are often found in conjunction with similar changes elsewhere in the body. A common feature of these syndromes is microangiopathic haemolytic anaemia, in which haemolysis and red cell fragmentation arise as consequences of damage incurred to red blood cells during passage through the abnormal vessels.

Haemolytic uraemic syndrome

Haemolytic uraemic syndrome (HUS) is characterised by thrombotic microangiopathy that causes damage to

17.37 Microvascular disorders associated with acute renal damage

- Thrombotic microangiopathy (haemolytic uraemic syndrome and thrombotic thrombocytopenic purpura)
  - Associated with verotoxin-producing *E. coli*
  - Other (familial, drugs, cancer)
- Disseminated intravascular coagulation
- Malignant hypertension
- Small-vessel vasculitis
- Systemic sclerosis (scleroderma)
- Atheroemboli ('cholesterol' emboli)

endothelial cells of the microcirculation. This is accompanied by swelling of the endothelial cells, increased platelet adherence and intravascular thrombosis. There is a marked reduction in the platelet count and anaemia, with features of intravascular haemolysis (p. 1026), such as a raised unconjugated bilirubin level, raised levels of LDH and decreased circulating levels of haptoglobin. A reticulocytosis is often seen. The kidney microcirculation tends to be most affected in HUS, with involvement of other organs (including the brain) in more severe cases. The most common cause of classical HUS is infection associated with organisms that produce enterotoxins called verotoxins: so-called diarrhoea-positive HUS (D+HUS). In about 10% of cases, however, no infective cause can be identified and this is termed atypical HUS.

The organisms most commonly implicated in D+HUS are enterohaemorrhagic *Escherichia coli* (p. 342). The O157:H7 serotype is the best known but other serotypes that produce verotoxins can also be responsible. Although these bacteria live as commensals in the gut of cattle and other domestic livestock, they can cause haemorrhagic diarrhoea in humans when the infection is contracted from contaminated food products, water or other infected individuals. In a proportion of cases, verotoxin produced by the organisms enters the circulation and binds to specific glycolipid receptors that are expressed on the surface of microvascular endothelial cells. In developed countries, D+HUS is now the most common cause of AKI in children. Recovery is good in most patients but sometimes RRT may be required for up to 14 days. No other specific treatments have been shown to help the renal lesion.

Atypical HUS is subclassified into familial and sporadic subtypes but both are associated with abnormalities of the complement system. Up to 70% of sporadic cases are associated with the development of autoantibodies to complement factor H, whereas the inherited forms are due to mutations in various genes that encode components of the complement cascade, including factor H (*CFH*), factor B (*CFB*) and complement component 3 (*C3*). The penetrance of familial HUS is incomplete, indicating that environmental triggers are also involved, but the nature of these triggers is poorly understood. Management of atypical HUS involves supportive care, optimising fluid and electrolyte balance, transfusion and RRT if necessary. Infusion of fresh frozen plasma can be helpful (presumably by replacing complement components), as can plasma exchange (presumably by removing pathogenic autoantibodies). Recently, impressive results have been reported with the anti-C5 monoclonal antibody, eculizumab, which binds to C5, thereby preventing activation of the terminal complement cascade.

Thrombotic thrombocytopenic purpura

Like HUS, thrombotic thrombocytopenic purpura (TTP) is characterised by thrombotic microangiopathy, which causes damage to endothelial cells of the microcirculation. This leads to swelling of the endothelial cells, increased platelet adherence and intravascular thrombosis. In contradistinction to HUS, the brain is more commonly affected in TTP and involvement of the kidney is usually less prominent. TTP is an autoimmune disorder caused by antibodies against ADAMTS-13, which is involved in regulating platelet aggregation. More details are provided on page 1056.

Disseminated intravascular coagulation

This may occur as a complication of a range of illnesses and can be accompanied by multi-organ failure and renal failure. Pathogenesis and management are discussed in more detail on pages 201 and 1055.

Systemic sclerosis

Renal involvement is a serious complication of systemic sclerosis, which is more likely to occur in diffuse cutaneous systemic sclerosis (DCSS) than in limited cutaneous systemic sclerosis (LCSS). The renal lesion is caused by intimal cell proliferation and luminal narrowing of intrarenal arteries and arterioles. There is intense intrarenal vasospasm and plasma renin activity is markedly elevated. Renal involvement usually presents clinically with severe hypertension, microangiopathic features and progressive oliguric renal failure (scleroderma renal crisis). Use of ACE inhibitors to control the hypertension has improved the 1-year survival from 20% to 75% but about 50% of patients continue to require RRT. Onset or acceleration of the syndrome after stopping ACE inhibitors is now well described.

Cholesterol emboli

These present with renal impairment, haematuria, proteinuria and sometimes eosinophilia with inflammatory features that can mimic a small-vessel vasculitis. The symptoms are provoked by showers of cholesterol-containing microemboli, arising in atheromatous plaques in major arteries. The diagnosis should be suspected when these clinical features occur in patients with widespread atheromatous disease, who have undergone interventions such as surgery or arteriography. It may also be precipitated by anticoagulants and thrombolytic agents. On clinical examination, signs of large-vessel disease and microvascular occlusion in the lower limbs (ischaemic toes, livedo reticularis) are common but not invariable (Fig. 17.18). There is no specific treatment.

Fig. 17.18 The foot of a patient who suffered extensive atheroembolism following coronary artery stenting.

Small-vessel vasculitis

Renal disease caused by small-vessel vasculitis usually affects the glomeruli, as described in the next section and on page 519.

Accelerated phase hypertension

Accelerated phase hypertension (p. 609) is deemed to exist when it is associated with acute damage to renal and other arterioles. It is often symptomatic, with headache, impaired vision and renal impairment (Fig. 17.19). Physical examination reveals severe hypertension with evidence of hypertensive retinopathy. Papilloedema is almost always present. Clinical features of microangiopathy, such as fragmented red cells and anaemia, may be present and, in the absence of a previous history, it may be difficult to distinguish patients with accelerated phase hypertension from those with HUS and hypertension. Most patients respond to effective control of blood pressure, although renal function is permanently lost in 20% of cases.

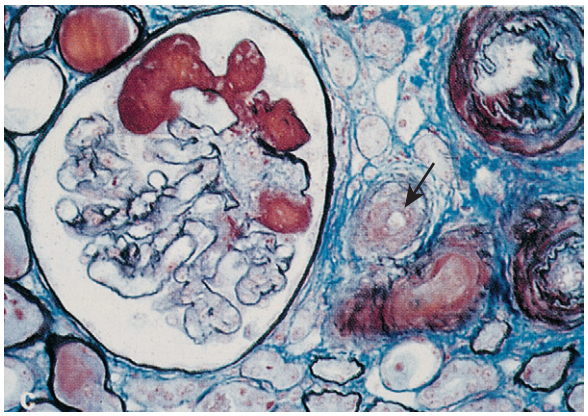

Fig. 17.19 Glomerular capillary thrombosis in malignant hypertension. Similar changes occur in thrombotic microangiopathy. The adjacent arteriole (arrow) shows gross intimal thickening. From Beutler and Koomans 1977 – see p. 523.

GLOMERULAR DISEASES

Glomerular diseases account for a significant proportion of acute and chronic kidney disease. There are many causes of glomerular damage, including immunological injury, inherited diseases such as Alport's syndrome

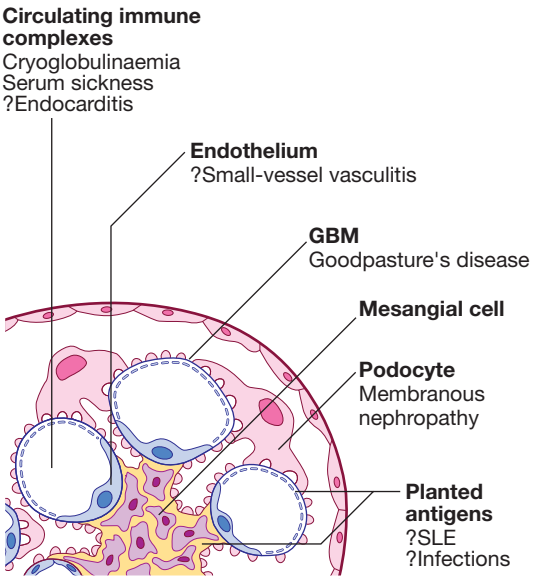

Fig. 17.20 Cells of the glomerulus and targets of immunity and autoimmunity. Antibodies and antigen–antibody (immune) complexes are described according to their site of deposition: subepithelial, between podocyte and GBM; intramembranous, within the GBM; subendothelial, between endothelial cell and GBM; and mesangial, within the mesangial matrix. (GBM = glomerular basement membrane; SLE = systemic lupus erythematosus)

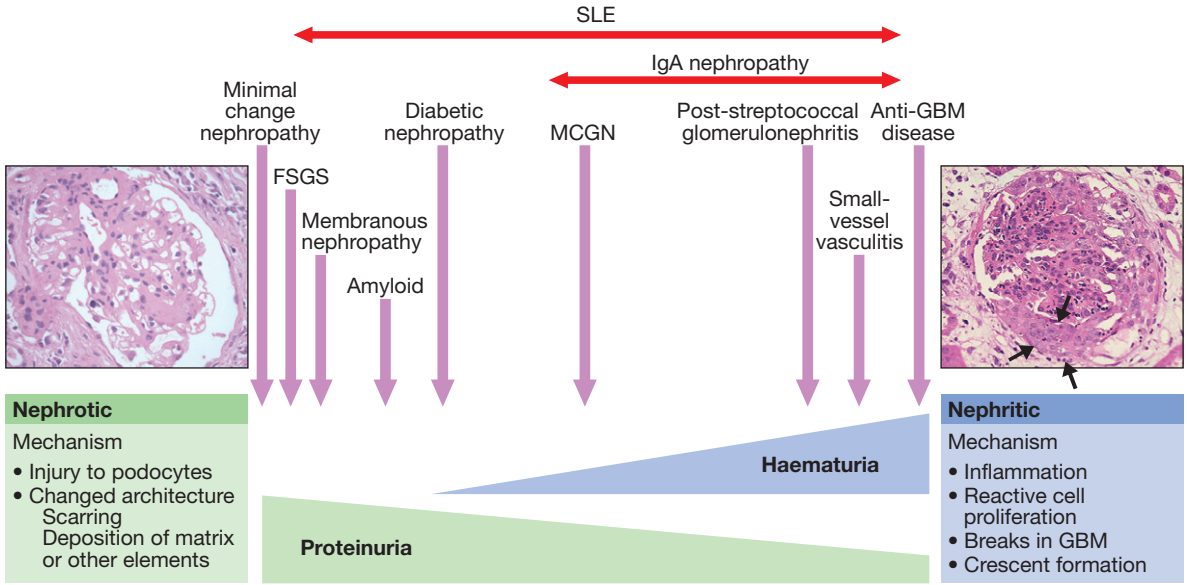

Fig. 17.21 Spectrum of glomerular diseases. At one extreme, specific injury to podocytes or structural alteration of the glomerulus affecting podocyte function (for example, by scarring or deposition of excess matrix or other material) causes proteinuria and nephrotic syndrome (see Box 17.11, p. 475). The histology to the left shows diabetic nephropathy. At the other end of the spectrum, inflammation leads to cell damage and proliferation, breaks form in the GBM and blood leaks into urine. In its extreme form, with acute sodium retention and hypertension, such disease is labelled nephritic syndrome. The histology to the right shows a glomerulus with many extra nuclei from proliferating intrinsic cells, and influx of inflammatory cells shows crescent formation (arrows) in response to severe post-infectious glomerulonephritis. (FSGS = focal and segmental glomerulosclerosis; MCGN = mesangiocapillary glomerulonephritis)

17.38 Clinical and laboratory features of glomerular injury

- Leakage of cells and macromolecules across the glomerular filtration barrier
  - Proteinuria: characteristic of diseases that affect the podocyte, scarring and deposition of foreign material
  - Haematuria: characteristic of inflammatory and destructive processes
- Impaired renal function and reduced GFR
- Hypertension

(p. 502), metabolic diseases such as diabetes mellitus (p. 830), and deposition of abnormal proteins such as amyloid in the glomeruli. The cell types of the glomerulus that may be the target of injury are shown in Figure 17.20. The response of the glomerulus to injury and hence the predominant clinical features vary according to the nature of the insult (Fig. 17.21). Clinical and laboratory features common to many glomerular diseases are shown in Box 17.38. Most patients with glomerular disease do not present acutely and are asymptomatic until abnormalities are detected on routine screening of blood or urine samples.

Glomerulonephritis

Glomerulonephritis literally means 'inflammation of glomeruli'. The term is used to describe all types of glomerular disease, even though some of these (such as minimal change nephropathy) are not associated with inflammation.

Most types of glomerulonephritis are immunologically mediated and several respond to immunosuppressive drugs. Deposition of antibody occurs in many types of glomerulonephritis (Box 17.39) but, frequently, the presumed mechanisms involve cellular immunity, which is more difficult to investigate. Although deposition of circulating immune complexes was previously thought to be a common mechanism, it now seems that most granular deposits of immunoglobulin are formed 'in situ' by antibodies which complex with glomerular antigens, or with other extraneous antigens derived from viruses and bacteria that have become deposited in the glomeruli (see Fig. 17.20).

Glomerulonephritis is generally classified in terms of the histopathological appearances, as summarised in Box 17.39 and Figure 17.22. The most common subtypes are discussed in more detail below.

Minimal change nephropathy

Minimal change disease occurs at all ages but accounts for nephrotic syndrome (see Box 17.11, p. 475) in most children and about one-quarter of adults. It is caused by reversible dysfunction of podocytes. The presentation is with proteinuria or nephrotic syndrome, which typically remits with high-dose corticosteroid therapy (1 mg/kg prednisolone for 6 weeks). Some patients who respond incompletely or relapse frequently need maintenance

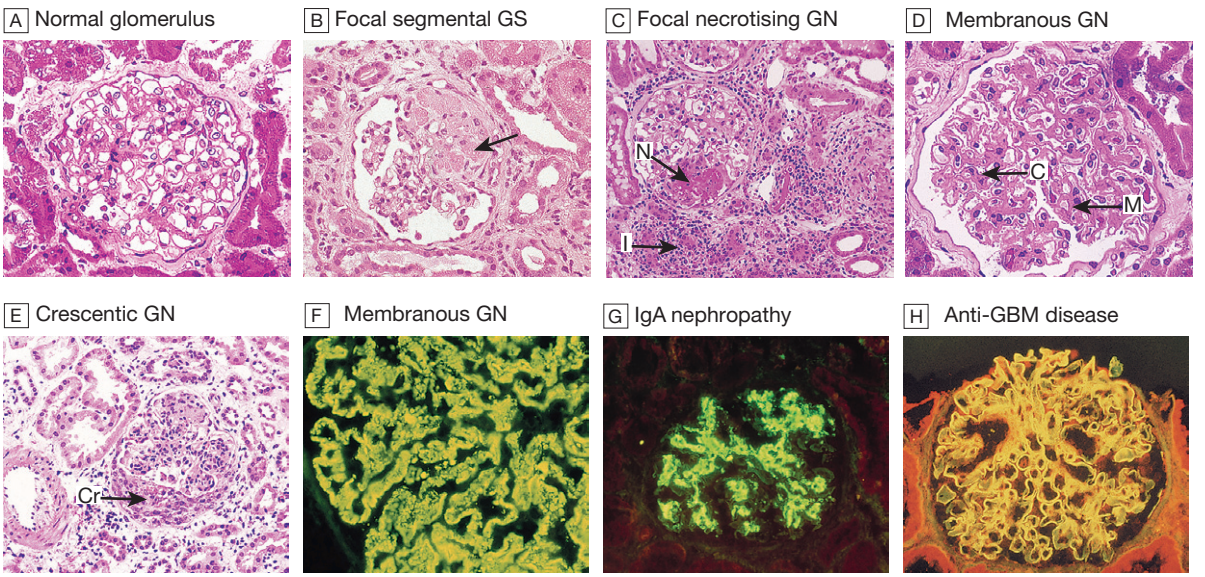

Fig. 17.22 Histopathology of glomerular disease. (A–E light microscopy) A A normal glomerulus. Note the open capillary loops and thinness of their walls – 'should look as if you could cut yourself on them'. B Focal segmental glomerulosclerosis (GS). The portion of the glomerulus arrowed shows loss of capillary loops and cells, which are replaced by matrix. C Focal necrotising glomerulonephritis (GN). A portion of the glomerulus (N = focal necrotising lesion) is replaced by bright pink material with some 'nuclear dust'. Neutrophils may be seen elsewhere in the glomerulus. There is surrounding interstitial inflammation (I). This is most commonly associated with small-vessel vasculitis and may progress to crescentic nephritis (see E). D Membranous glomerulonephritis. The capillary loops (C) are thickened (compare with the normal glomerulus) and there is expansion of the mesangial regions by matrix deposition (M). However, there is no gross cellular proliferation or excess of inflammatory cells. **E** Crescentic glomerulonephritis. The lower part of Bowman's space is occupied by a semicircular formation ('crescent', Cr) of large pale cells, compressing the glomerular tuft. This is seen in aggressive inflammatory glomerulonephritis. **Antibody deposition in the glomerulus. (F–H direct immunofluorescence)** F Granular deposits of IgG along the basement membrane in a subepithelial pattern, typical of membranous GN. G Immunoglobulin A (IgA) deposits in the mesangium, as seen in IgA nephropathy. H Ribbon-like linear deposits of anti-GBM antibodies along the glomerular basement membrane in Goodpasture's disease. The glomerular structure is well preserved in all of these examples.

17.39 Glomerulonephritis: types, associations and causes

Histology	Immune deposits	Pathogenesis	Associations	Comments
Minimal change				
Normal, except on electron microscopy, where fusion of podocyte foot processes is seen (a non-specific finding)	None	Unknown	Atopy HLA-DR7 Drugs	Acute and often severe nephrotic syndrome Good response to corticosteroids Dominant cause of idiopathic nephrotic syndrome in childhood
Focal segmental glomerulosclerosis (FSGS)				
Segmental scars in some glomeruli No acute inflammation Podocyte foot process fusion seen in primary FSGS with nephrotic syndrome	Non-specific trapping in focal scars	Unknown; in some, circulating factors increase glomerular permeability Injury to podocytes may be a common feature	Healing of previous local glomerular injury HIV infection Heroin misuse Morbid obesity	*Primary FSGS* presents as idiopathic nephrotic syndrome but is less responsive to treatment than minimal change; may progress to renal impairment, can recur after transplantation *Secondary FSGS* presents with variable proteinuria and outcome
Focal segmental glomerulonephritis				
Segmental inflammation and/or necrosis in some glomeruli ± crescent formation	Variable according to cause, but typically negative (or 'pauci-immune')	Small-vessel vasculitis	Primary or secondary small-vessel vasculitis	Often occurs in systemic disease. Responds to treatment with corticosteroids and immunosuppressants Check ANCA, ANA
Membranous glomerulonephritis				
Thickening of GBM Progressing to increased matrix deposition and glomerulosclerosis	Granular subepithelial IgG	Antibodies to a podocyte surface antigen, with complement-dependent podocyte injury	HLA-DR3 (for idiopathic) Drugs Mercury, heavy metals Hepatitis B virus Malignancy	Usually idiopathic; common cause of adult idiopathic nephrotic syndrome One-third progress; may respond to corticosteroids and immunosuppressants
IgA nephropathy				
Increased mesangial matrix and cells Focal segmental nephritis in acute disease	Mesangial IgA	Unknown	Usually idiopathic Liver disease	Common disease with a range of presentations, usually including haematuria and hypertension
Mesangiocapillary glomerulonephritis				
Immunoglobulin type	Immunoglobulins	Deposition of circulating immune complexes or 'planted' antigens	Infections, autoimmunity, or monoclonal immunoglobulin-related	Most common pattern found in association with subacute bacterial infection, but also with Cryoglobulinaemia ± hepatitis C virus, and others
Complement type	Complement components	Complement abnormalities, inherited or acquired. Dense deposit disease is associated with abnormal activation of the alternative complement pathway	Complement gene mutations C3 nephritic factor and partial lipodystrophy	In dense deposit disease, intramembranous deposits No proven treatments
Post-infection				
Diffuse proliferation of endothelial and mesangial cells Infiltration by neutrophils and macrophages ± crescent formation	Subendothelial	Immune response to streptococcal infection with presumed cross-reactive epitopes	Streptococcal and other infections	Now rare in developed countries Presents with severe sodium and fluid retention, hypertension, haematuria, oliguria Usually resolves spontaneously

Continued

17.39 Glomerulonephritis: types, associations and causes – cont'd

Histology	Immune deposits	Pathogenesis	Associations	Comments
Goodpasture's disease Usually crescentic nephritis	Linear IgG along GBM	Autoantibodies to α3 chain of type IV collagen in the GBM	HLA-DR15 (previously known as DR2)	Associated with lung haemorrhage but either may occur alone Treat with corticosteroids, cyclophosphamide and plasma exchange
Lupus nephritis Almost any histological type	Always positive and often profuse Pattern varies according to type	Some anti-DNA antibodies also bind to glomerular targets	Complement deficiencies Complement consumption	Variable presentation, sometimes as renal disease alone without systemic features Responds to cytotoxic therapy in addition to prednisolone

(ANCA = antineutrophil cytoplasmic antibodies; ANA = antinuclear antibody; HLA = human leucocyte antigen)

corticosteroids, cytotoxic therapy or other agents. Minimal change disease does not progress to CKD but can present with problems related to the nephrotic syndrome and complications of treatment.

Focal segmental glomerulosclerosis

Primary focal segmental glomerulosclerosis (FSGS) (Fig. 17.22B) can occur in all age groups. In some patients, FSGS can have specific causes, such as HIV infection, podocyte toxins and massive obesity, but in most cases the underlying cause is unknown (primary FSGS). Patients with primary FSGS present with massive proteinuria and idiopathic nephrotic syndrome. Histological analysis shows sclerosis affecting segments of the glomeruli, which may also show positive staining for deposits of C3 and IgM on immunofluorescence. Since FSGS is a focal process, abnormal glomeruli may not be seen on renal biopsy if only a few are sampled, leading to an initial diagnosis of minimal change nephropathy. Juxtamedullary glomeruli are more likely to be affected in early disease. Although nephrotic syndrome is typical, some patients present with the histological features of FSGS but less proteinuria. In these patients, the focal scarring may reflect healing of previous focal glomerular injury, such as HUS, cholesterol embolism or vasculitis. These examples of secondary FSGS have different course and treatments.

Primary FSGS can respond to high-dose corticosteroid therapy (0.5–2.0 mg/kg/day) but most patients show little or no response. Immunosuppressive drugs, such as ciclosporin, cyclophosphamide and mycophenolate mofetil, have also been used but their efficacy is uncertain. Progression to CKD is common in patients who do not respond to steroids and the disease frequently recurs after renal transplantation, with an almost immediate return of proteinuria following transplant in some cases.

Membranous glomerulonephritis

Membranous glomerulonephritis, also known as membranous nephropathy, is the most common cause of nephrotic syndrome in adults. It is caused by antibodies (usually autoantibodies) directed at antigen(s) expressed on the surface of podocytes. Recent studies suggest that one such antigen is the M-type phospholipase A_2 receptor 1. A proportion of cases are associated with other causes, such as heavy metal poisoning, drugs, infections and tumours (see Box 17.39 and Fig. 17.22D and F) but most are idiopathic. Approximately one-third of patients with idiopathic membranous glomerulonephritis undergo spontaneous remission; one-third remain in a nephrotic state, and one-third go on to develop CKD. Short-term treatment with high doses of corticosteroids and cyclophosphamide may improve both the nephrotic syndrome and the long-term prognosis. However, because of the toxicity of these regimens, many nephrologists reserve such treatment for those with severe nephrotic syndrome or deteriorating renal function.

IgA nephropathy

This is one of the most common types of glomerulonephritis and can present in many ways (Fig. 17.22G). Haematuria is the earliest sign and is almost universal, and hypertension is also very common. Proteinuria can also occur but is usually a later feature. In many cases, there is slowly progressive loss of renal function leading to ESRD. Clinical presentations are protean and vary with age. A particular hallmark of IgA nephropathy in young adults is the occurrence of acute self-limiting exacerbations, often with gross haematuria, in association with minor respiratory infections. This may be so acute as to resemble acute post-infectious glomerulonephritis, with fluid retention, hypertension and oliguria with dark or red urine. Characteristically, the latency from clinical infection to nephritis is short: a few days or less. Asymptomatic presentations dominate in older adults, with haematuria, hypertension and loss of GFR. Occasionally, IgA nephropathy progresses rapidly and crescent formation may be seen. The response to immunosuppressive therapy is usually poor. The management of less acute disease is largely directed towards the control of blood pressure in an attempt to prevent or retard progressive renal disease. There is some evidence

for additional benefit from several months of high-dose corticosteroid treatment in high-risk disease, but no strong evidence for other immunosuppressive agents. Other therapies are under investigation.

Henoch–Schönlein purpura

This condition most commonly occurs in children but can also be observed in adults. It is characterised by a systemic vasculitis that often arises in response to an infectious trigger. The presentation is with a characteristic petechial rash typically affecting buttocks and lower legs, and abdominal pain due to the occurrence of vasculitis involving the gastrointestinal tract. The presence of glomerulonephritis is usually indicated by the occurrence of haematuria. When Henoch–Schönlein purpura occurs in older children or adults, the glomerulonephritis is usually more prominent and less likely to resolve completely. Renal biopsy shows mesangial IgA deposition and appearances that are indistinguishable from acute IgA nephropathy. Treatment is supportive in nature; in most patients, the prognosis is good, with spontaneous resolution, but some, particularly adults, progress to develop ESRD.

Mesangiocapillary glomerulonephritis

Mesangiocapillary glomerulonephritis (MCGN), also known as membranoproliferative glomerulonephritis (MPGN), is characterised by an increase in mesangial cellularity with thickening of glomerular capillary walls and subendothelial deposition of immune complexes and/or components of the complement pathway. The typical presentation is with proteinuria and haematuria. Several underlying causes have been identified, as summarised in Box 17.39. It can be classified into two main subtypes. The first is characterised by deposition of immunoglobulins within the glomeruli. This subtype is associated with chronic infections, autoimmune diseases and monoclonal gammopathy. The second is characterised by deposition of complement in the glomeruli and is associated with inherited or acquired abnormalities in the complement pathway. Within this category is so-called 'dense deposit disease', which is typified by deposition of electron-dense deposits within the GBM. A third subtype is recognised, in which neither immunoglobulins nor complement are deposited in the glomeruli. This is associated with healing following thrombotic microangiopathies, such as HUS and TTP.

Treatment of MCGN associated with immunoglobulin deposits consists of identifying and treating the underlying disease, if possible, and the use of immunosuppressive drugs such as mycophenolate mofetil or cyclophosphamide. There is no specific treatment for MCGN associated with deposition of complement in the glomeruli or for dense deposit disease.

Infection-related glomerulonephritis

Glomerulonephritis may occur in connection with infections of various types, including subacute bacterial endocarditis. The most common histological pattern in bacterial infection is mesangiocapillary glomerulonephritis, often associated with extensive immunoglobulin deposition in the glomeruli with evidence of complement consumption (low serum C3, Box 17.40). In the developed world, hospital-acquired infections with various organisms are a common cause of these syndromes.

17.40 Causes of glomerulonephritis associated with low serum complement

- Post-infection glomerulonephritis
- Subacute bacterial infection: especially endocarditis
- Systemic lupus erythematosus
- Cryoglobulinaemia
- Mesangiocapillary glomerulonephritis, usually complement type

Worldwide, glomerulonephritis more commonly follows hepatitis B, hepatitis C, schistosomiasis, leishmaniasis, malaria and other chronic infections. Infection with HIV may be associated with FSGS (see above), particularly in people of African descent.

Post-streptococcal glomerulonephritis

This is a specific subtype of post-infectious glomerulonephritis. It is much more common in children than adults but is now rare in the developed world. The latency is usually about 10 days after a throat infection or longer after skin infection, suggesting an immune mechanism rather than direct infection. An acute nephritis of varying severity occurs. Sodium retention, hypertension and oedema are particularly pronounced. There is also reduction of GFR, proteinuria, haematuria and reduced urine volume. Characteristically, this gives the urine a red or smoky appearance. As in other causes of post-infectious glomerulonephritis, serum concentrations of C3 and C4 are typically reduced, reflecting complement consumption (see Box 17.40), and evidence of streptococcal infection may be found. Renal function begins to improve spontaneously within 10–14 days, and management by fluid and sodium restriction with diuretic and hypotensive agents is usually adequate. Remarkably, the renal lesion in almost all children and many adults seems to resolve completely, despite the severity of the glomerular inflammation and proliferation seen histologically.

Rapidly progressive glomerulonephritis

Rapidly progressive glomerulonephritis (also known as crescentic glomerulonephritis) is characterised by rapid loss of renal function over days to weeks. Renal biopsy shows crescentic lesions, often associated with necrotising lesions within the glomerulus, termed focal segmental (necrotising) glomerulonephritis. It is typically seen in Goodpasture's disease, where the underlying cause is the development of antibodies to the glomerular basement membrane (anti-GBM antibodies), and in small-vessel vasculitides (pp. 519 and 1115). It can also be observed in SLE (pp. 520 and 1109) and occasionally IgA and other nephropathies. Rapid-onset disease may be associated with relatively little proteinuria (see Fig. 17.21). Management depends on the underlying cause but immunosuppressive drugs are often required. Patients with anti-GBM disease should be treated with plasma exchange combined with corticosteroids and immunosuppressants. Patients

with renal involvement secondary to ANCA-associated vasculitis and SLE should also be treated with corticosteroids and immunosuppressants, as described on pages 1118 and 1112.

Inherited glomerular diseases

Alport's syndrome

A number of uncommon diseases may involve the glomerulus in childhood, but the most important one affecting adults is Alport's syndrome. Most cases arise from a mutation or deletion of the *COL4A5* gene on the X chromosome, which encodes type IV collagen, resulting in inheritance as an X-linked recessive disorder (p. 53). Mutations in *COL4A3* or *COL4A4* genes are less common and cause autosomal recessive disease. The accumulation of abnormal collagen results in a progressive degeneration of the GBM (Fig. 17.23). Affected patients progress from haematuria to ESRD in their late teens or twenties. Female carriers of *COL4A5* mutations usually have haematuria but less commonly develop significant renal disease. Some other basement membranes containing the same collagen isoforms are similarly involved, notably in the cochlea, so that Alport's syndrome is associated with sensorineural deafness and ocular abnormalities.

ACE inhibitors may slow but not prevent loss of kidney function. Patients with Alport's syndrome are good candidates for RRT, as they are young and usually otherwise healthy. They can develop an immune response to the normal collagen antigens present in the GBM of the donor kidney and, in a small minority, anti-GBM disease develops and destroys the allograft.

Thin glomerular basement membrane disease

In thin glomerular basement membrane disease there is glomerular bleeding, usually only at the microscopic or dipstick level, without associated hypertension, proteinuria or a reduction in GFR. The glomeruli appear normal by light microscopy but, on electron microscopy, the GBM is abnormally thin. The condition may be familial and some patients are carriers of Alport mutations. This does not appear to account for all cases, and in many patients the cause is unclear. Monitoring of these patients is advisable, as proteinuria may develop in some and there seems to be an increased rate of progressive CKD in the long term.

TUBULO-INTERSTITIAL DISEASES

These diseases primarily affect the renal tubules and interstitial components of the renal parenchyma. They are characterised by tubular dysfunction with electrolyte abnormalities, moderate levels of proteinuria and varying degrees of renal impairment. Acute tubular necrosis falls into this category but this is described separately on page 479, since it usually presents with AKI.

Acute interstitial nephritis

Acute interstitial nephritis (AIN) is characterised by acute inflammation affecting the tubulo-interstitium of the kidney. It is commonly drug-induced but can be caused by other factors, such as renal toxins, and can complicate a variety of systemic diseases and infections (Box 17.41).

Clinical features

The clinical presentation is typically with renal impairment but, in some patients with drug-induced acute interstitial nephritis, there may be signs of a generalised drug hypersensitivity reaction with fever, rash and eosinophilia. Proteinuria is generally modest (PCR < 100 mg/mmol) and tubular in type (p. 476). The urine may contain red and white blood cells but is sterile on

17.41 Causes of acute interstitial nephritis

Allergic	
Many drugs, but particularly	
• Penicillins	• Proton pump inhibitors
• NSAIDs	• Mesalazine (delayed)
Immune	
• Autoimmune nephritis ± uveitis	• Transplant rejection
Infections	
• Acute bacterial pyelonephritis	• Tuberculosis
• Leptospirosis	• Hantavirus
Toxic	
• Myeloma light chains	• Mushrooms (*Cortinarius*)

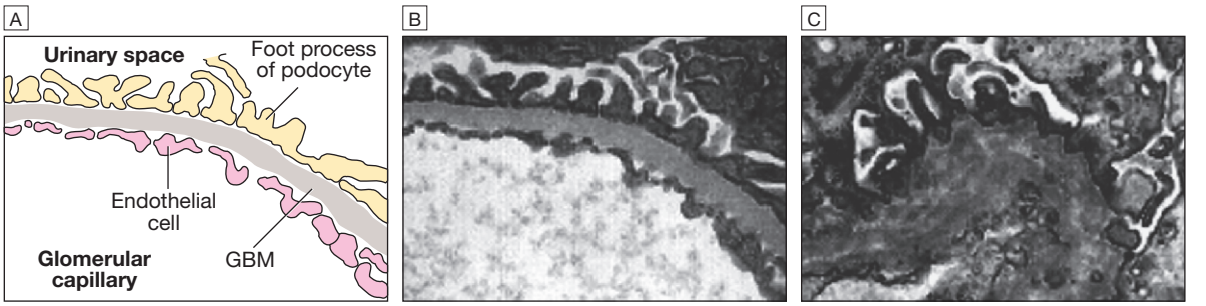

Fig. 17.23 Alport's syndrome. A Diagrammatic structure of the normal GBM. B The normal GBM (electron micrograph) contains mostly the tissue-specific (α3, α4 and α5) chains of type IV collagen. C In Alport's syndrome, this network is disrupted and replaced by α1 and α2 chains. Although the GBM appears structurally normal in early life, in time thinning appears, progressing to thickening, splitting and degeneration.

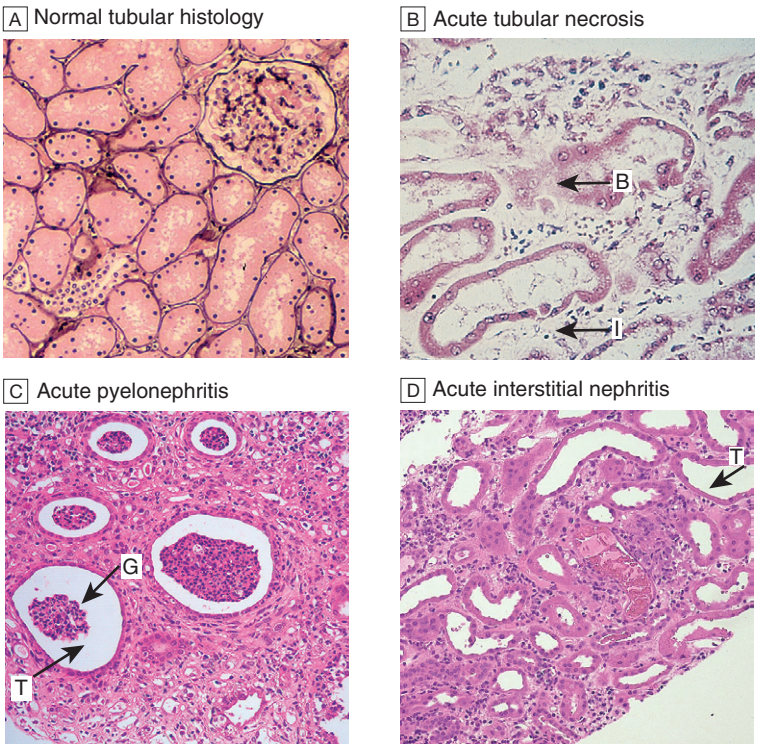

Fig. 17.24 Tubular histopathology. A Normal tubular histology. The tubules are back to back. Brush borders can be seen on the luminal borders of cells in the proximal tubule. B Acute tubular necrosis. There are scattered breaks (B) in tubular basement membranes, swelling and vacuolation of tubular cells, and, in places, apoptosis and necrosis of tubular cells with shedding of cells into the lumen. During the regenerative phase, there is increased tubular mitotic activity. The interstitium (I) is oedematous and infiltrated by inflammatory cells. The glomeruli (not shown) are relatively normal, although there may be endothelial cell swelling and fibrin deposition. C Acute bacterial pyelonephritis. A widespread inflammatory infiltrate that includes many neutrophils is seen. Granulocyte casts (G) are forming within some dilated tubules (T). Other tubules are scarcely visible because of the extent of the inflammation and damage. D Acute (allergic) interstitial nephritis. In this patient who received an NSAID, an extensive mononuclear cell infiltrate (no neutrophils) involving tubules (T) is seen. This inflammation does not involve the glomeruli (not shown). Sometimes eosinophils are prominent. Transplant rejection looks similar to this.

culture. Eosinophils are present in up to 70% of patients but this is a non-specific finding. Many patients are not oliguric, despite moderately severe renal impairment, and AIN should always be considered in patients with non-oliguric AKI. There may be a rapid deterioration of renal function in some cases of drug-induced AIN, causing the condition to be mistaken for rapidly progressive glomerulonephritis.

Investigations

Renal biopsy is usually required to confirm the diagnosis (Fig. 17.24). This typically shows evidence of intense inflammation, with infiltration of the tubules and interstitium by polymorphonuclear leucocytes, and lymphocytes. Eosinophils may also be observed, especially in drug-induced AIN. The degree of chronic inflammation in a biopsy is a useful predictor of the eventual outcome for renal function.

Management

Some patients with drug-induced AIN recover following withdrawal of the drug alone, but high-dose corticosteroids (prednisolone 1 mg/kg/day) accelerate recovery and may prevent long-term scarring. Dialysis is sometimes necessary but is usually only short-term. Other specific causes (see Box 17.41) should be treated, if possible.

Chronic interstitial nephritis

Chronic interstitial nephritis (CIN) is characterised by renal dysfunction with fibrosis and infiltration of the renal parenchyma by lymphocytes, plasma cells and macrophages, in association with tubular damage.

Pathophysiology

The disease may follow on from acute interstitial nephritis that does not resolve, or may be associated with ingestion of various toxins and drugs, or with metabolic and chronic inflammatory diseases, as summarised in Box 17.42. In many patients, CIN presents at a late stage and no underlying cause can be identified. Toxins that have been associated with CIN include those contained within the plant *Aristolochia clematitis*. These are probably responsible for the severe nephrotoxicity that can be associated with treatment with herbal medicines in Asia. There is some evidence that these toxins are also responsible for Balkan nephropathy, which affects isolated rural communities in Bosnia, Bulgaria, Croatia, Romania and Serbia. The nephropathy is commonly linked with tumours of the collecting system and is probably due to the mutagenic effects of the plant toxin on the urothelial epithelium. Ingestion of mushrooms within the *Cortinarius* genus can cause a devastating and irreversible renal tubular toxicity. The typical scenario is when a

17.42 Causes of chronic interstitial nephritis

Acute interstitial nephritis

- Any of the causes of AIN, if persistent (see Box 17.41)

Glomerulonephritis

- Varying degrees of interstitial inflammation occur in association with most types of inflammatory glomerulonephritis

Immune/inflammatory

- Sarcoidosis
- Sjögren's syndrome
- Chronic transplant rejection
- Systemic lupus erythematosus, primary autoimmune

Toxic

- *Aristolochia* in herbal medicines
- Lead
- Balkan nephropathy
- Mushrooms (*Cortinarius*)

Drugs

- All drugs causing AIN
- Tenofovir
- Lithium toxicity
- Analgesic nephropathy
- Ciclosporin, tacrolimus

Infection

- Consequence of severe pyelonephritis

Congenital/developmental

- Vesico-ureteric reflux: associated but causation not clear
- Renal dysplasias: often associated with reflux
- Inherited: now well recognised but mechanisms unclear
- Other: Wilson's disease, medullary sponge kidney, sickle-cell nephropathy

Metabolic and systemic diseases

- Calcium phosphate crystallisation after excessive phosphate administration (e.g. phosphate enemas in patients with CKD)
- Hypokalaemia
- Hyperoxaluria

patient mistakes a poisonous mushroom for an edible type. It is encountered occasionally in Scandinavia and Scotland.

Clinical features

Most patients with CIN present in adult life with CKD, hypertension and small kidneys. The CKD is often moderate (stage 3) but, because of tubular dysfunction, electrolyte abnormalities are typically more severe, resulting in hyperkalaemia and acidosis. Urinalysis abnormalities are non-specific. A minority of patients present with salt-losing nephropathy, characterised by hypotension, polyuria and features of sodium and water depletion. Patients with CIN have an impairment of urine-concentrating ability and sodium conservation, which puts them at risk of AKI due to salt and water depletion during an acute illness. Renal tubular acidosis (p. 446) may complicate CIN but is seen most often in myeloma, sarcoidosis, cystinosis, amyloidosis and Sjögren's syndrome.

Management

Management is supportive in nature, with correction of acidosis and hyperkalaemia; replacement of fluid and electrolytes, as required; and RRT if irreversible renal damage has occurred.

Reflux nephropathy

This condition, which was previously known as chronic pyelonephritis, is a specific type of chronic interstitial nephritis (see previous section) associated with vesicoureteric reflux (VUR) in early life and with the appearance of scars in the kidney, as demonstrated by various imaging techniques. About 12% of patients in Europe requiring treatment for ESRD may have this disorder but diagnostic criteria are imprecise.

Pathophysiology

Reflux nephropathy is thought to be due to chronic reflux of urine from the bladder into the ureters, in association with recurrent urinary tract infection (UTI) in childhood. It was previously assumed that ascending infection was necessary for progressive renal damage in patients with VUR, but there is evidence to suggest that renal scars can occur, even in the absence of infection. Furthermore, epidemiological surveys and controlled trials have found that efforts to correct VUR by using surgical or other means are ineffective in halting progression of the disease.

Susceptibility to VUR has a genetic component and may be associated with renal dysplasia and other congenital abnormalities of the urinary tract. It can be connected with outflow obstruction, usually caused by urethral valves, but usually occurs with an apparently normal bladder.

Clinical features

Usually, the renal scarring and dilatation are asymptomatic and the patient may present at any age with hypertension (sometimes severe), proteinuria or features of CKD. There may be no history of overt UTI. However, symptoms arising from the urinary tract may be present and include frequency of micturition, dysuria and aching lumbar pain. VUR may occur in children but diminishes as the child grows, and usually has disappeared by adulthood. Urinalysis often shows the presence of leucocytes and moderate proteinuria (usually < 1 g/24 hrs) but these are not invariable. The risk of renal stone formation is increased. A number of women first present with hypertension and/or proteinuria in pregnancy. Children and adults with small or unilateral renal scars have a good prognosis, provided renal growth is normal. With significant unilateral scars there is usually compensatory hypertrophy of the contralateral kidney. In patients with more severe bilateral disease, prognosis is related to the severity of renal dysfunction, hypertension and proteinuria. If the serum creatinine is normal and hypertension and proteinuria are absent, then the long-term prognosis is usually good.

Investigations

Renal scarring can be detected by ultrasound but it has poor sensitivity and is only capable of detecting major defects and excluding significant obstruction. Radionuclide DMSA scans are more sensitive (see Fig. 17.6, p. 471), and longitudinal imaging by MRI or CT may be useful in assessing progression. Abnormalities may be unilateral or bilateral and of any grade of severity. Gross scarring of the kidneys, commonly at the poles, is seen, with reduced kidney size and narrowing of the cortex

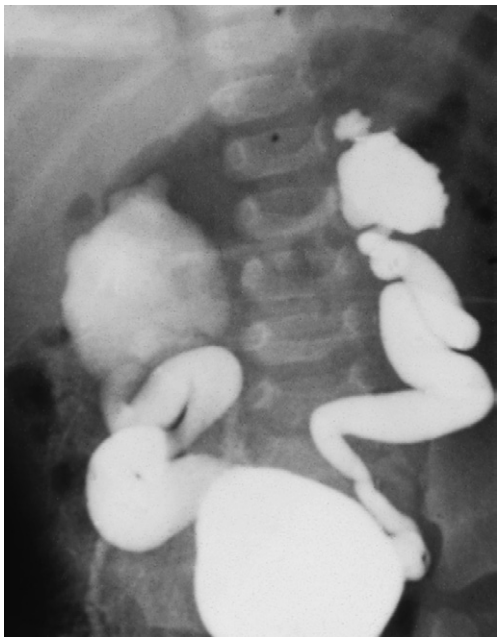

Fig. 17.25 Vesico-ureteric reflux (grade IV) shown by micturating cystogram. The bladder has been filled with contrast medium through a urinary catheter. After micturition, there was gross VUR into widely distended ureters and pelvicalyceal systems.

and medulla. Renal scars may be juxtaposed to dilated calyces. In patients who develop heavy proteinuria and hypertension, renal biopsies show glomerulomegaly and focal glomerulosclerosis, probably as a secondary response to reduced nephron numbers. Radionuclide techniques can also be used to demonstrate VUR as an alternative to micturating cystourethrography (MCUG; the bladder is filled with contrast media through a urinary catheter and images are taken during and after micturition – Fig. 17.25). However, as surgical intervention for VUR has declined in popularity (see below), this type of imaging is used less often.

Management

Infection, if present, should be treated (Box 17.43); if recurrent, it should be prevented with prophylactic therapy, as described for UTI (p. 512). If recurrent pyelonephritis occurs in an abnormal kidney with minimal function, nephrectomy may be indicated. Occasionally, hypertension is cured by the removal of a diseased kidney when the disease is predominantly or entirely unilateral.

As most childhood reflux tends to disappear spontaneously and trials have shown small or no benefits from anti-reflux surgery, such intervention is now less common.

EBM 17.43 Prophylactic antibiotics and vesico-ureteric reflux

'Prophylactic antibiotics reduce recurrences of UTI but there is no evidence that they protect against further renal scarring or dysfunction.'

- Smellie JM, et al. Lancet 2001; 357:1329–1333.

Papillary necrosis

The renal papillae lie within a hypertonic environment in the renal medulla, at the end of the vasa recta. They are susceptible to ischaemic damage because of this and can undergo necrosis when their vascular supply is impaired as the result of diabetes mellitus and sickle-cell disease or with long-term ingestion of NSAID. The condition may occasionally occur in other diseases. There is an association with pyelonephritis but it is difficult to determine whether this is a cause of papillary necrosis or a complication. The clinical presentation is variable. Some patients are asymptomatic and clinically silent, whereas others present with renal colic and renal impairment as necrosed papillae slough off and cause ureteric obstruction. Urinalysis may be normal but, more frequently haematuria and sterile pyuria are present. Significant proteinuria is unusual, unless there is renal failure. The imaging method of choice to make the diagnosis is pyelography. Management is based on relieving obstruction, where present, and withdrawal of the offending drugs.

Sickle-cell nephropathy

The longer survival of patients with sickle-cell disease (p. 1033) means that a high proportion now live to develop chronic complications of microvascular occlusion. In the kidney, these changes are most pronounced in the medulla, where the vasa recta are the site of sickling because of hypoxia and hypertonicity. Loss of urinary concentrating ability and polyuria are the earliest changes; distal renal tubular acidosis and impaired potassium excretion are typical. Papillary necrosis may also occur (see above). A minority of patients develop ESRD. This is managed according to the usual principles, but response to recombinant erythropoietin is poor due to the haemoglobinopathy. Patients with sickle trait have an increased incidence of unexplained microscopic haematuria.

CYSTIC DISEASES OF THE KIDNEY

It is common to encounter patients with a single renal cyst or even multiple ones as an incidental finding, especially in those aged 50 years and over. Usually, these cysts are of no clinical consequence and are asymptomatic, but occasionally they can cause pain or haematuria. In addition, several specific diseases are recognised as being caused by the formation of multiple renal cysts. These are discussed in more detail below.

Adult polycystic kidney disease

Adult polycystic kidney disease (PKD) is a common condition, with a prevalence of approximately 1:1000, and is inherited as an autosomal dominant trait. Small cysts lined by tubular epithelium develop from infancy or childhood and enlarge slowly and irregularly. The surrounding normal kidney tissue is compressed and progressively damaged. Mutations in the *PKD1* gene account for 85% of cases and *PKD2* for about 15%. ESRD occurs in approximately 50% of patients with *PKD1*

17.44 Adult polycystic kidney disease: common clinical features

- Vague discomfort in loin or abdomen due to increasing mass of renal tissue
- Acute loin pain or renal colic due to haemorrhage into a cyst
- Hypertension
- Haematuria (with little or no proteinuria)
- Urinary tract or cyst infections
- Renal failure

mutations, with a mean age of onset of 52 years, but in a minority of patients with *PKD2* mutations, with a mean age of onset of 69 years. It has been estimated that between 5% and 10% of patients on RRT have adult PKD.

Clinical features

Common clinical features are shown in Box 17.44. Affected subjects are usually asymptomatic until later life but hypertension usually occurs from the age of 20 onwards. One or both kidneys may be palpable and the surface may feel nodular. About 30% of patients with PKD also have hepatic cysts (see Fig. 23.38, p. 970) but disturbance of liver function is rare. Sometimes (almost always in women) this causes massive and symptomatic hepatomegaly, usually concurrent with renal enlargement but occasionally with only minor renal involvement. Berry aneurysms of cerebral vessels are an associated feature and about 10% of patients have a subarachnoid haemorrhage. This feature appears to be largely restricted to certain families (and presumably specific mutations). Mitral and aortic regurgitation is frequent but rarely severe, and colonic diverticula and abdominal wall hernias may occur.

Investigations

The diagnosis is usually based on family history, clinical findings and ultrasound examination. Ultrasound examination demonstrates cysts in approximately 95% of affected patients over the age of 20 and is the screening method of choice but may not detect small developing cysts in younger subjects. Cysts may also be identified by other imaging modalities, such as MRI (Fig. 17.26). It is now possible to make a molecular diagnosis by mutation screening of *PDK1* or *PDK2* but this is seldom used in routine clinical practice. Screening for intracranial aneurysms is not generally indicated but can be done by MR angiography in families with a history of subarachnoid haemorrhage. The yield of screening is low, however, and the risk–benefit ratio of intervention in asymptomatic aneurysms in this disease is not clear.

Management

Good control of blood pressure is important because cardiovascular morbidity and mortality are so common in renal disease, but there is no evidence that control of moderate hypertension retards the development of renal failure in PKD, in contrast to the evidence for glomerular diseases. There is some evidence that the vasopressin V2 receptor antagonist, tolvaptan, can slow cyst formation in some patients but its place in treatment has yet to be established.

Patients with PKD are usually good candidates for dialysis and transplantation. Sometimes kidneys are so large that one or both have to be removed to make space for a renal transplant. Otherwise, unless they are a source of pain or infection, they are usually left in situ.

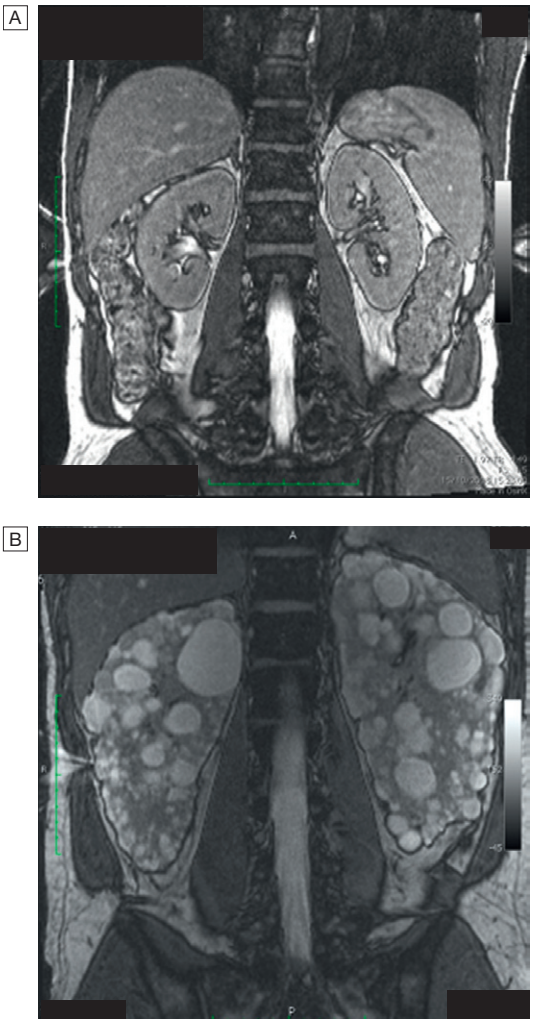

Fig. 17.26 MRI images of the kidneys. A Normal kidneys. B Polycystic kidneys; although the kidney enlargement is extreme, this patient had only slightly reduced GFR.

Medullary sponge kidney disease

Medullary sponge kidney is characterised by cysts confined to papillary collecting ducts. The disease is not inherited and its cause is unknown. Patients usually present as adults with renal stones. These are often recurrent, and preventive measures (p. 509) need to be implemented if so, but the prognosis is generally good. The diagnosis is made by ultrasound or IVU (Fig. 17.27). Contrast medium is seen to fill dilated or cystic tubules, which are sometimes calcified.

Medullary cystic kidney disease

This is a heterogenous group of inherited disorders, known as nephronophthisis in children. Small cortical cysts are associated with progressive destruction of the nephron. The childhood variants are characterised by thirst and polyuria due to nephrogenic diabetes insipidus, often with a family history of similar disease. Sometimes, affected patients are 'salt-losing', which

Fig. 17.27 Medullary sponge kidney. Intravenous urogram showing contrast medium filling both the collecting system and cavities arising from collecting ducts, especially within papillae of the upper pole. The cavities have been likened to bunches of grapes. A plain abdominal X-ray may show calcification in the same regions.

aggravates the degree of renal failure. Even when they are treated appropriately, serious renal failure is usual. Several of these conditions are associated with retinal dystrophies and brain or other abnormalities. The genetic basis of these disorders is emerging; several genes are involved.

Other cystic diseases

A number of other rarer inherited cystic diseases are recognised that have some similarities to PKD but distinct genetic causes. Multicystic dysplastic kidneys are often unilateral and are a developmental abnormality found in children. Most of these seem to involute during growth, leaving a solitary kidney in adults. Acquired cystic kidney disease can develop in patients with a very long history of renal failure, including those who have had many years of dialysis. It is associated with increased erythropoietin production and sometimes with the development of renal cell carcinoma.

RENAL STONE DISEASE

Renal stone disease is common, affecting individuals of all countries and ethnic groups. In the UK, the prevalence is about 1.2%, with a lifetime risk of developing a renal stone at age 60–70 of about 7% in men. In some regions, the risk is higher, most notably in countries like Saudi Arabia, where the lifetime risk of developing a renal stone in men aged 60–70 is just over 20%.

Pathophysiology

Urinary calculi consist of aggregates of crystals, usually containing calcium or phosphate in combination with small amounts of proteins and glycoproteins. The most common types are summarised in Box 17.45. A number of risk factors have been identified for renal stone formation (Box 17.46). In developed countries, however, most calculi occur in healthy young men, in whom investigations reveal no clear predisposing cause. Renal stones vary greatly in size. There may be particles like sand anywhere in the urinary tract, or large round stones in the bladder. In developing countries, bladder stones are common, particularly in children. In developed countries, the incidence of childhood bladder stones is low; renal stones in adults are more common. Staghorn calculi fill the whole renal pelvis and branch into the calyces (Fig. 17.28); they are usually associated with infection and composed largely of struvite. Deposits of calcium may be present throughout the renal parenchyma, giving rise to fine calcification within it (nephrocalcinosis), especially in patients with renal tubular acidosis, hyperparathyroidism, vitamin D intoxication and healed renal tuberculosis. Cortical nephrocalcinosis may occur in areas of cortical necrosis, typically after AKI in pregnancy or other severe AKI.

17.45 Composition of renal stones

Calcium oxalate[1]	60%
Calcium phosphate	15%
Uric acid	10%
Magnesium ammonium phosphate (struvite)[2]	15%
Cystine and others	1%

[1]Stones often contain small amounts of calcium phosphate.
[2]Associated with urine infection.

17.46 Predisposing factors for kidney stones

Environmental and dietary causes

- Low urine volumes: high ambient temperatures, low fluid intake
- Diet: high protein, high sodium, low calcium
- High sodium excretion
- High oxalate excretion
- High urate excretion
- Low citrate excretion

Acquired causes

- Hypercalcaemia of any cause (p. 767)
- Ileal disease or resection (increases oxalate absorption and urinary excretion)
- Renal tubular acidosis type I (distal, p. 446)

Congenital and inherited causes

- Familial hypercalciuria
- Medullary sponge kidney
- Cystinuria
- Renal tubular acidosis type I (distal)
- Primary hyperoxaluria

Clinical features

The clinical presentation is highly variable. Most patients with renal stone disease are asymptomatic, whereas others present with pain, haematuria, UTI or urinary tract obstruction. A common presentation is with acute

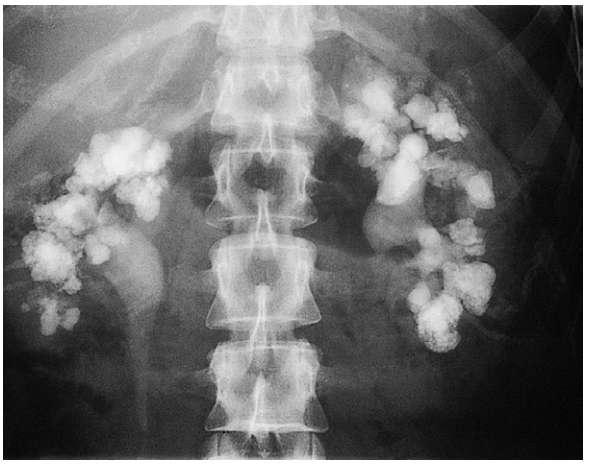

Fig. 17.28 Radio-opaque bilateral staghorn calculi visible during intravenous urography. The intravenous pyelogram demonstrates that, while some dye is being excreted by the right kidney, there is little function on the left.

Fig. 17.29 Unilateral ureteric obstruction. Intravenous urogram of a patient with a stone (not visible) at the lower end of the right ureter. This film, taken 2 hours post-contrast injection, demonstrates persistence of contrast medium in the right kidney, pelvicalyceal system and ureter, whereas only a small amount remains visible in the normal left pelvicalyceal system.

loin pain radiating to the anterior abdominal wall, together with haematuria: a symptom complex termed renal or ureteric colic. This is most commonly caused by ureteric obstruction by a calculus but the same symptoms can occur in association with a sloughed renal papilla, tumour or blood clot. The patient is suddenly aware of pain in the loin, which radiates round the flank to the groin and often into the testis or labium, in the sensory distribution of the first lumbar nerve. The pain steadily increases in intensity to reach a peak in a few minutes. The patient is restless and generally tries unsuccessfully to obtain relief by changing position or pacing the room. There is pallor, sweating and often vomiting. Frequency, dysuria and haematuria may occur. The intense pain usually subsides within 2 hours but may continue unabated for hours or days. It is usually constant during attacks, although slight fluctuations in severity may be seen. Subsequent to an attack of renal colic, intermittent dull pain in the loin or back may persist for several hours.

Investigations

Patients with symptoms of renal colic should be investigated to determine whether or not a stone is present, to identify its location and to assess whether it is causing obstruction. About 90% of stones contain calcium and these can be visualised on plain abdominal X-ray but CTKUB is the gold standard for diagnosing a stone within the kidney or ureter, as 99% are visible using this method. Alternatively, an IVU can be performed. The advantage of CTKUB over IVU is that it is more sensitive and can identify non-radio-opaque stones, such as those containing uric acid and cystine. When the stone is in the ureter, an IVU shows delayed excretion of contrast from the kidney, and a ureter that is dilated down as far as the stone (Fig. 17.29). Ultrasound can show stones within the kidney and dilatation of the renal pelvis and ureter if the stone is obstructing urine flow; it is useful in unstable patients or young women, in whom exposure to ionising radiation is undesirable.

A minimum set of investigations (Box 17.47) should be performed in patients with a first renal stone. The yield of more detailed investigation is low, and hence usually reserved for young patients, those with recurrent or multiple stones, or those with complicated or unexpected presentations. Chemical analysis of stones is often helpful in defining the underlying cause. Since most stones pass spontaneously through the urinary tract, urine should be sieved for a few days after an episode of colic in order to collect the calculus for analysis.

17.47 Investigations for renal stones

Sample	Test	First stone	Recurrent stone
Stone	Chemical composition[1]		✓
Blood	Calcium	✓	✓
	Phosphate	✓	✓
	Uric acid	✓	✓
	Urea and electrolytes	✓	✓

	Sodium		✓
	Calcium		✓
	Oxalate		✓
	Uric acid		✓

[1]The most valuable test if a stone can be obtained.
[2]Only if serum calcium or urinary calcium excretion high.

Management

The immediate treatment of renal colic is with analgesia and antiemetics. Renal colic is often unbearably painful and demands powerful analgesia; diclofenac orally or as a suppository (100 mg) is often very effective, followed by morphine (10–20 mg) or pethidine (100 mg) intramuscularly. Around 90% of stones of less than 4 mm diameter pass spontaneously, but only 10% of stones bigger than 6 mm, and these may require endoscopic surgical intervention (see below). Patients with renal stones are at high risk of infection; if surgery is contemplated, it should be covered with appropriate antibiotics. Immediate action is required if infection occurs in the stagnant urine proximal to the stone (pyonephrosis), and in patients with a solitary kidney who develop anuria in association with a stone in the ureter.

Stones that do not pass spontaneously through the urinary tract may need to be removed surgically or fragmented by extracorporeal shock wave lithotripsy (ESWL), in which shock waves generated outside the body are focused on the stone, breaking it into small pieces that can pass easily down the ureter. The indications for intervention to remove stones from the renal tract are summarised in Box 17.48. Procedures vary, depending on the site (Fig. 17.30).

Measures to prevent further stone formation are guided by the investigations in Box 17.47. Some general principles apply to almost every patient with calcium-containing stones (Box 17.49). More specific measures

17.48 Indications for intervention to remove stones from the urinary tract

Clinical presentation	Procedure
Obstruction and/or anuria	Emergency PCNL or stent
Pyonephrosis associated with stone	Emergency PCNL or stent
Stone in a patient with solitary kidney	Urgent PCNL, stent, ESWL or ureteroscopy*
Severe pain and persistence of stone in renal tract	Urgent PCNL, stent, ESWL or ureteroscopy*
Pain and persistence of stone in renal tract	Elective PCNL, ESWL or ureteroscopy*

*Procedure depends on site of stone – see Fig. 17.30. (ESWL = extracorporeal shock wave lithotripsy; PCNL = percutaneous nephrolithotomy)

17.49 Measures to prevent calcium stone formation

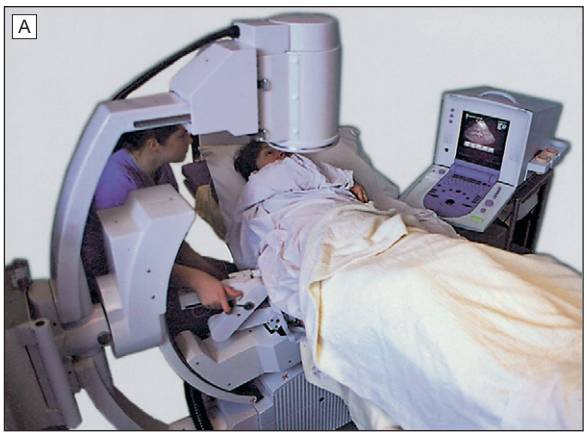
Diet

Fluid
- At least 2 L output per day (intake 3–4 L): check with 24-hr urine collections
- Intake distributed throughout the day (especially before bed)

Sodium
- Restrict intake

Protein
- Moderate, not high

Calcium
- Maintain good calcium intake (calcium forms an insoluble salt with dietary oxalate, lowering oxalate absorption and excretion)
- Avoid calcium supplements separate from meals (increase calcium excretion without reducing oxalate excretion)



Oxalate
- Avoid foods that are rich in oxalate (spinach, rhubarb)

Drugs

Thiazide diuretics
- Reduce calcium excretion
- Valuable in recurrent stone-formers and hypercalciuria

Allopurinol
- If urate excretion high (unproven except for urate stones)

Avoid
- Vitamin D supplements (increase calcium absorption and excretion)
- Vitamin C supplementation (increases oxalate excretion)

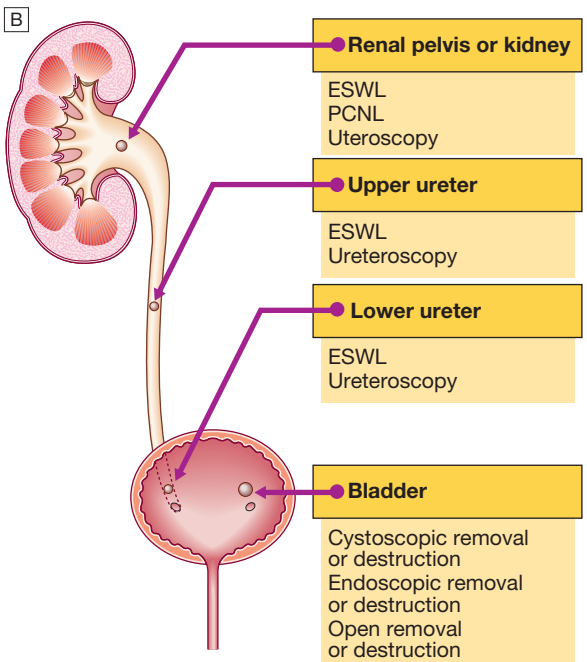


Fig. 17.30 Options for removal of urinary stones. A A patient undergoing extracorporeal shock wave lithotripsy (ESWL). B The procedures that are used for removal of stones in the urinary tract, shown in relation to the site of the stone. Very rarely, open or laparoscopic surgery may be necessary for removal of stones in the upper renal tract, if other methods fail. (PCNL = percutaneous nephrolithotomy)

apply to some types. Urate stones can be prevented by allopurinol, but its role in patients with calcium stones and high urate excretion is uncertain. Stones formed in cystinuria can be reduced by penicillamine therapy. It may also be helpful to attempt to alkalinise the urine with sodium bicarbonate, as a high pH discourages urate and cystine stone formation.

ISOLATED DEFECTS OF TUBULAR FUNCTION

An increasing number of disorders have been identified that are caused by specific defects in transporter molecules expressed in renal tubular cells. Only the most common are mentioned here. Renal glycosuria is a benign autosomal recessive defect of tubular reabsorption of glucose, caused by mutations of the sodium/glucose co-transporter *SGLT2*. Glucose appears in the urine in the presence of a normal blood glucose concentration. Cystinuria is a rare condition, in which reabsorption of filtered cystine, ornithine, arginine and lysine is defective. It is caused by mutations in the *SLC3A1* amino acid transporter gene. The high concentration of cystine in urine leads to cystine stone formation (p. 507).

Other uncommon tubular disorders include hereditary hypophosphataemic rickets (pp. 127 and 1128), in which reabsorption of filtered phosphate is reduced; nephrogenic diabetes insipidus (p. 794), in which the tubules are resistant to the effects of vasopressin; and Bartter's and Gitelman's syndromes, in which there is sodium-wasting and hypokalaemia (p. 440).

The term 'Fanconi syndrome' is used to describe generalised proximal tubular dysfunction. The condition typically presents with low blood phosphate and uric acid, glycosuria, amino aciduria and proximal renal tubular acidosis. In addition to the causes of interstitial nephritis described above, some congenital metabolic disorders are associated with Fanconi syndrome, notably Wilson's disease, cystinosis and hereditary fructose intolerance.

Renal tubular acidosis describes the common endpoint of a variety of diseases affecting distal (classical or type 1) or proximal (type 2) renal tubular function. These syndromes are described on page 446.

DISEASES OF THE COLLECTING SYSTEM AND URETERS

Congenital abnormalities

Various congenital anomalies of the urinary tract can occur (Fig. 17.31); they affect more than 10% of infants. If not immediately lethal, they can lead to complications in later life, including obstructive nephropathy and CKD.

Single kidneys

About 1 in 500 infants is born with only one kidney. Although this is usually compatible with normal life, it may be associated with other abnormalities.

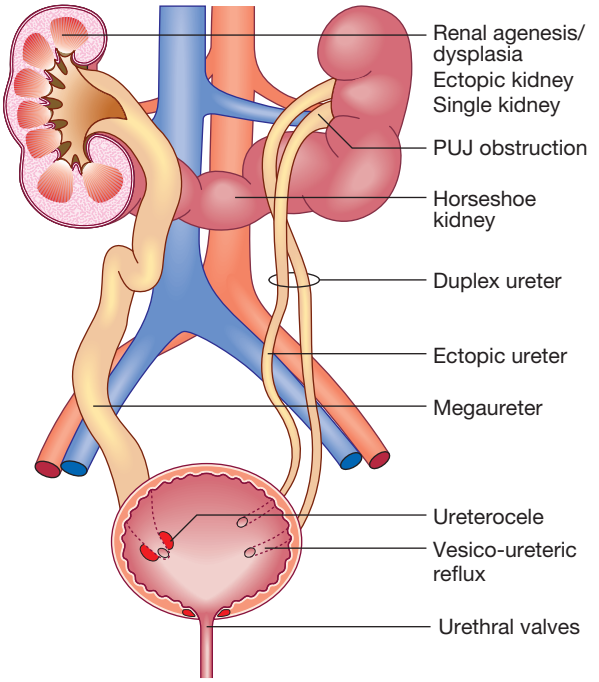

Fig. 17.31 Congenital abnormalities of the urinary tract.

Ureterocele

A ureterocele occurs behind a pin-hole ureteric orifice when the intramural part of the ureter dilates and bulges into the bladder. It can become very large and cause lower urinary tract obstruction. Incision of the pin-hole opening relieves the obstruction.

Ectopic ureters and duplex kidneys

Ectopic ureters occur with congenital duplication of one or both kidneys (duplex kidneys). Developmentally, the ureter has two main branches and, if this arrangement persists, the two ureters of the duplex kidneys may drain separately into the bladder. The lower pole moiety enters the bladder superiorly and laterally, while the upper pole moiety enters the bladder inferomedially to the lower pole moiety ureter or, more rarely, the vagina or seminal vesicle. The lower pole moiety has an ineffective valve mechanism, so that urine passes up the ureter on voiding (vesico-ureteric reflux, p. 504), whereas the upper pole moiety is often associated with a ureterocele.

Obstructive megaureter

In primary obstructive megaureter, there is dilatation of the ureter in all but its terminal segment without obvious cause and without vesico-ureteric reflux. Radiographic and pressure/flow studies may be needed to determine whether there is obstruction to urine flow. Narrowing of the ureter and re-implantation may be necessary.

Pelvi-ureteric junction obstruction

This causes idiopathic hydronephrosis and results from a functional obstruction at the junction of the ureter and renal pelvis. The abnormality is likely to be congenital and is often bilateral. It can be seen in very young

children but gross hydronephrosis may present at any age. The common presentation is ill-defined renal pain or ache, exacerbated by drinking large volumes of liquid (Dietl's crisis). Rarely, it is asymptomatic. The diagnosis is often suspected after ultrasound or IVU, and can be confirmed with a ^{99m}Tc-MAG3 renogram followed by diuretic. Treatment is surgical excision of the PUJ and re-anastomosis (pyeloplasty), which can now be performed laparoscopically. Less invasive alternatives are also possible, including balloon dilatation and endoscopic pyelotomy, but are generally less effective.

Retroperitoneal fibrosis

Fibrosis of the retroperitoneal connective tissues may encircle and compress the ureter(s), causing obstruction. The fibrosis is most commonly idiopathic, but can represent a reaction to infection, radiation or aortic aneurysm, or be caused by cancer or a drug reaction – methysergide, for example. Patients usually present with ill-defined symptoms of ureteric obstruction. Typically, there is an acute-phase response (high CRP and ESR). Imaging with UVI or CT shows ureteric obstruction with medial deviation of the ureters. Idiopathic retroperitoneal fibrosis responds well to corticosteroids and may respond more slowly to tamoxifen, but ureteric stenting is often necessary to relieve obstruction. Failure to improve indicates the need for surgery (ureterolysis) both to relieve obstruction and to exclude malignancy.

INFECTIONS OF THE URINARY TRACT

In health, bacterial colonisation is confined to the lower end of the urethra and the remainder of the urinary tract is sterile (see Ch. 6). The urinary tract can become infected with various bacteria but the most common is *E. coli* derived from the gastrointestinal tract. The most common presenting problem is cystitis with urethritis (generally referred to as urinary tract infection) but this is only part of a spectrum of severity (Box 17.50).

Urinary tract infection

Urinary tract infection (UTI) is the term used to describe acute urethritis and cystitis caused by a microorganism. It is a common disorder accounting for 1–3% of consultations in general medical practice. The prevalence of UTI in women is about 3% at the age of 20, increasing by about 1% in each subsequent decade. In males, UTI is uncommon, except in the first year of life and in men over 60, when it may complicate bladder outflow obstruction.

Pathophysiology

Urine is an excellent culture medium for bacteria; in addition, the urothelium of susceptible persons may have more receptors, to which virulent strains of *E. coli* become adherent. In women, the ascent of organisms into the bladder is easier than in men; the urethra is shorter and the absence of bactericidal prostatic secretions may be relevant. Sexual intercourse may cause minor urethral trauma and transfer bacteria from the perineum into the bladder. Instrumentation of the bladder may also introduce organisms. Multiplication of organisms then depends on a number of factors, including the size of the inoculum and virulence of the bacteria. Conditions that predispose to UTI are shown in Box 17.51.

17.50 The spectrum of presentations of urinary tract infection

- Asymptomatic bacteriuria
- Symptomatic acute urethritis and cystitis
- Acute pyelonephritis (p. 513)
- Acute prostatitis (p. 515)
- Septicaemia (usually Gram-negative bacteria)

17.51 Risk factors for urinary tract infection

Incomplete bladder emptying

- Bladder outflow obstruction
  - Benign prostatic enlargement
  - Prostate cancer
  - Urethral stricture
  - Vesico-ureteric reflux
- Uterine prolapse
- Neurological problems
  - Multiple sclerosis
  - Spina bifida
  - Diabetic neuropathy

Foreign bodies

- Urethral catheter or ureteric stent
- Urolithiasis

Loss of host defences

- Atrophic urethritis and vaginitis in post-menopausal women
- Diabetes mellitus

Clinical features

Typical features of cystitis and urethritis include:

- abrupt onset of frequency of micturition and urgency
- scalding pain in the urethra during micturition (dysuria)
- suprapubic pain during and after voiding
- intense desire to pass more urine after micturition, due to spasm of the inflamed bladder wall (strangury)
- urine that may appear cloudy and have an unpleasant odour
- microscopic or visible haematuria.

Systemic symptoms are usually slight or absent. However, infection in the lower urinary tract can spread (see Box 17.50); acute pyelonephritis is suggested by prominent systemic symptoms with fever, rigors, vomiting, hypotension and loin pain, guarding or tenderness, and may be an indication for hospitalisation. Only about 30% of patients with acute pyelonephritis have associated symptoms of cystitis or urethritis. Prostatitis is suggested by perineal or suprapubic pain, pain on ejaculation and prostatic tenderness on rectal examination.

The differential diagnosis of lower urinary tract symptoms includes urethritis due to sexually transmitted disease, notably chlamydia (p. 422) or Reiter's syndrome (p. 1107). Some patients, usually female, have symptoms suggestive of urethritis and cystitis but no bacteria are cultured from the urine (the 'urethral syndrome'). Possible explanations include infection with

organisms not readily cultured by ordinary methods (such as *Chlamydia* and certain anaerobes), intermittent or low-count bacteriuria, reaction to toiletries or disinfectants, symptoms related to sexual intercourse, or post-menopausal atrophic vaginitis.

The differential diagnosis of acute pyelonephritis includes pyelonephrosis, acute appendicitis, diverticulitis, cholecystitis, salpingitis, ruptured ovarian cyst or ectopic pregnancy. In pyelonephrosis due to upper urinary tract obstruction, patients may become extremely ill, with fever, leucocytosis and positive blood cultures. With a perinephric abscess, there is marked pain and tenderness, and often bulging of the loin on the affected side. Urinary symptoms may be absent in this situation and urine testing negative, containing neither pus cells nor organisms.

Investigations

An approach to investigation is shown in Box 17.52. In an otherwise healthy woman with a single lower urinary tract infection, urine culture prior to treatment is not mandatory. Investigation is necessary, however, in patients with recurrent infection or after failure of initial treatment, during pregnancy, or in patients susceptible to serious infection, such as the immunocompromised, those with diabetes or an indwelling catheter, and older people (Box 17.53). The diagnosis can be made from the combination of typical clinical features and abnormalities on urinalysis. Most urinary pathogens can reduce nitrate to nitrite, and neutrophils and nitrites can usually be detected in symptomatic infections by urine dipstick tests for leucocyte esterase and nitrite, respectively. The absence of both nitrites and leucocyte esterase in the urine makes UTI unlikely. Interpretation of bacterial counts in the urine, and of what is a 'significant' culture result, is based on probabilities. Urine taken by suprapubic aspiration should be sterile, so the presence of any organisms is significant. If the patient has symptoms and there are neutrophils in the urine, a small number of organisms is significant. In asymptomatic patients, more than 10^5 organisms/mL is usually regarded as significant (asymptomatic bacteriuria, see below).

17.52 Investigation of patients with urinary tract infection

All patients
• Dipstick* estimation of nitrite, leucocyte esterase and glucose • Microscopy/cytometry of urine for white blood cells, organisms • Urine culture
Infants, children, and anyone with fever or complicated infection
• Full blood count; urea, electrolytes, creatinine • Blood cultures
Pyelonephritis; males; children; women with recurrent infections
• Renal tract ultrasound or CT • Pelvic examination in women, rectal examination in men
Continuing haematuria or other suspicion of bladder lesion
• Cystoscopy

*May substitute for microscopy and culture in simple uncomplicated infection.

17.53 Urinary infection in old age

- **Prevalence of asymptomatic bacteriuria**: rises with age. Amongst the most frail in institutional care it rises to 40% in women and 30% in men.
- **Decision to treat**: treating asymptomatic bacteriuria does not improve chronic incontinence or decrease mortality or morbidity from symptomatic urinary infection. It risks adverse effects from the antibiotic and promoting the emergence of resistant organisms.
- **Source of infection**: the urinary tract is the most frequent source of bacteraemia in older patients admitted to hospital.
- **Incontinence**: new or increased incontinence is a common presentation of UTI in older women.
- **Treatment**: post-menopausal women with acute lower urinary tract symptoms may require longer than 3 days' therapy.

Typical organisms causing UTI in the community include *E. coli* derived from the gastrointestinal tract (about 75% of infections), *Proteus* spp., *Pseudomonas* spp., streptococci and *Staphylococcus epidermidis*. In hospital, *E. coli* still predominates, but *Klebsiella* or streptococci are more common. Certain strains of *E. coli* have a particular propensity to invade the urinary tract.

Investigations to detect underlying predisposing factors for UTI are used selectively, most commonly in children, men or patients with recurrent infections (see Box 17.52).

Management

Antibiotics are recommended in all cases of proven UTI (Box 17.54). If urine culture has been performed, treatment may be started while awaiting the result. For infection of the lower urinary tract, treatment for 3 days is the norm and is less likely to induce significant alterations in bowel flora than more prolonged therapy. Trimethoprim is the usual choice for initial treatment; however, between 10% and 40% of organisms causing UTI are resistant to trimethoprim, the lower rates being seen in community-based practice. Nitrofurantoin, quinolone antibiotics such as ciprofloxacin and norfloxacin, and cefalexin are also generally effective. Co-amoxiclav or amoxicillin should only be used when the organism is known to be sensitive. Penicillins and cephalosporins are safe to use in pregnancy but trimethoprim, sulphonamides, quinolones and tetracyclines should be avoided.

In more severe infection, antibiotics should be continued for 7–14 days. Seriously ill patients may require intravenous therapy with a cephalosporin, quinolone or gentamicin for a few days (see Box 17.54), later switching to an oral agent.

A fluid intake of at least 2 L/day is usually recommended, although this is not based on evidence and may make symptoms of dysuria worse.

Persistent or recurrent UTI

If the causative organism persists on repeat culture despite treatment, or if there is re-infection with any organism after an interval, then an underlying cause is more likely to be present (see Box 17.51) and more detailed investigation is justified (see Box 17.52). In women, recurrent infections are common and

17.54 Antibiotic regimens for urinary tract infection in adults[1]

Scenario	Drug	Regimen	Duration	Comment
Cystitis				
First choice	Trimethoprim	200 mg twice daily	3 days	7–10 days in men
Second choices[1]	Amoxicillin	250 mg 3 times daily		
	Nitrofurantoin	50 mg 4 times daily		
	Cefalexin	250 mg 4 times daily		
	Ciprofloxacin	100 mg twice daily		
In pregnancy	Co-amoxiclav	250/125 mg 3 times daily	7 days	Avoid trimethoprim and quinolones during pregnancy
	Cefalexin	250 mg 4 times daily		
	Amoxicillin	250 mg 3 times daily		
Prophylactic therapy				
First choice	Trimethoprim	100 mg at night	Continuous	
Second choices[1]	Nitrofurantoin	50 mg at night		
	Co-amoxiclav	250/125 mg at night		
Pyelonephritis				
First choice	Co-amoxiclav	500/125 mg 3 times daily	14 days	Admit to hospital if no response within 24 hrs
	Ciprofloxacin	500 mg twice daily	7 days	
Second choice	Gentamicin[2]	Adjust dose according to renal function and serum levels	14 days	Switch to appropriate oral agent as soon as possible
	Cefuroxime	150–1500 mg 3 times daily		
Epididymo-orchitis				
First choice	Ciprofloxacin	500 mg twice daily	14 days	Refer to genito-urinary department to exclude *N. gonorrhoeae*
Acute prostatitis				
First choice	Trimethoprim	200 mg twice daily	28 days	
Second choice	Ciprofloxacin	500 mg twice daily		

[1]In all cases, the choice of drug should take locally determined antibiotic resistance patterns into account. [2]See Hartford nomogram (p. 157).

17.55 Prophylactic measures to be adopted by women with recurrent urinary infections

- Fluid intake of at least 2 L/day
- Regular complete emptying of bladder
- Good personal hygiene
- Emptying of bladder before and after sexual intercourse
- Cranberry juice may be effective

investigation is only justified if infections are frequent (three or more per year) or unusually severe. Recurrent UTI, particularly in the presence of an underlying cause, may result in permanent renal damage, whereas uncomplicated infections rarely (if ever) do so (see chronic reflux nephropathy, p. 504).

If an underlying cause cannot be treated, suppressive antibiotic therapy (see Box 17.54) can be used to prevent recurrence and reduce the risk of septicaemia and renal damage. Urine should be cultured at regular intervals; a regime of two or three antibiotics in sequence, rotating every 6 months, is often used in an attempt to reduce the emergence of resistant organisms. Other simple measures may help to prevent recurrence (Box 17.55).

Asymptomatic bacteriuria

This is defined as more than 10^5 organisms/mL in the urine of apparently healthy asymptomatic patients. Approximately 1% of children under the age of one, 1% of schoolgirls, 0.03% of schoolboys and men, 3% of non-pregnant adult women and 5% of pregnant women have asymptomatic bacteriuria. It is increasingly common in those aged over 65. There is no evidence that this condition causes renal scarring in adults who are not pregnant and have a normal urinary tract and, in general, treatment is not indicated. However, up to 30% will develop symptomatic infection within 1 year. Treatment is required in infants, pregnant women and those with urinary tract abnormalities.

Catheter-related bacteriuria

In patients with a urethral catheter, bacteriuria increases the risk of Gram-negative bacteraemia fivefold. Bacteriuria is common, however, and almost universal during long-term catheterisation. Treatment is usually avoided in asymptomatic patients, as this may promote antibiotic resistance. Careful sterile insertion technique is important, and the catheter should be removed as soon as it is not required.

Acute pyelonephritis

The kidneys are infected in a minority of patients with UTI. Acute renal infection (pyelonephritis) presents as a classic triad of loin pain, fever and tenderness over the kidneys. The renal pelvis is inflamed and small abscesses are often evident in the renal parenchyma (see Fig. 17.24C, p. 503).

Renal infection is almost always caused by organisms ascending from the bladder, and the bacterial profile is the same as for lower urinary tract infection (p. 512). Rarely, bacteraemia may give rise to renal or perinephric abscesses, most commonly due to staphylococci. Predisposing factors, such as cysts or renal scarring, facilitate infection.

Rarely, acute pyelonephritis is associated with papillary necrosis. Fragments of renal papillary tissue are passed per urethra and can be identified histologically. They may cause ureteric obstruction and, if this occurs bilaterally or in a single kidney, it may lead to AKI. Predisposing factors include diabetes mellitus, chronic urinary obstruction, analgesic nephropathy and sickle-cell disease. A necrotising form of pyelonephritis with gas formation, 'emphysematous pyelonephritis', is occasionally seen in patients with diabetes mellitus. Xanthogranulomatous pyelonephritis is a chronic infection that can resemble renal cell cancer. It is usually associated with obstruction, is characterised by accumulation of foamy macrophages and generally requires nephrectomy. Infection of cysts in polycystic kidney disease (p. 505) calls for prolonged antibiotic treatment.

Appropriate investigations are shown in Box 17.52 and management is described above and in Box 17.54. Intravenous rehydration may be needed in severe cases. If complicated infection is suspected or response to treatment is not prompt, urine should be recultured and renal tract ultrasound performed to exclude urinary tract obstruction or a perinephric collection. If obstruction is present, drainage by a percutaneous nephrostomy or ureteric stent should be considered.

Tuberculosis

Tuberculosis of the kidney and renal tract is secondary to tuberculosis elsewhere (p. 688) and is the result of blood-borne infection. Initially, lesions develop in the renal cortex; these may ulcerate into the renal pelvis and involve the ureters, bladder, epididymis, seminal vesicles and prostate. Calcification in the kidney and stricture formation in the ureter are typical.

Clinical features may include symptoms of bladder involvement (frequency, dysuria); haematuria (sometimes macroscopic); malaise, fever, night sweats, lassitude and weight loss; loin pain; associated genital disease; and chronic renal failure as a result of urinary tract obstruction or destruction of kidney tissue.

Neutrophils are present in the urine but routine urine culture may be negative ('sterile pyuria'). Special techniques of microscopy and culture may be required to identify tubercle bacilli and are most usefully performed on early morning urine specimens. Bladder involvement should be assessed by cystoscopy. Radiology of the urinary tract and a chest X-ray to look for pulmonary tuberculosis are mandatory. Anti-tuberculous chemotherapy follows standard regimes (p. 693). Surgery to relieve urinary tract obstruction or to remove a very severely infected kidney may be required.

BENIGN PROSTATIC ENLARGEMENT

Benign prostatic enlargement (BPE) is extremely common. It has been estimated that about half of all men aged 80 years and over will have lower urinary tract symptoms associated with BPE. Benign prostatic hyperplasia (BPH) is the histological abnormality that underlies BPE.

Pathophysiology

The prostate gland increases in volume by 2.4 cm^3 per year on average from 40 years of age. The process begins in the peri-urethral (transitional) zone and involves both glandular and stromal tissue to a variable degree. The cause is unknown, although BPE does not occur in patients with hypogonadism, suggesting that hormonal factors may be important.

Clinical features

The primary symptoms of BPE arise because of difficulty in voiding urine due to obstruction of the urethra by the prostate; they consist of hesitancy, poor urinary flow and a sensation of incomplete emptying. Other symptoms include urinary frequency, urgency of micturition and urge incontinence, although these are not specific to BPE. Some patients present suddenly with acute urinary retention, when they are unable to micturate and develop a painful distended bladder. This is often precipitated by excessive alcohol intake, constipation and prostatic infection. Severity of symptoms can be ascertained by using the International Prostate Symptom Score questionnaire (IPSS, Box 17.56), which serves as a valuable starting point for assessment of the patient. Once a baseline value is established, any improvement or deterioration may be monitored on subsequent visits. The IPSS may be combined with a quality of life score, in which patients are asked the following question 'If you were to spend the rest of your life with your

17.56 The International Prostate Symptom Score (IPSS)

Symptom	Question	Example score
Straining	How often have you had to push or strain to begin urination?	1
Urgency	How often have you found it difficult to postpone urination?	2
Hesitancy	How often have you found that you stopped and started again several times when you urinated?	1
Incomplete emptying	How often have you had a sensation of not emptying your bladder completely after you finished urinating?	3
Frequency	How often have you had to urinate again less than 2 hours after you finished urinating?	1
Weak stream	How often have you had a weak urinary stream?	2
Nocturia	How many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	1
Total score		11

0 = not at all; 1 = less than one-fifth of the time; 2 = less than half the time; 3 = about half of the time; 4 = more than half of the time; 5 = almost always

A score of 0–1 indicates mild symptoms, 8–19 moderate symptoms and 20–35 severe symptoms. In the example shown, the patient had moderate symptoms.

urinary condition the way it is now, how would you feel about that?' Responses range from 0 (delighted) to 6 (terrible).

Patients may also present with chronic urinary retention. Here, the bladder slowly distends due to inadequate emptying over a long period of time. Patients with chronic retention can also develop acute retention: so-called acute-on-chronic retention. This condition is characterised by pain-free bladder distension, which may result in hydroureter, hydronephrosis and renal failure (high-pressure chronic retention). On digital rectal examination, patients with BPE have evidence of prostatic enlargement with a smooth prostate gland. Abdominal examination may also reveal evidence of bladder enlargement in patients with urinary retention.

Investigations

The diagnosis of BPE is a clinical one but flow rates can be accurately measured with a flow meter, and prostate volume by transrectal ultrasound scan (TRUS). Objective assessment of obstruction is possible by urodynamics but this is seldom required. If symptoms or signs, such as a palpable bladder, nocturnal enuresis, recurrent urinary tract infections or a history of renal stones, are present, renal function should be assessed; if it is abnormal, screening should be conducted for evidence of obstructive nephropathy by ultrasound examination.

Management

Patients who present with acute retention require urgent treatment and should undergo immediate catheterisation to relieve the obstruction. Those with mild to moderate symptoms can be treated by medication (Boxes 17.57 and 17.58). The first-line treatments are α_{1A}-adrenoceptor blockers such as tamsulosin, which reduce the tone of smooth muscle cells in the prostate and bladder neck, thereby reducing the obstruction. The 5α-reductase inhibitors, finasteride and dutasteride, inhibit conversion of testosterone to the more potent dihydrotestosterone in the prostate and so cause the prostate to shrink. This class of drugs is indicated in patients with an estimated prostate size of more than 30 g or a prostate specific antigen (PSA) of more than 1.4 μg/L. Patients who fail to respond to a single drug may be treated with a combination of α-blockers and 5α-reductase inhibitors, since this is more efficacious than either agent alone. Symptoms that are resistant to medical therapy require surgical treatment to remove some of the prostate tissue that is causing urethral obstruction. This is usually achieved by transurethral resection of the prostate (TURP) but enucleation of the prostate by holmium laser is equally effective and has potentially fewer complications. Open surgery is rarely needed, unless the gland is very large.

17.57 Treatment for benign prostatic enlargement

Medical

- Prostate < 30 g: α-adrenoceptor blockers
- Prostate > 30 g: 5α-reductase inhibitors ± α-adrenoceptor blockers

Surgical

- Transurethral resection of prostate (TURP)
- Holmium laser enucleation
- Open prostatectomy

EBM 17.58 Medical management of benign prostatic enlargement

'Oral α-adrenoceptor blockers produce rapid improvement in urinary flow in 60–70% of patients. The 5α-reductase inhibitor, finasteride, causes slow shrinkage of large prostate glands with improvement in symptoms.'

- Clifford GM, et al. Eur Urol 2000; 38:2–19.
- Boyle R, et al. Urology 2001; 58:717–722.

Prostatitis

This condition is due to inflammation of the prostate gland. Acute or chronic bacterial prostatitis can be caused by infection with the same bacteria that are associated with UTI (p. 511) but prostatitis can also be 'non-bacterial', in which case no organism can be cultured from the urine. This is also known as chronic pelvic pain syndrome. Clinical features of prostatitis include frequency, dysuria, painful ejaculation, perineal or groin pain, difficulty passing urine and, in acute disease, considerable systemic disturbance. The prostate is enlarged and tender. Bacterial prostatitis is confirmed by a positive culture from urine or from urethral discharge obtained after prostatic massage, and the treatment of choice is trimethoprim or a quinolone antibiotic. A 4–6-week course is required (see Box 17.54). Treatment of chronic pelvic pain syndrome is challenging but some patients respond to a combination of α-blockers, NSAIDs and amitriptyline.

TUMOURS OF THE KIDNEY AND URINARY TRACT

Several malignant tumours can affect the kidney and urinary tract, including renal adenocarcinoma, bladder carcinoma, prostate carcinoma, and tumours of the testis and penis. The urogenital tract can also be affected by benign tumours and secondary tumour deposits, which can cause obstructive uropathy.

Renal adenocarcinoma

Renal adenocarcinoma is by far the most common malignant tumour of the kidney in adults, making up 2.5% of all adult cancers, with a prevalence of 16 cases per 100 000 population. It is twice as common in males as in females. The peak incidence is between 65 and 75 years of age and it is uncommon before 40. The tumour arises from renal tubular cells. Haemorrhage and necrosis give the cut surface a characteristic mixed golden-yellow and red appearance (Fig. 17.32B). Microscopically, clear cell carcinomas are the most common histological subtype (85%), with papillary, chromophobe and collecting duct tumours making up the remaining 15%. With clear cell

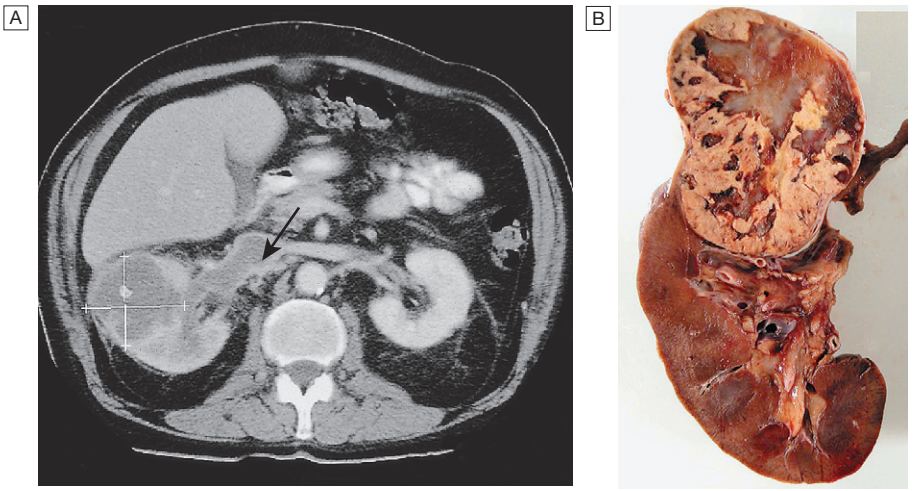

Fig. 17.32 Renal adenocarcinoma. A In this CT, the right kidney is expanded by a low-density tumour, which fails to take up contrast material. Tumour is shown extending into the renal vein and inferior vena cava (arrow). B Pathology specimen showing typical necrosis.

carcinomas, there is early spread of the tumour into the renal pelvis, causing haematuria, and along the renal vein, often extending into the inferior vena cava. Direct invasion of perinephric tissues is common. Lymphatic spread to para-aortic nodes occurs, while blood-borne metastases (which may be solitary) most commonly develop in the lungs, bone and brain.

Clinical features

In 50% of patients, asymptomatic renal tumours are identified as an incidental finding during imaging investigations carried out for other reasons. Amongst symptomatic patients, about 60% present with haematuria, 40% with loin pain and 25% with a mass; about 10% present with a triad of pain, haematuria and a mass. A remarkable range of systemic effects may be present, including fever, raised ESR, polycythaemia, disorders of coagulation, hypercalcaemia, and abnormalities of plasma proteins and liver function tests. The patient may present with pyrexia of unknown origin or, rarely, with neuropathy. Some of these systemic effects are caused by secretion of products by the tumour, such as renin, erythropoietin, PTH-related protein (PTHrP) and gonadotrophins. The effects disappear when the tumour is removed but may re-appear when metastases develop, and so can be used as markers of tumour activity.

Investigations

Ultrasound is the investigation of first choice and allows differentiation between solid tumour and simple renal cysts. If the results are suggestive of a tumour, contrast-enhanced CT of the abdomen and chest should be performed for staging (see Fig. 17.32A). For tumours more than 3 cm in diameter with no evidence of metastatic spread and when the nature of the lesion is uncertain, ultrasound or CT-guided biopsy may be used to avoid nephrectomy for benign disease.

Management

Radical nephrectomy that includes the perirenal fascial envelope and ipsilateral para-aortic lymph nodes is the treatment of choice. Nephrectomy is commonly performed laparoscopically, with equivalent outcomes to open surgery. Partial nephrectomy is recommended for tumours of 4 cm or less, as there is a lower incidence of cardiac and renal morbidity. Patients at high operative risk, who have small tumours, may also be treated percutaneously by cryoablation or radiofrequency ablation. Surgery may also play a role in the treatment of solitary metastases, since these can remain single for long periods and excision may be worthwhile.

Renal adenocarcinoma is resistant to most chemotherapeutic agents. For many years, cytokine therapy with interferon and interleukin-2 was used in metastatic renal cancer but, in recent years, two new classes of targeted drugs have been introduced and are now the mainstay of therapy. These are the tyrosine kinase inhibitors, sunitinib and pazopanib, and the mammalian target of rapamycin (mTOR) inhibitors, temsirolimus and everolimus.

In previous years, patients who presented with distant metastases were treated with cytoreductive nephrectomy, in which nephrectomy was coupled with systemic cytokine treatment, since this was shown to improved survival as compared with either treatment in isolation. It is, at present, unclear whether this survival benefit still prevails with the newer agents mentioned above.

Studies that antedate the introduction of these new agents show that, if the tumour is confined to the kidney, 5-year survival is 75%, but this falls to 5% when there are distant metastases.

Urothelial tumours

Tumours arising from the transitional epithelium of the renal tract can affect the renal pelvis, ureter, bladder or urethra. They are rare under the age of 40, affect males about 3–4 times as commonly as females, and account for about 3% of all malignant tumours. The bladder is by far the most frequently affected site. Although almost all tumours are transitional cell carcinomas, squamous carcinoma may occur in urothelium that has undergone metaplasia, usually following chronic inflammation or irritation due to stones or schistosomiasis. The

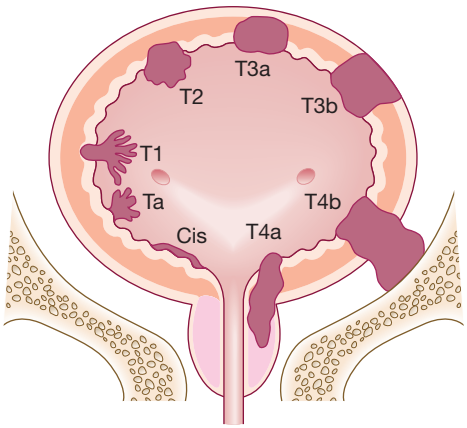

Fig. 17.33 Transitional cell carcinoma of the bladder. Stages are shown from carcinoma in situ (Cis) to invasive tumour progressing beyond the bladder and prostate (T4b).

appearance of a transitional cell tumour ranges from a delicate papillary structure with relatively good prognosis to a solid ulcerating mass in more aggressive disease (Fig. 17.33).

Pathophysiology

Risk factors include cigarette smoking and exposure to industrial carcinogens like aromatic amines, aniline dyes and aldehydes. Chronic inflammatory processes, such as schistosomiasis and chronic bladder stones, predispose to squamous carcinomas by causing squamous metaplasia.

Clinical features

More than 80% of patients present with painless, visible haematuria. It should be assumed that such bleeding is from a tumour until proven otherwise (p. 474). Tumours of the ureter or bladder may also cause symptoms of obstruction, depending on the site of involvement, and tumours of the bladder present with dysuria or storage symptoms. Physical examination is usually unremarkable, except in patients with very advanced disease, when bimanual examination may reveal a palpable mass.

Investigations

Cystoscopy (usually flexible cystoscopy under a local anaesthetic) is mandatory to evaluate the bladder in cases of haematuria or suspected bladder cancer. Imaging of the upper urinary tract (CT urogram is the gold standard but IVU and renal ultrasound are also acceptable) is also important to rule out abnormalities of the kidney, ureters and renal pelvis in patients with haematuria. If a suspicious defect is seen on CTU or IVU in the ureter or renal pelvis, a retrograde ureteropyelogram, ureteroscopy and biopsy are required. If evidence of a solid invasive urothelial tumour is found, CT of the abdomen, pelvis and chest should be performed as a staging procedure.

Management

Most bladder tumours are low-grade superficial lesions that can be successfully treated endoscopically by transurethral resection of the tumour. Intravesical chemotherapy with mitomycin C is usually administered as a one-off treatment post resection to prevent tumour recurrence, or may be given as a prolonged course to treat multiple low-grade bladder tumours. Patients with carcinoma in situ have a high risk of progression to invasive cancer. These patients often respond well to intravesical bacille Calmette–Guérin (BCG) treatment but more radical treatment may also be needed if this is unsuccessful. Following initial treatment and endoscopic clearance of bladder tumours, regular check cystoscopies are required to look for evidence of recurrence. Patients with recurrences of superficial disease can usually be treated by further resection and diathermy, but if this is unsuccessful, a cystectomy may be needed.

The management of invasive bladder tumours involves radical cystectomy with urinary diversion into an incontinent ileal conduit or a continent catheterisable bowel pouch; the latter is usually reserved for patients under the age of 70 years.

The prognosis of bladder tumours depends on tumour stage and grade. About 5% of patients with low-grade superficial bladder cancer progress to develop invasion of the bladder muscle, compared with about 50% of those with high-grade superficial bladder cancers. Overall, the 5-year survival for patients with muscle-invasive bladder cancer of either grade is about 50–70%.

Transitional cell carcinoma of the renal pelvis and ureter is usually treated by open or laparoscopic nephroureterectomy, but if the tumour is solitary and low-grade, it can be treated endoscopically.

Prostate cancer

Prostate cancer is the most common malignancy in men in the UK, with a prevalence of 105 per 100 000 population. It is also common in northern Europe and the USA (particularly in the black population) but is rare in China and Japan. It rarely occurs before the age of 50 and has a mean age at presentation of 70 years.

Pathophysiology

Prostate cancers tend to arise within the peripheral zone of the prostate and almost all are adenocarcinomas. Metastatic spread to pelvic lymph nodes occurs early and metastases to bone, mainly the lumbar spine and pelvis, are common. Genetic factors are known to play an important role in pathogenesis, and multiple predisposing loci have been found to predispose to the disease in genome-wide association studies. A family history of prostate cancer greatly increases a man's chances of developing the disease. It seems likely that the differences in incidence between different ethnic groups may be explained by genetic factors.

Clinical features

Most patients either are asymptomatic or present with lower urinary tract symptoms indistinguishable from benign prostatic enlargement. On digital rectal examination (DRE), the prostate may feel nodular and stony-hard, and the median sulcus may be lost, but up to 45% of tumours are impalpable. Symptoms and signs due to

metastases are much less common at the initial presentation but may include back pain, weight loss, anaemia and obstruction of the ureters.

Investigations

Measurement of PSA levels in a peripheral blood sample, together with DRE, is the cornerstone of diagnosis. Prior to a PSA test, men should be given careful counselling about the limitations of the test: namely, a normal level does not exclude prostate cancer; a high value does not confirm the diagnosis but will open a discussion about biopsy. The need for radical treatment of localised prostate cancer is still not established; radical treatments have significant potential morbidity and mortality; and early identification and treatment of prostate cancer may save lives. Current evidence suggests that population-based screening for prostate cancer with PSA is of limited value, due in part to the fact that over 1000 patients would need to be screened to cure one man of prostate cancer. Individuals suspected of having prostate cancer, based on an elevated PSA and/or abnormal DRE, should undergo transrectal ultrasound-guided prostate biopsies. About 40% of patients with a serum PSA of 4.0–10 ug/L or more will have prostate cancer on biopsy, although 25% patients with a PSA of less than 4 ng/mL may also have prostate cancer. Occasionally, a small focus of tumour is found incidentally in patients undergoing transurethral resection of the prostate for benign hyperplasia. If the diagnosis of prostate cancer is confirmed, staging should be performed by pelvic MRI to assess the presence and extent of local involvement. An isotope bone scan should be carried out if distant metastases are suspected (rare if the PSA is below 20 ng/mL); very high levels of serum PSA (> 100 ng/mL) almost always indicate distant bone metastases. Following diagnosis, serial assessment of PSA levels is useful for monitoring response to treatment and disease progression.

Management

Tumour confined to the prostate is potentially curable by radical prostatectomy, radical radiotherapy or brachytherapy (implantation of small radioactive particles into the prostate). These options should only be considered in patients with more than 10 years' life expectancy. Patients who are found to have small foci of tumour do not require specific treatment but should be followed up periodically with PSA, DRE and a schedule of biopsies; this is known as active surveillance. Prostatic cancer, like breast cancer, is sensitive to steroid hormones; metastatic prostate cancer is treated by androgen depletion, involving either surgery (orchidectomy) or, more commonly, androgen-suppressing drugs (Box 17.59). Androgen receptor blockers, such as bicalutamide or cyproterone acetate, may also prevent tumour cell growth. Gonadotrophin-releasing hormone (GnRH) analogues, such as goserelin, continuously occupy pituitary receptors, preventing them from responding to the GnRH pulses that normally stimulate luteinising hormone (LH) and follicle-stimulating hormone (FSH) release. This initially causes an increase in testosterone before producing a prolonged reduction, and for this reason the initial dose must be covered with an androgen receptor blocker to prevent a tumour flare.

EBM 17.59 Hormone manipulation in prostate cancer

'Reducing circulating testosterone levels (either by castration or by medication) results in a 70% initial response rate. Additional androgen blockade produces a small increase in survival but with poorer quality of life.'

For further information: www.cochrane.org/cochrane-reviews

A small proportion of patients fail to respond to endocrine treatment. A larger number respond for a year or two but then the disease progresses. Chemotherapy with docetaxel can then be effective and provide a modest (around 3 months) survival advantage. Radiotherapy is useful for localised bone pain but the basis of treatment remains pain control by analgesia (p. 286). Provided that patients do not die of another cause, the 10-year survival rate of patients with tumours localised to the prostate is 95%, but if metastases are present, this falls to 10%. Life expectancy is not reduced in patients with small foci of tumour.

Testicular tumours

Testicular tumours are uncommon, with a prevalence of 5 cases per 100000 population. They occur mainly in young men aged between 20 and 40 years. They often secrete α-fetoprotein (AFP) and β-human chorionic gonadotrophin (β-hCG), which are useful biochemical markers for both diagnosis and prognosis. Seminoma and teratoma account for 85% of all tumours of the testis. Leydig cell tumours are less common.

Seminomas arise from seminiferous tubules and represent a relatively low-grade malignancy. Metastases can occur through lymphatic spread, however, and typically involve the lungs.

Teratomas arise from primitive germinal cells and tend to occur at a younger age than seminomas. They may contain cartilage, bone, muscle, fat and a variety of other tissues, and are classified according to the degree of differentiation. Well-differentiated tumours are the least aggressive; at the other extreme, trophoblastic teratoma is highly malignant. Occasionally, teratoma and seminoma occur together.

Leydig cell tumours are usually small and benign but secrete oestrogens, leading to presentation with gynaecomastia (p. 762).

Clinical features and investigations

The common presentation is incidental discovery of a painless testicular lump, although some patients complain of a testicular ache.

All suspicious scrotal lumps should be imaged by ultrasound. Serum levels of AFP and β-hCG are elevated in extensive disease. Oestradiol may be elevated, suppressing luteinising hormone (LH), follicle-stimulating hormone (FSH) and testosterone. Accurate staging is based on CT of the lungs, liver and retroperitoneal area.

Management and prognosis

The primary treatment is surgical orchidectomy. Subsequent treatment depends on the histological type and stage. Radiotherapy is the treatment of choice for early-stage seminoma. Teratoma confined to the testes may be managed conservatively, but more advanced cancers are treated with chemotherapy, usually the combination of bleomycin, etoposide and cisplatin. Follow-up is by CT and assessment of AFP and β-hCG. Retroperitoneal lymph node dissection is now only performed for residual or recurrent nodal masses.

The 5-year survival rate for patients with seminoma is 90–95%. For teratomas, the 5-year survival varies between 60% and 95%, depending on tumour type, stage and volume.

Inherited tumour syndromes affecting the renal tract

Some uncommon autosomal dominantly inherited conditions are associated with multiple renal tumours in adult life. In tuberous sclerosis (p. 1302), replacement of renal tissue by multiple angiomyolipomas (tubers) may occasionally cause renal failure in adults. Other organs affected include the skin (adenoma sebaceum on the face) and brain (causing seizures and mental retardation). The von Hippel–Lindau syndrome (p. 1216) is connected with multiple renal cysts, renal adenomas and renal adenocarcinoma. Other organs affected include the central nervous system (haemangioblastomas) and the adrenals (phaeochromocytoma).

RENAL INVOLVEMENT IN SYSTEMIC CONDITIONS

The kidneys may be directly involved in a number of multisystem diseases or secondarily affected by diseases of other organs. Involvement may be at a pre-renal, renal (glomerular or interstitial) or post-renal level. Many of the diseases are described in other sections of this chapter or in other chapters of the book.

Diabetes mellitus

Diabetes mellitus is the most common cause of CKD in developed countries. In patients with diabetes, there is a steady advance from microalbuminuria to dipstick-positive proteinuria, and a progression to renal failure, as described on page 830. Few patients require renal biopsy to establish the diagnosis, but atypical features or progression should lead to suspicion that an alternative condition could be present.

Management with ACE inhibitors and other hypotensive agents to slow progression is described on page 831 and has been dramatically effective. In some patients, proteinuria may be eradicated and progression completely halted, even if renal function is abnormal.

Hepatic–renal disease

Severe hepatic dysfunction may cause a haemodynamically mediated type of renal failure, hepatorenal syndrome, described on page 940. Patients with chronic liver disease are also predisposed to develop AKI (acute tubular necrosis) in response to relatively minor insults, including bleeding and infection. Such patients are often difficult to treat by dialysis and have a poor prognosis. Where treatment is justified – for example, if there is a good chance of recovery or of a liver transplant – slow or continuous treatments are less likely to precipitate or exacerbate hepatic encephalopathy. IgA nephropathy (p. 500) is more common in patients with liver disease.

Pulmonary-renal syndrome

The pulmonary–renal syndrome is a dramatic presentation with renal and respiratory failure that is not explained by excess intravascular fluid or by severe pneumonia; it occurs in Goodpasture's (anti-GBM) disease and small-vessel vasculitis (see below). There are some other uncommon causes of a similar syndrome, including poisoning with the herbicide paraquat.

Malignant diseases

The kidney may be affected in many different ways in patients with malignant disease (Box 17.60). Direct involvement of the kidneys or other parts of the urinary tract can occur, causing obstructive uropathy, and glomerulonephritis may occur, presumably as the result of an immunological reaction to the tumour. Hypercalcaemia can be caused by parathyroid hormone-related protein (PTHrP) production by tumours, whereas treatment of leukaemia and lymphoma can sometimes be complicated by interstitial nephritic and acute kidney injury due to uric acid release from necrotic tumour cells. Finally, in myeloma and other monoclonal gammopathies, renal impairment can occur as the result of the nephrotoxic effects of immunoglobulin light chains released by the tumour.

17.60 Renal effects of malignancies

Direct involvement	
• Renal adenocarcinoma	• Cervical carcinoma
• Urothelial tumours	• Lymphoma
Immune reaction	
• Glomerulonephritis*	
Metabolic consequences	
• Hypercalcaemia	• Uric acid nephropathy
Remote effects of tumour products	
• Light chains in myeloma	

*Especially membranous nephropathy.

Systemic vasculitis

Small-vessel vasculitis (p. 1115) commonly affects the kidneys, with rapid and profound impairment of glomerular function. Histologically, there is a focal inflammatory glomerulonephritis, usually with focal necrosis (see Box 17.39, p. 499, and Fig. 17.22, p. 498) and often with crescentic changes. Typically, the patient is systemically unwell with an acute phase response, weight loss and arthralgia. In some patients, pulmonary haemorrhage may occur, which can be life-threatening. In others, it presents as a kidney-limited disorder, with

EBM 17.61 Role of rituximab in ANCA-associated vasculitis

'The RAVE study compared the effectiveness of rituximab and oral cyclophosphamide for inducing remission in 197 patients with ANCA-associated vasculitis with renal and/or pulmonary involvement. Both groups received high-dose glucocorticoids. The rituximab-based regimen was non-inferior to the cyclophosphamide-based regimen at inducing remission and was superior in patients with a history of relapsing disease. Rituximab was equally effective as cyclophosphamide in the treatment of major renal disease and alveolar haemorrhage. There were no significant differences between the treatment groups with respect to glucocorticoid dose or adverse events.'

- Stone JH. N Engl J Med 2010; 363(3):221–232.

rapidly deteriorating renal function and crescentic nephritis.

The most important cause is antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis (p. 1118). Two subtypes are recognised. Microscopic polyangiitis (MPA) typically presents with glomerulonephritis and pulmonary haemorrhage, along with gastrointestinal involvement and neuropathy, whereas polyangiitis with granulomatosis (also known as Wegener's granulomatosis) typically presents with glomerulonephritis and granulomatous lesions affecting the nasal passages and lungs. Serological testing for myeloperoxidase (MPO) and proteinase 3 (PR3) is usually positive but these antibodies are not specific and a biopsy of affected tissue should be obtained if possible to confirm the diagnosis.

The standard treatment of glomerulonephritis associated with systemic vasculitis is high-dose glucocorticoids combined with pulse cyclophosphamide, or mycophenolate mofetil (p. 1118). Recent studies indicate that rituximab (p. 1103), when combined with high-dose steroids, is as effective as oral cyclophosphamide and high-dose steroids in the treatment of ANCA-associated vasculitis (Box 17.61). Plasma exchange can offer additional benefit in patients with progressive renal damage who are not responding adequately to immunosuppressive therapy.

Glomerulonephritis secondary to vasculitis may rarely also be seen in rheumatoid arthritis, SLE and cryoglobulinaemia, although SLE usually involves the kidney in different ways (see below).

Medium- to large-vessel vasculitis, such as polyarteritis nodosa, p. 1117), does not cause glomerulonephritis but can cause hypertension, renal infarction or haematuria if the renal vessels are involved.

Systemic lupus erythematosus

Subclinical renal involvement, with low-level haematuria and proteinuria but minimally impaired or normal renal function, is common in systemic lupus erythematosus (SLE). Usually, this is due to glomerular disease, although interstitial nephritis may also occur, particularly in patients with overlap syndromes such as mixed connective tissue disease and Sjögren's syndrome (p. 499 and Figure 17.21 (p. 497)).

Almost any histological pattern of glomerular disease can be observed in SLE and the clinical presentation ranges from florid, rapidly progressive glomerulonephritis to nephrotic syndrome. The most common presentation is with subacute disease and inflammatory features (haematuria, hypertension, variable renal impairment), accompanied by heavy proteinuria that often reaches nephrotic levels. In severely affected patients, the most common histological pattern is a proliferative glomerulonephritis with substantial deposits of immunoglobulins on immunofluorescence. Randomised controlled trials have shown that the risk of ESRD in lupus nephritis is significantly reduced by high-dose steroids administered in combination with cyclophosphamide, usually given as regular intravenous pulses. More recently, it has been shown that the combination of corticosteroids and mycophenolate mofetil is as effective as corticosteroids and cyclophosphamide, at least in short-term studies.

Many patients with SLE who develop ESRD go into remission, possibly because of immunosuppression related to the ESRD. Patients with ESRD caused by SLE are usually good candidates for dialysis and transplantation. Although it may recur in renal allografts, the immunosuppression required to prevent allograft rejection usually controls the SLE too.

PREGNANCY AND RENAL DISEASE

Pregnancy has important physiological effects on the renal system. Some diseases are more common in pregnancy, the manifestations of others are modified during pregnancy, and a few diseases, such as pre-eclampsia, are unique to pregnancy.

Physiological adaptations begin in the first few weeks. Peripheral vascular resistance declines, blood volume, cardiac output and GFR increase, and there is usually a reduction in blood pressure and plasma creatinine and urea values in the first trimester. Baseline blood pressure and urine testing from the first antenatal clinic visit are valuable if problems arise later.

Infections

Pyelonephritis is more common during pregnancy, perhaps because of dilatation of the urinary collecting system and ureters. It is important to treat asymptomatic bacteriuria during pregnancy, since this can progress to pyelonephritis, which, in turn, can trigger premature labour (Box 17.62 and p. 513).

Glomerular diseases

Proteinuria caused by glomerular disease is usually exacerbated, and nephrotic syndrome may develop

EBM 17.62 Treatment of asymptomatic bacteriuria in pregnancy

'Antibiotic therapy for asymptomatic bacteriuria reduces the incidence of pyelonephritis (risk ratio (RR) 0.23, 95% confidence interval (CI) 0.13–0.41) and is also associated with a reduction in the incidence of low-birthweight babies (RR 0.66, 95% CI 0.49–0.89), but does not affect the incidence of preterm delivery.'

- Smaill F, Vazquez JC. Antibiotics for asymptomatic bacteriuria in pregnancy. Cochrane Database of Systematic Reviews, 2007, issue 2. Art. no. CD000490.

For further information: www.cochrane.org/cochrane-reviews

without any alteration in the underlying disease activity in individuals who had only slight proteinuria before pregnancy. This further increases the risk of venous thromboembolism, the leading cause of maternal deaths in developed countries.

Autoimmune diseases

Systemic autoimmune diseases typically are relatively quiescent during pregnancy but tend to relapse in the first few weeks and months following delivery. Pre-existing renal disease increases the fetal and maternal risk involved in pregnancy, to a degree dependent on the level of renal function, proteinuria and hypertension. Patients with such diseases who may become pregnant should be aware of the associated risks. During pregnancy, therapy should not usually be stopped, but blood pressure targets may be modified and agents altered to those of proven safety.

Pre-eclampsia

Pre-eclampsia is a systemic disorder that occurs in or near the third trimester of pregnancy (triplets > twins > singleton). The cause is unknown, although a number of risk factors have been identified (Box 17.63).

Clinical features

Pre-eclampsia is traditionally defined by the triad of oedema, proteinuria and hypertension. However, oedema is common in late pregnancy, proteinuria is a late sign and, while hypertension is usually present, it may be relative, mild or even absent. Furthermore, all these features occur in pre-existing renal disease exacerbated by pregnancy.

It is important to distinguish pre-eclampsia from pre-existing renal disease, since this affects management. Pre-eclampsia presents progressively, increasing risks to mother and fetus, which can be reversed almost immediately by early delivery. In contrast, continuing the pregnancy for as long as possible in patients with pre-existing renal disease, may permit delivery of a healthier, more mature baby. Proteinuria and hypertension in the first trimester of pregnancy suggest pre-existing renal disease.

Management

The only effective management for pre-eclampsia is delivery. The role of antiplatelet therapy (low-dose aspirin) remains controversial. Hypertension is a consequence and not the cause of the disorder, and treatment is only justified to lower it from severe and immediately dangerous levels (> 150–160/100–110 mmHg). Treating lower levels has been shown to confer no benefit and exposes the fetus to additional drugs. If life-threatening complications are not present and the baby is immature, corticosteroids may be given to induce maturation of fetal lungs, and delivery postponed while mother and baby are closely observed. Magnesium sulphate reduces the incidence of eclamptic convulsions.

Acute kidney injury

Maternal AKI may occur in almost any of the pre-eclamptic syndromes. Worldwide, a more important cause of AKI is septic abortion, when the uterus becomes infected because of retained products of conception or poor sterility in an often illegally induced abortion. Renal function is usually recoverable, but AKI in pregnancy is particularly prone to progress to cortical necrosis, with incomplete or total failure to recover renal function.

17.63 Pre-eclampsia and related diseases in pregnancy

Clinical syndromes

- Eclampsia: severe hypertension, encephalopathy and fits
- Disseminated intravascular coagulation
- Thrombotic microangiopathy: may also occur post-partum (post-partum haemolytic uraemic syndrome)
- Acute fatty liver of pregnancy
- 'HELLP' syndrome: haemolysis, elevated liver enzymes, low platelets (thrombotic microangiopathy with abnormal liver function)

Risk factors

- First pregnancy
- First pregnancy with a new partner or long inter-pregnancy interval
- Pre-eclampsia in previous pregnancies
- Age < 20 yrs or > 35 yrs
- Multiple pregnancy (triplets > twins > singleton)
- Pre-existing hypertension
- Pre-existing renal disease

Clinical signs

- Hypertension
- Proteinuria
- Oedema
- Evidence of the clinical syndromes listed above

Investigations

- Uric acid levels increased (before renal impairment apparent)
- Platelets decreased
- Reduced GFR (late)
- Fetus small for dates and growing slowly
- Fetal distress (late)

KIDNEY DISEASE IN ADOLESCENCE

Many causes of renal failure present during infancy or childhood, such as congenital urological malformations and inherited disorders like cystinosis and autosomal recessive polycystic kidney disease. The consequences continue throughout the patient's life and the situation often arises whereby patients transition from paediatric to adult nephrology services. Some of the issues and challenges surrounding this transition are summarised in Box 17.64.

17.64 Kidney disease in adolescence

- **Adherence**: young adults moving from parental supervision may become disengaged. There may also be reduced adherence to prophylactic and therapeutic treatment.
- **Adverse events**: there is an increased risk of transplant loss and other adverse events in young adults on RRT.
- **Management**: joint clinics should be established with the paediatric team to facilitate transfer to regional specialist clinics.

17

DRUGS AND THE KIDNEY

Drug-induced renal disease

The kidney is susceptible to damage by drugs because it is the route of excretion of many water-soluble compounds, including drugs and their metabolites. Some may reach high concentrations in the renal cortex as a result of proximal tubular transport mechanisms. Others are concentrated in the medulla by the operation of the countercurrent system. The same applies to certain toxins.

Toxic renal damage may occur by a variety of mechanisms (Box 17.65). Very commonly, drugs contribute to the development of acute tubular necrosis as one of multiple insults. Numerically, reactions to NSAIDs and ACE inhibitors are the most important. Haemodynamic renal impairment, acute tubular necrosis and allergic reactions are usually reversible if recognised early enough. Other types, however, especially those associated with extensive fibrosis, are less likely to be reversible.

NSAIDs

Impairment of renal function may develop in patients on NSAID, since prostaglandins play an important role in regulating renal blood flow. This is particularly likely in patients with other disorders, such as heart failure, cirrhosis, sepsis and pre-existing renal impairment. In addition, idiosyncratic immune reactions may occur, causing minimal change nephrotic syndrome (p. 498) and acute interstitial nephritis (p. 502). Analgesic nephropathy (p. 504) is now a rare complication of long-term use.

ACE inhibitors

These abolish the compensatory angiotensin II-mediated vasoconstriction of the glomerular efferent arteriole that takes place in order to maintain glomerular perfusion pressure distal to a renal artery stenosis and in renal hypoperfusion (see Fig. 17.1, p. 465). Monitoring of renal function before and after initiation of therapy is essential.

17.65 Mechanisms and examples of drug-induced renal disease/dysfunction

Mechanism	Drug or toxin	Comments
Haemodynamic	NSAIDs	Reduced renal blood flow due to inhibition of prostaglandin synthesis
	ACE inhibitors	Reduce efferent glomerular arteriolar tone. Toxic in the presence of renal artery stenosis and other conditions of renal hypoperfusion
	Radiographic contrast media	Multifactorial aetiology may include intense vasoconstriction
Acute tubular necrosis	Aminoglycosides, amphotericin	In most examples, there is evidence of direct tubular toxicity but haemodynamic and other factors probably contribute
	Paracetamol overdose	May occur with or without serious hepatotoxicity
	Radiographic contrast media	May be secondary to precipitation in tubules. Furosemide is a co-factor
Loss of tubular/collecting duct function	Lithium Cisplatin Aminoglycosides, amphotericin	Dose-related, partially reversible loss of concentrating ability. Occurs at lower exposures than cause acute tubular necrosis
Glomerulonephritis (immune-mediated)	Penicillamine, gold	Membranous nephropathy
	Penicillamine	Crescentic or focal necrotising glomerulonephritis in association with ANCA and systemic small-vessel vasculitis
	NSAIDs	Minimal change nephropathy
Interstitial nephritis (immune-mediated)	NSAIDs, penicillins, proton pump inhibitors, many others	Acute interstitial nephritis
Interstitial nephritis (toxicity)	Lithium Ciclosporin, tacrolimus	As a consequence of acute toxicity. Otherwise controversial The major problem with these drugs
Interstitial nephritis (with papillary necrosis)	Various NSAIDs (p. 505)	Ischaemic damage secondary to NSAID effects on renal blood flow
Tubular obstruction (crystal formation)	Aciclovir	Crystals of the drug form in tubules. Aciclovir is now more common than the original example of sulphonamides
	Chemotherapy	Uric acid crystals form as a consequence of tumour lysis (typically, a first-dose effect in haematological malignancy)
Nephrocalcinosis	Oral sodium phosphate-containing bowel cleansing agents	Precipitation of calcium phosphate occurring in 1–4% and exacerbated by volume depletion. Usually mild but damage can be irreversible
Retroperitoneal fibrosis	Ergolinic dopamine agonists (cabergoline), methysergide*, practolol*	Idiopathic is more common (p. 511)

*These drugs are no longer in use in the UK.

Prescribing in renal disease

Many drugs and drug metabolites are excreted by the kidney and so the presence of renal impairment alters the required dose and frequency (p. 36).

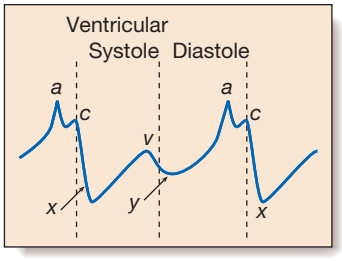
4 Examination of the arterial pulse

- The character of the pulse is determined by stroke volume and arterial compliance, and is best assessed by palpating a major artery, such as the carotid or brachial artery.
- Aortic regurgitation, anaemia, sepsis and other causes of a large stroke volume typically produce a bounding pulse with a high amplitude and wide pulse pressure (panel A).
- Aortic stenosis impedes ventricular emptying and may cause a slow-rising, weak and delayed pulse (panel A).
- Normal sinus rhythm produces a pulse that is regular in time and force. Arrhythmias may cause irregularity. Atrial fibrillation produces a pulse that is irregular in time and volume (panel B).



Waveform of the arterial pulse.
A Aortic regurgitation (red line) and stenosis (blue line). B Atrial fibrillation.

5 Examination of the jugular venous pulse

The internal jugular vein, superior vena cava and right atrium are in continuity, so the height of the jugular venous pulsation reflects right atrial pressure. When the patient is placed at 45°, with the head supported and turned a few degrees to the left, the jugular venous pulse is visible along the line of the sternocleidomastoid muscle (see opposite).

- The height of the jugular venous pulse is determined by right atrial pressure and is therefore elevated in right heart failure and reduced in hypovolaemia.
- If the jugular venous pulse is not easily seen, it may be highlighted by gentle pressure on the abdomen.
- In normal sinus rhythm, the two venous peaks, the *a* and *v* waves, approximate to atrial and ventricular systole respectively.
- The *x* descent reflects atrial relaxation and apical displacement of the tricuspid valve ring. The *y* descent reflects atrial emptying early in diastole. These signs are subtle.
- Tricuspid regurgitation produces giant *v* waves that coincide with ventricular systole.

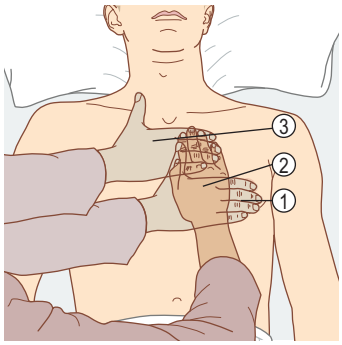
Waveform of the jugular venous pulse.

Distinguishing venous/arterial pulsation in the neck

- Venous pulse has two peaks in each cardiac cycle; the arterial pulse has one peak.
- The height of the venous pulse varies with respiration (falls on inspiration) and position.
- Abdominal compression causes the venous pulse to rise.
- Venous pulse is not palpable and can be occluded by light pressure.

7 Palpation of the precordium

Technique



- Place fingertips over apex (1) to assess for position and character. Place heel of hand over left sternal edge (2) for a parasternal heave or 'lift'. Assess for the presence of thrills in all areas, including the aortic and pulmonary areas (3).

Common abnormalities of the apex beat

- Volume overload, such as mitral or aortic regurgitation: displaced, forceful
- Pressure overload, such as aortic stenosis, hypertension: discrete, thrusting
- Dyskinetic, such as left ventricular aneurysm: displaced, incoordinate

Other abnormalities

- Palpable S1 (tapping apex beat: mitral stenosis)
- Palpable P2 (severe pulmonary hypertension)
- Left parasternal heave or 'lift' felt by heel of hand (right ventricular hypertrophy)
- Palpable thrill (aortic stenosis)

Palpation of the precordium.

8 Auscultation of the heart

- Use the diaphragm to examine at the apex, lower left sternal edge (tricuspid area) and upper left (pulmonary area) and right (aortic area) sternal edges.
- Use the bell to examine low-pitched noises, particularly at the apex for mid-diastolic murmurs.
- Time the sounds and murmurs by feeling the carotid pulse; systolic murmurs are synchronous with the pulse.
- Listen for radiation of systolic murmurs, over the base of the neck (aortic stenosis) and in the axilla (mitral incompetence).
- Listen over the left sternal border with the patient sitting forward (aortic incompetence), then at the apex with the patient rolled on to the left side (mitral stenosis).

The haemodynamic effects of respiration are discussed on page 532.

See page 560 for analysis and interpretation of heart sounds and murmurs.

Cardiovascular disease is the most frequent cause of adult death in the Western world; in the UK, one-third of men and one-quarter of women will die as a result of ischaemic heart disease. In many developed countries, the incidence of ischaemic heart disease has been falling for the last two or three decades, but it is rising in Eastern Europe and Asia. Cardiovascular disease may thus soon become the leading cause of death on all continents. Strategies for the treatment and prevention of heart disease can be highly effective and have been subjected to rigorous evaluation. The evidence base for the treatment of cardiovascular disease is stronger than for almost any other disease group.

Valvular heart disease is common, but the aetiology varies in different parts of the world. On the Indian subcontinent and in Africa, it is predominantly due to rheumatic fever, whereas calcific aortic valve disease is the most common problem in developed countries.

Prompt recognition of the development of heart disease is limited by two key factors. Firstly, it is often latent; coronary artery disease can proceed to an advanced stage before the patient notices any symptoms. Secondly, the diversity of symptoms attributable to heart disease is limited, so different pathologies may frequently present with the same symptoms.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Anatomy

The heart acts as two serial pumps that share several electrical and mechanical components. The right heart circulates blood to the lungs where it is oxygenated, and the left heart receives this and circulates it to the rest of the body (Fig. 18.1). The atria are thin-walled structures that act as priming pumps for the ventricles, which provide most of the energy to the circulation. Within the mediastinum, the atria are situated posteriorly and the left atrium (LA) sits anterior to the oesophagus and descending aorta. The interatrial septum separates the two atria. In 20% of adults, a patent foramen ovale is found; this communication in the fetal circulation between the right and left atria normally closes at birth (p. 629). The right atrium (RA) receives blood from the superior and inferior venae cavae and the coronary sinus. The LA receives blood from four pulmonary veins, two from each of the left and right lungs. The ventricles are thick-walled structures, adapted to circulating blood through large vascular beds under pressure. The atria and ventricles are separated by the annulus fibrosus, which forms the skeleton for the atrioventricular (AV) valves and which electrically insulates the atria from the ventricles. The right ventricle (RV) is roughly triangular in shape and extends from the annulus fibrosus to near the cardiac apex, which is situated to the left of the midline. Its anterosuperior surface is rounded and convex, and its posterior extent is bounded by the interventricular septum, which bulges into the chamber. Its upper extent is conical, forming the conus arteriosus or outflow tract, from which the pulmonary artery arises. The RV sits anterior to, and to the right of, the left ventricle (LV). The LV is more conical in shape and in cross-section is nearly circular. It extends from the LA to the apex of the heart. The LV myocardium is normally around 10 mm thick (c.f. RV thickness of 2–3 mm) because it pumps blood at a higher pressure.

The normal heart occupies less than 50% of the transthoracic diameter in the frontal plane, as seen on a chest X-ray. On the patient's left, the cardiac silhouette is formed by the aortic arch, the pulmonary trunk, the left atrial appendage and the LV. On the right, the RA is joined by superior and inferior venae cavae, and the lower right border is made up by the RV (Fig. 18.2). In disease states or congenital cardiac abnormalities, the

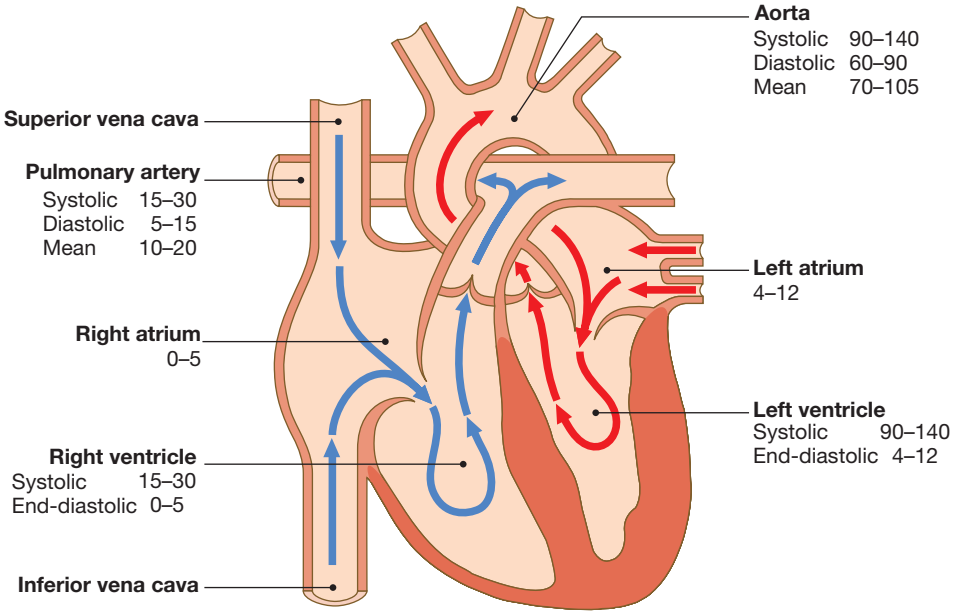


Fig. 18.1 Direction of blood flow through the heart. The blue arrows show deoxygenated blood moving through the right heart to the lungs. The red arrows show oxygenated blood moving from the lungs to the systemic circulation. The normal pressures are shown for each chamber in mmHg.

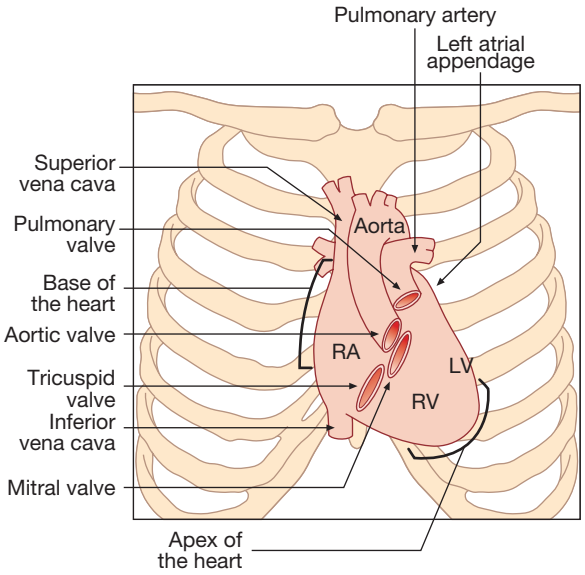

Fig. 18.2 Surface anatomy of the heart. The positions of the major cardiac chambers and heart valves are shown.

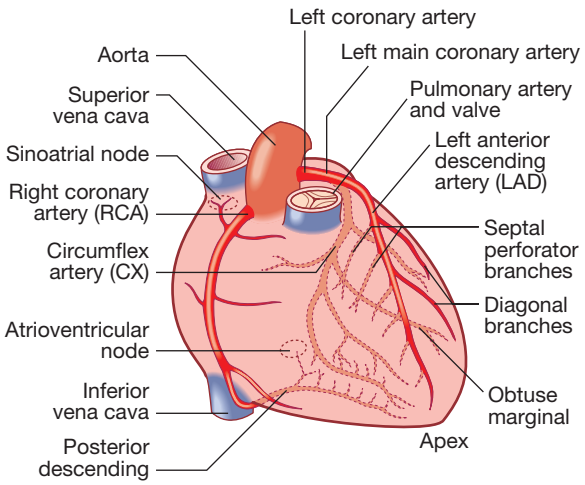

Fig. 18.3 The coronary arteries. Diagram of the anterior view.

silhouette may change as a result of hypertrophy or dilatation.

The coronary circulation

The left main and right coronary arteries arise from the left and right sinuses of the aortic root, distal to the aortic valve (Fig. 18.3). Within 2.5 cm of its origin, the left main coronary artery divides into the left anterior descending artery (LAD), which runs in the anterior interventricular groove, and the left circumflex artery (CX), which runs posteriorly in the atrioventricular groove. The LAD gives branches to supply the anterior part of the septum (septal perforators) and the anterior, lateral and apical walls of the LV. The CX gives marginal branches that supply the lateral, posterior and inferior segments of the LV. The right coronary artery (RCA) runs in the right atrioventricular groove, giving branches that supply the RA, RV and inferoposterior aspects of the LV. The posterior descending artery runs in the posterior interventricular groove and supplies the inferior part of the interventricular septum. This vessel is a branch of the RCA in approximately 90% of people (dominant right system) and is supplied by the CX in the remainder (dominant left system). The coronary anatomy varies greatly from person to person and there are many 'normal variants'.

The RCA supplies the sinoatrial (SA) node in about 60% of individuals and the AV node in about 90%. Proximal occlusion of the RCA therefore often results in sinus bradycardia and may also cause AV nodal block. Abrupt occlusions in the RCA, due to coronary thrombosis, result in infarction of the inferior part of the LV and often the RV. Abrupt occlusion of the LAD or CX causes infarction in the corresponding territory of the LV, and occlusion of the left main coronary artery is usually fatal.

The venous system follows the coronary arteries but drains into the coronary sinus in the atrioventricular groove, and then to the RA. An extensive lymphatic system drains into vessels that travel with the coronary vessels and then into the thoracic duct.

Conducting system of the heart

The SA node is situated at the junction of the superior vena cava and RA (Fig. 18.4). It comprises specialised atrial cells that depolarise at a rate influenced by the autonomic nervous system and by circulating catecholamines. During normal (sinus) rhythm, this depolarisation wave propagates through both atria via sheets of atrial myocytes. The annulus fibrosus forms a conduction barrier between atria and ventricles, and the only pathway through it is the AV node. This is a midline structure, extending from the right side of the interatrial septum, penetrating the annulus fibrosus anteriorly. The AV node conducts relatively slowly, producing a necessary time delay between atrial and ventricular contraction. The His–Purkinje system is comprised of the bundle of His extending from the AV node into the interventricular septum, the right and left bundle branches passing along the ventricular septum and into the respective ventricles, the anterior and posterior fascicles

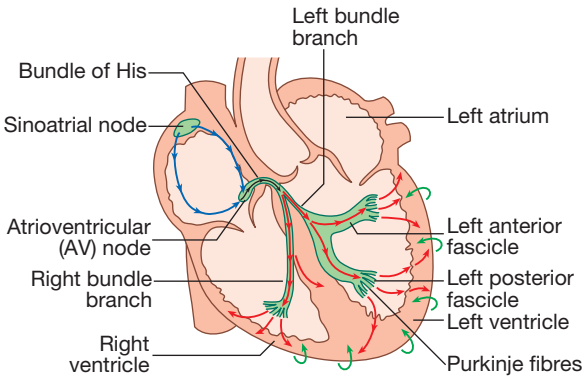

Fig. 18.4 The cardiac conduction system. Depolarisation starts in the sinoatrial node and spreads through the atria (blue arrows), and then through the atrioventricular node (black arrows). Depolarisation then spreads through the bundle of His and the bundle branches to reach the ventricular muscle (red arrows). Repolarisation spreads from epicardium to endocardium (green arrows).

of the left bundle branch, and the smaller Purkinje fibres that ramify through the ventricular myocardium. The tissues of the His–Purkinje system conduct very rapidly and allow near-simultaneous depolarisation of the entire ventricular myocardium.

Nerve supply of the heart

The heart is innervated by both sympathetic and parasympathetic fibres. Adrenergic nerves from the cervical sympathetic chain supply muscle fibres in the atria and ventricles and the electrical conducting system. Positive inotropic and chronotropic effects are mediated by β_1-adrenoceptors, whereas β_2-adrenoceptors predominate in vascular smooth muscle and mediate vasodilatation. Parasympathetic pre-ganglionic fibres and sensory fibres reach the heart through the vagus nerves. Cholinergic nerves supply the AV and SA nodes via muscarinic (M2) receptors. Under resting conditions, vagal inhibitory activity predominates and the heart rate is slow. Adrenergic stimulation, associated with exercise, emotional stress, fever and so on, causes the heart rate to increase. In disease states, the nerve supply to the heart may be affected. For example, in heart failure the sympathetic system may be up-regulated, and in diabetes mellitus the nerves themselves may be damaged (autonomic neuropathy, p. 831) so that there is little variation in heart rate.

Physiology

The circulation

The RA receives deoxygenated blood from the superior and inferior venae cavae and discharges blood to the RV, which in turn pumps it into the pulmonary artery. Blood passes through the pulmonary arterial and alveolar capillary bed, where it is oxygenated, then drains via four pulmonary veins into the LA. This, in turn, fills the LV, which delivers blood into the aorta (see Fig. 18.1). During ventricular contraction (systole), the tricuspid valve in the right heart and the mitral valve in the left heart close, and the pulmonary and aortic valves open. In diastole, the pulmonary and aortic valves close, and the two AV valves open. Collectively, these atrial and ventricular events constitute the cardiac cycle of filling and ejection of blood from one heartbeat to the next.

Myocardial contraction

Myocardial cells (myocytes) are about 50–100 µm long; each cell branches and interdigitates with adjacent cells. An intercalated disc permits electrical conduction via gap junctions, and mechanical conduction via the fascia adherens, to adjacent cells (Fig. 18.5A). The basic unit of contraction is the sarcomere (2 µm long), which is aligned to those of adjacent myofibrils, giving a striated appearance due to the Z-lines (Fig. 18.5B and C). Actin filaments are attached at right angles to the Z-lines and interdigitate with thicker parallel myosin filaments. The cross-links between actin and myosin molecules contain myofibrillar adenosine triphosphatase (ATPase), which breaks down adenosine triphosphate (ATP) to provide the energy for contraction (Fig. 18.5E). Two chains of actin molecules form a helical structure, with a second molecule, tropomyosin, in the grooves of the actin helix, and a further molecule complex, troponin, attached to every seventh actin molecule (Fig. 18.5D).

During the plateau phase of the action potential, calcium ions enter the cell and are mobilised from the sarcoplasmic reticulum. They bind to troponin and thereby precipitate contraction by shortening of the sarcomere through the interdigitation of the actin and myosin molecules. The force of cardiac muscle contraction, or inotropic state, is regulated by the influx of calcium ions through 'slow calcium channels'. The extent to which the sarcomere can shorten determines stroke volume of the ventricle. It is maximally shortened in response to powerful inotropic drugs or marked exercise. However, the enlargement of the heart seen in heart failure is due to slippage of the myofibrils and adjacent cells rather than lengthening of the sarcomere.

Cardiac output

Cardiac output is the product of stroke volume and heart rate. Stroke volume is the volume of blood ejected in each cardiac cycle (see Fig. 18.36, p. 561), and is dependent upon end-diastolic volume and pressure (preload), myocardial contractility and systolic aortic pressure (afterload). Stretch of cardiac muscle (from increased end-diastolic volume) causes an increase in the force of contraction, producing a greater stroke volume: Starling's Law of the heart (see Fig. 18.22, p. 547).

The contractile state of the myocardium is controlled by neuro-endocrine factors, such as adrenaline (epinephrine), and can be influenced by inotropic drugs and their antagonists. The response to a physiological change or to a drug can be predicted on the basis of its combined influence on preload, afterload and contractility (see Fig. 18.26, p. 551).

Blood flow

Blood passes from the heart through the large central elastic arteries into muscular arteries before encountering the resistance vessels, and ultimately the capillary bed, where there is exchange of nutrients, oxygen and waste products of metabolism. The central arteries, such as the aorta, are predominantly composed of elastic tissue with little or no vascular smooth muscle cells. When blood is ejected from the heart, the compliant aorta expands to accommodate the volume of blood before the elastic recoil sustains blood pressure (BP) and flow following cessation of cardiac contraction. This 'Windkessel effect' prevents excessive rises in systolic BP whilst sustaining diastolic BP, thereby reducing cardiac afterload and maintaining coronary perfusion. These benefits are lost with progressive arterial stiffening: a feature of ageing and advanced renal disease.

Passing down the arterial tree, vascular smooth muscle cells progressively play a greater role until the resistance arterioles are encountered. Although all vessels contribute, the resistance vessels (diameter 50–200 µm) provide the greatest contribution to systemic vascular resistance, with small changes in radius having a marked influence on blood flow; resistance is proportional to the fourth power of the radius (Poiseuille's Law). The tone of these resistance vessels is tightly regulated by humoral, neuronal and mechanical factors. Neurogenic constriction operates via α-adrenoceptors on vascular smooth muscle, and dilatation

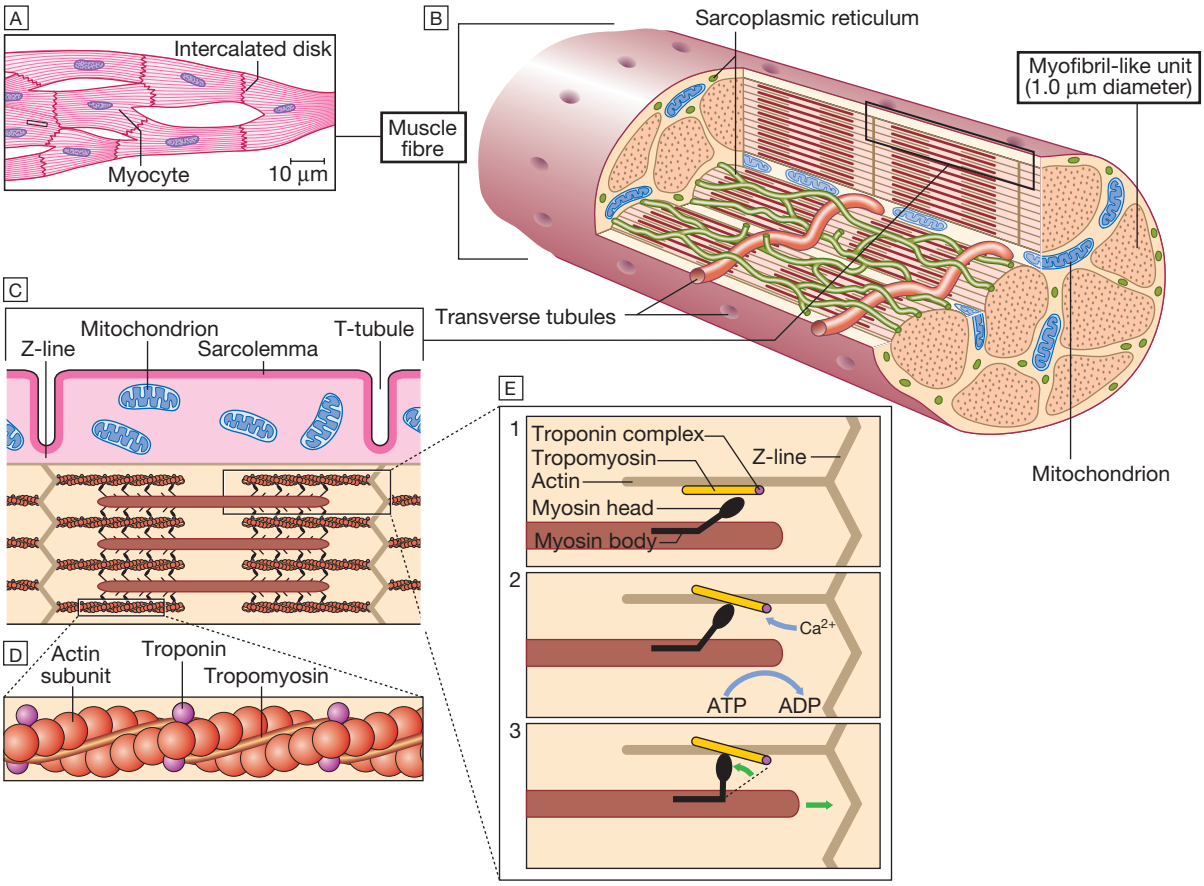

Fig. 18.5 Schematic of myocytes and the contraction process within a muscle fibre. A Myocytes are joined together through intercalated discs. B Within the myocytes, myofibrils are composed of longitudinal and transverse tubules extending from the sarcoplasmic reticulum. C The expanded section shows a schematic of an individual sarcomere with thick filaments composed of myosin and thin filaments composed primarily of actin. D Actin filaments are composed of troponin, tropomyosin and actin subunits. E The three stages of contraction, resulting in shortening of the sarcomere. (1) The actin-binding site is blocked by tropomyosin. (2) ATP-dependent release of calcium ions, which bind to troponin, displacing tropomyosin. The binding site is exposed. (3) Tilting of the angle of attachment of the myosin head, resulting in fibre shortening. (ADP = adenosine diphosphate; ATP = adenosine triphosphate)

via muscarinic and β_2-adrenoceptors. In addition, systemic and locally released vasoactive substances influence tone; vasoconstrictors include noradrenaline (norepinephrine), angiotensin II and endothelin-1, whereas adenosine, bradykinin, prostaglandins and nitric oxide are vasodilators. Resistance to blood flow rises with viscosity and is mainly influenced by red cell concentration (haematocrit).

Coronary blood vessels receive sympathetic and parasympathetic innervation. Stimulation of α-adrenoceptors causes vasoconstriction; stimulation of β_2-adrenoceptors causes vasodilatation; the predominant effect of sympathetic stimulation in coronary arteries is vasodilatation. Parasympathetic stimulation also causes modest dilatation of normal coronary arteries. As a result of vascular regulation, an atheromatous narrowing (stenosis) in a coronary artery does not limit flow, even during exercise, until the cross-sectional area of the vessel is reduced by at least 70%.

Endothelial function

The endothelium plays a vital role in the control of vascular homeostasis. It synthesises and releases many vasoactive mediators that cause vasodilatation, including nitric oxide, prostacyclin and endothelium-derived hyperpolarising factor, and vasoconstriction, including endothelin-1 and angiotensin II. A balance exists whereby the release of such factors contributes to the maintenance and regulation of vascular tone and BP. Damage to the endothelium may disrupt this balance and lead to vascular dysfunction, tissue ischaemia and hypertension.

The endothelium also has a major influence on key regulatory steps in the recruitment of inflammatory cells and on the formation and dissolution of thrombus. Once activated, the endothelium expresses surface receptors such as E-selectin, intercellular adhesion molecule type 1 (ICAM-1) and platelet endothelial cell adhesion molecule type 1 (PECAM-1), which mediate rolling, adhesion and migration of inflammatory leucocytes into the subintima. The endothelium also stores and releases the multimeric glycoprotein, von Willebrand factor, which promotes thrombus formation by linking platelet adhesion to denuded surfaces, especially in the arterial vasculature. In contrast, once intravascular thrombus forms, tissue plasminogen activator is rapidly released from a dynamic storage pool within the endothelium to induce

fibrinolysis and thrombus dissolution. These processes are critically involved in the development and progression of atherosclerosis, and endothelial function and injury are seen as central to the pathogenesis of many cardiovascular disease states.

Effects of respiration

There is a fall in intrathoracic pressure during inspiration that tends to promote venous flow into the chest, producing an increase in the flow of blood through the right heart. However, a substantial volume of blood is sequestered in the chest as the lungs expand; the increase in the capacitance of the pulmonary vascular bed usually exceeds any increase in the output of the right heart and therefore there is a reduction in the flow of blood into the left heart during inspiration. In contrast, expiration is accompanied by a fall in venous return to the right heart, a reduction in the output of the right heart, a rise in the venous return to the left heart (as blood is squeezed out of the lungs) and an increase in the output of the left heart (Box 18.1).

18.1 Haemodynamic effects of respiration

	Inspiration	Expiration
Jugular venous pressure	Falls	Rises
Blood pressure	Falls (up to 10 mmHg)	Rises
Heart rate	Accelerates	Slows
Second heart sound	Splits*	Fuses*

*Inspiration prolongs RV ejection, delaying P_2, and shortens LV ejection, bringing forward A_2; expiration produces the opposite effects.

Pulsus paradoxus

This term is used to describe the exaggerated fall in BP during inspiration that is characteristic of cardiac tamponade (pp. 545 and 640) and severe airways obstruction. In airways obstruction, it is due to accentuation of the change in intrathoracic pressure with respiration. In cardiac tamponade, compression of the right heart prevents the normal increase in flow through the right heart on inspiration, which exaggerates the usual drop in venous return to the left heart and produces a marked fall in BP (> 10 mmHg fall during inspiration).

INVESTIGATION OF CARDIOVASCULAR DISEASE

Specific investigations may be required to confirm a diagnosis of cardiac disease. Basic tests, such as electrocardiography, chest X-ray and echocardiography, can be performed in an outpatient clinic or at the bedside. Procedures such as cardiac catheterisation, radionuclide imaging, computed tomography (CT) and magnetic resonance imaging (MRI) require specialised facilities.

Electrocardiogram

The electrocardiogram (ECG) is used to assess cardiac rhythm and conduction. It provides information about chamber size and is the main test used to assess for myocardial ischaemia and infarction.

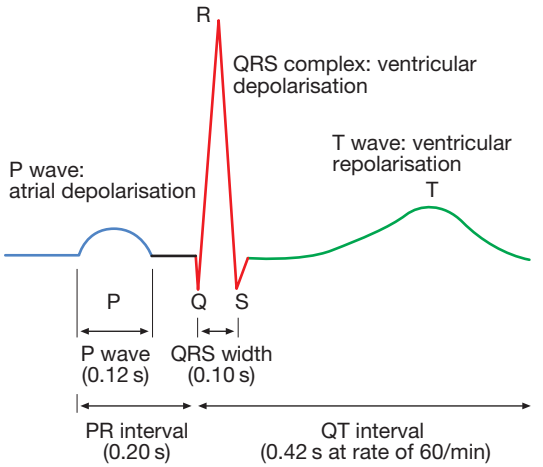

Fig. 18.6 The electrocardiograph. The components correspond to depolarisation and repolarisation, as depicted in Figure 18.4. The upper limit of the normal range for each interval is given in brackets.

The basis of an ECG recording is that the electrical depolarisation of myocardial tissue produces a small dipole current which can be detected by electrode pairs on the body surface. These signals are amplified and either printed or displayed on a monitor (Fig. 18.6). During sinus rhythm, the SA node triggers atrial depolarisation, producing a P wave. Depolarisation proceeds slowly through the AV node, which is too small to produce a depolarisation wave detectable from the body surface. The bundle of His, bundle branches and Purkinje system are then activated, initiating ventricular myocardial depolarisation, which produces the QRS complex. The muscle mass of the ventricles is much larger than that of the atria, so the QRS complex is larger than the P wave. The interval between the onset of the P wave and the onset of the QRS complex is termed the 'PR interval' and largely reflects the duration of AV nodal conduction. Injury to the left or right bundle branch delays ventricular depolarisation, widening the QRS complex. Selective injury of one of the left fascicles (hemiblock, p. 573) affects the electrical axis. Repolarisation is slower and spreads from the epicardium to the endocardium. Atrial repolarisation does not cause a detectable signal but ventricular repolarisation produces the T wave. The QT interval represents the total duration of ventricular depolarisation and repolarisation.

The standard 12–lead ECG

The 12-lead ECG (Box 18.2) is generated from ten physical electrodes that are attached to the skin. One electrode is attached to each limb and six electrodes are attached to the chest. In addition, the left arm, right arm and left leg electrodes are attached to a central terminal acting as an additional virtual electrode in the centre of the chest (the right leg electrode acts as an earthing electrode). The twelve 'leads' of the ECG refer to recordings made from pairs or sets of these electrodes. They comprise three groups: three dipole limb leads, three augmented voltage limb leads and six unipole chest leads.

Leads I, II and III are the dipole limb leads and refer to recordings obtained from pairs of limb electrodes.

18.2 How to read a 12–lead ECG: examination sequence

Rhythm strip (lead II)	To determine heart rate and rhythm
Cardiac axis	Normal if QRS complexes +ve in leads I/II
P-wave shape	Tall P waves denote right atrial enlargement (P pulmonale) and notched P waves denote left atrial enlargement (P mitrale)
PR interval	Normal = 0.12–0.20 secs. Prolongation denotes impaired AV nodal conduction. A short PR interval occurs in Wolff–Parkinson–White syndrome (p. 568)
QRS duration	If > 0.12 secs, ventricular conduction is abnormal (left or right bundle branch block)
QRS amplitude	Large QRS complexes occur in slim young patients and in patients with left ventricular hypertrophy
Q waves	May signify previous myocardial infarction
ST segment	ST elevation may signify myocardial infarction, pericarditis or left ventricular aneurysm; ST depression may signify ischaemia or infarction)
T waves	T-wave inversion has many causes, including myocardial ischaemia or infarction, and electrolyte disturbances
QT interval	Normal < 0.42 secs. QT prolongation may occur with congenital long QT syndrome, low K^+, Mg^{2+} or Ca^{2+}, and some drugs (see Box 18.34, p. 571)
ECG conventions	Depolarisation towards electrode: positive deflection Depolarisation away from electrode: negative deflection Sensitivity: 10 mm = 1 mV Paper speed: 25 mm per second Each large (5 mm) square = 0.2 s Each small (1 mm) square = 0.04 s Heart rate = 1500/RR interval (mm) (i.e. 300 ÷ number of large squares between beats)

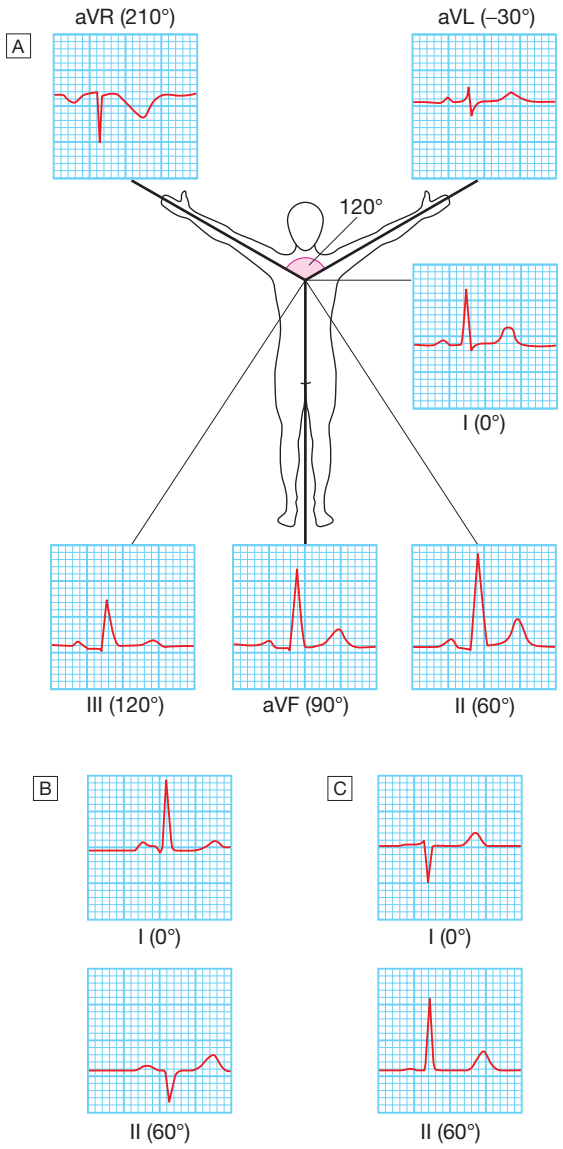

Fig. 18.7 The appearance of the ECG from different leads in the frontal plane. A Normal. B Left axis deviation, with negative deflection in lead II and positive in lead I. C Right axis deviation, with negative deflection in lead I and positive in lead II.

Lead I records the signal between the right (negative) and left (positive) arms. Lead II records the signal between the right arm (negative) and left leg (positive). Lead III records the signal between the left arm (negative) and left leg (positive). These three leads thus record electrical activity along three different axes in the frontal plane. Leads aVR, aVL and aVF are the augmented voltage limb leads. These record electrical activity between a limb electrode and a modified central terminal. For example, lead aVL records the signal between the left arm (positive) and a central (negative) terminal, formed by connecting the right arm and left leg electrodes (Fig. 18.7). Similarly augmented signals are obtained from the right arm (aVR) and left leg (aVF). These leads also record electrical activity in the frontal plane, with each lead 120° apart. Lead aVF thus examines activity along the axis +90°, and lead aVL along the axis –30°, and so on.

When depolarisation moves towards a positive electrode, it produces a positive deflection in the ECG; depolarisation in the opposite direction produces a negative deflection. The average vector of ventricular depolarisation is known as the frontal cardiac axis. When the vector is at right angles to a lead, the depolarisation in that lead is equally negative and positive (isoelectric). In Figure 18.7A, the QRS complex is isoelectric in aVL, negative in aVR and most strongly positive in lead II; the main vector or axis of depolarisation is therefore 60°. The normal cardiac axis lies between –30° and +90°. Examples of left and right axis deviation are shown in Figures 18.7B and C.

There are six chest leads, V_1–V_6, derived from electrodes placed on the anterior and lateral left side of the chest, over the heart. Each lead records the signal between the corresponding chest electrode (positive) and the central terminal (negative). Leads V_1 and V_2 lie approximately over the RV, V_3 and V_4 over the

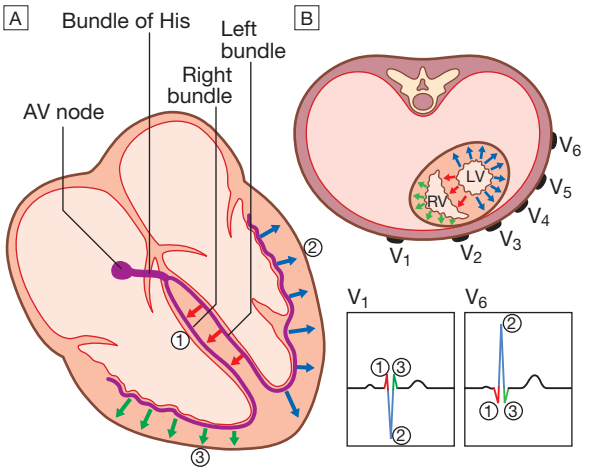

Fig. 18.8 The sequence of activation of the ventricles. A Activation of the septum occurs first (red arrows), followed by spreading of the impulse through the LV (blue arrows) and then the RV (green arrows). B Normal electrocardiographic complexes from leads V_1 and V_6.

interventricular septum, and V_5 and V_6 over the LV (Fig. 18.8). The LV has the greater muscle mass and contributes the major component of the QRS complex.

The shape of the QRS complex varies across the chest leads. Depolarisation of the interventricular septum occurs first and moves from left to right; this generates a small initial negative deflection in lead V_6 (Q wave) and an initial positive deflection in lead V_1 (R wave). The second phase of depolarisation is activation of the body of the LV, which creates a large positive deflection or R wave in V_6 (with reciprocal changes in V_1). The third and final phase involves the RV and produces a small negative deflection or S wave in V_6.

The ECG in ischaemia and infarction

When an area of the myocardium is ischaemic or undergoing infarction, repolarisation and depolarisation become abnormal relative to the surrounding myocardium. In transmural infarction, there is initial ST segment elevation (the current of injury) in the leads facing or overlying the infarct; Q waves (negative deflections) will then appear as the entire thickness of the myocardial wall becomes electrically neutral relative to the adjacent myocardium. The changes occurring in infarction are described in more detail on page 589, and shown in Figures 18.71–18.74 (pp. 592–593). In myocardial ischaemia, the ECG typically shows ST segment depression and/or T-wave inversion; it is usually the subendocardium that most readily becomes ischaemic. Other conditions, such as left ventricular hypertrophy and electrolyte disturbances, can cause similar ST and T-wave changes.

Exercise (stress) ECG

Exercise electrocardiography is used to detect myocardial ischaemia during physical stress and is helpful in the diagnosis of coronary artery disease. A 12-lead ECG is recorded during exercise on a treadmill or bicycle ergometer. The limb electrodes are placed on the shoulders and hips rather than the wrists and ankles. The

18.3 Exercise testing

Indications

- To confirm the diagnosis of angina
- To evaluate stable angina
- To assess prognosis following myocardial infarction
- To assess outcome after coronary revascularisation, e.g. coronary angioplasty
- To diagnose and evaluate the treatment of exercise-induced arrhythmias

High-risk findings

- Low threshold for ischaemia (i.e. within stage 1 or 2 of the Bruce Protocol)
- Fall in BP on exercise
- Widespread, marked or prolonged ischaemic ECG changes
- Exercise-induced arrhythmia

Bruce Protocol is the most commonly used for testing. BP is recorded and symptoms assessed throughout the test. Common indications for exercise testing are shown in Box 18.3. A test is 'positive' if anginal pain occurs, BP falls or fails to increase, or if there are ST segment shifts of more than 1 mm (see Fig. 18.64, p. 584). Exercise testing is useful in confirming the diagnosis in patients with suspected angina, and in such patients has good sensitivity and specificity (see Box 18.3). False-negative results can occur in patients with coronary artery disease, and some patients with a positive test will not have coronary disease (false-positive). It is an unreliable population screening tool because, in low-risk individuals (e.g. asymptomatic young or middle-aged women), an abnormal response is more likely to represent a false-positive than a true positive test.

Stress testing is contraindicated in the presence of acute coronary syndrome, decompensated heart failure and severe hypertension.

Ambulatory ECG

Continuous (ambulatory) ECG recordings can be obtained using a portable digital recorder. These devices usually provide limb lead ECG recordings only, and can record for between 1 and 7 days. Ambulatory ECG recording is principally used in the investigation of patients with suspected arrhythmia, such as those with intermittent palpitation, dizziness or syncope. For these patients, a 12-lead ECG provides only a snapshot of the cardiac rhythm and is unlikely to detect an intermittent arrhythmia, so a longer period of recording is useful (see Fig. 18.39, p. 563). These devices can also be used to assess rate control in patients with atrial fibrillation, and are sometimes used to detect transient myocardial ischaemia using ST segment analysis. For patients with more infrequent symptoms, small, patient-activated ECG recorders can be issued for several weeks until a symptom episode occurs. The patient places the device on the chest to record the rhythm during the episode. With some devices, the recording can be transmitted to hospital via telephone. Implantable 'loop recorders' resemble a leadless pacemaker and are implanted subcutaneously. They have a lifespan of 1–3 years and are used to investigate patients with infrequent but potentially serious symptoms, such as syncope.

Cardiac biomarkers

Plasma or serum biomarkers can be measured to assess myocardial dysfunction and ischaemia.

Brain natriuretic peptide

This is a 32-amino acid peptide and is secreted by the LV along with an inactive 76-amino acid N-terminal fragment (NT-proBNP). The latter is diagnostically more useful, as it has a longer half-life. It is elevated principally in conditions associated with left ventricular systolic dysfunction, and may aid the diagnosis and assess prognosis and response to therapy in patients with heart failure (p. 546).

Cardiac troponins

Troponin I and troponin T are structural cardiac muscle proteins (see Fig. 18.5, p. 531) that are released during myocyte damage and necrosis, and represent the cornerstone of the diagnosis of acute myocardial infarction (MI, p. 593). However, modern assays are extremely sensitive and some have a normal reference range and can detect very low levels of myocardial damage, so that elevated plasma troponin concentrations are seen in other acute conditions, such as pulmonary embolus, septic shock and acute pulmonary oedema. The diagnosis of MI therefore relies on the patient's clinical presentation (see Box 18.61, p. 590).

Chest X-ray

This is useful for determining the size and shape of the heart, and the state of the pulmonary blood vessels and lung fields. Most information is given by a postero-anterior (PA) projection taken in full inspiration. Antero-posterior (AP) projections are convenient when patient movement is restricted but result in magnification of the cardiac shadow.

An estimate of overall heart size can be made by comparing the maximum width of the cardiac outline with the maximum internal transverse diameter of the thoracic cavity. 'Cardiomegaly' is the term used to describe an enlarged cardiac silhouette where the 'cardiothoracic ratio' is greater than 0.5. It can be caused by chamber dilatation, especially left ventricular dilatation, or by a pericardial effusion. Artefactual cardiomegaly may be due to a mediastinal mass or pectus excavatum (p. 731), and cannot be reliably assessed from an AP film. Cardiomegaly is not a sensitive indicator of left ventricular systolic dysfunction since the cardiothoracic ratio is normal in many affected patients (false-negative) and also lacks specificity with many patients with apparent cardiomegaly having normal echocardiograms (false-positive).

Dilatation of individual cardiac chambers can be recognised by the characteristic alterations to the cardiac silhouette:

- Left atrial dilatation results in prominence of the left atrial appendage, creating the appearance of a straight left heart border, a double cardiac shadow to the right of the sternum, and widening of the angle of the carina (bifurcation of the trachea) as the left main bronchus is pushed upwards (Fig. 18.9).

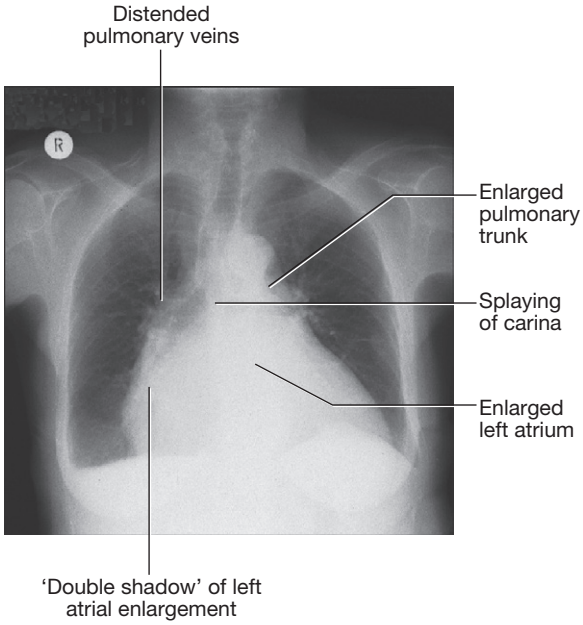

Fig. 18.9 Chest X-ray of a patient with mitral stenosis and regurgitation indicating enlargement of the LA and prominence of the pulmonary artery trunk.

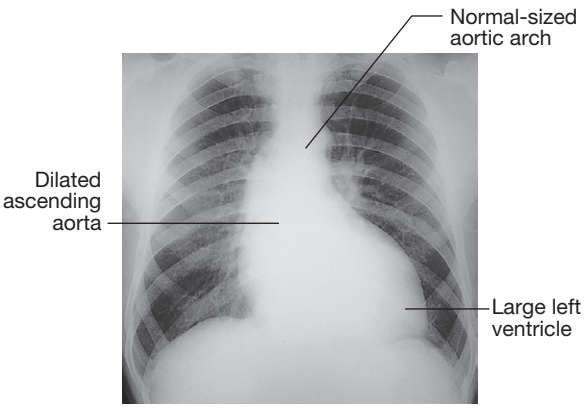

Fig. 18.10 Chest X-ray of a patient with aortic regurgitation, left ventricular enlargement and dilatation of the ascending aorta.

- Right atrial enlargement projects from the right heart border towards the right lower lung field.
- Left ventricular dilatation causes prominence of the left heart border and enlargement of the cardiac silhouette. Left ventricular hypertrophy produces rounding of the left heart border (Fig. 18.10).
- Right ventricular dilatation increases heart size, displaces the apex upwards and straightens the left heart border.

Lateral or oblique projections may be useful for detecting pericardial calcification in patients with constrictive pericarditis (p. 641) or a calcified thoracic aortic aneurysm, as these abnormalities may be obscured by the spine on the PA view.

The lung fields on the chest X-ray may show congestion and oedema in patients with heart failure (see Fig. 18.25, p. 550), and an increase in pulmonary blood flow

('pulmonary plethora') in those with left-to-right shunt. Pleural effusions may also occur in heart failure.

Echocardiography (echo)

Two-dimensional echocardiography

Echocardiography, or cardiac ultrasound, is obtained by placing an ultrasound transducer on the chest wall to image the heart structures as a real-time, two-dimensional 'slice'. This permits the rapid assessment of cardiac structure and function. Left ventricular wall thickness and ejection fraction can be estimated. Common indications for echocardiography are shown in Box 18.4.

Doppler echocardiography

This depends on the Doppler principle that sound waves reflected from moving objects, such as intracardiac red blood cells, undergo a frequency shift. The speed and direction of the red cells, and thus of blood, can be detected in the heart chambers and great vessels. The greater the frequency shift, the faster the blood is moving. The derived information can be presented either as a plot of blood velocity against time for a particular point in the heart (Fig. 18.11) or as a colour overlay on a two-dimensional real-time echo picture (colour-flow Doppler, Fig. 18.12). Doppler echocardiography can be used to detect valvular regurgitation, where the direction of

18.4 Common indications for echocardiography

- Assessment of left ventricular function
- Diagnosis and quantification of severity of valve disease
- Identification of vegetations in endocarditis
- Identification of structural heart disease in atrial fibrillation, cardiomyopathies or congenital heart disease
- Detection of pericardial effusion
- Identification of structural heart disease or intracardiac thrombus in systemic embolism

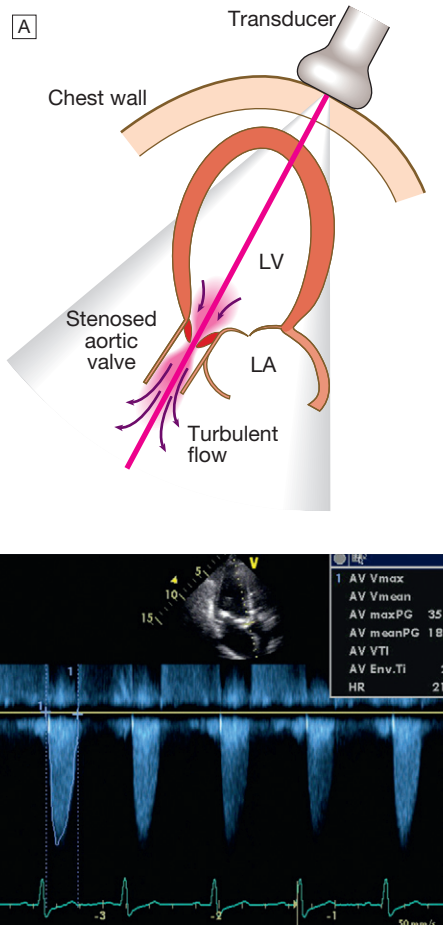

Fig. 18.11 Doppler echocardiography in aortic stenosis. A The aortic valve is imaged and a Doppler beam passed directly through the left ventricular outflow tract and the aorta into the turbulent flow beyond the stenosed valve. B The velocity of the blood cells is recorded to determine the maximum velocity and hence the pressure gradient across the valve. In this example, the peak velocity is approximately 450 cm/sec (4.5 m/sec), indicating severe aortic stenosis (peak gradient of 81 mmHg).

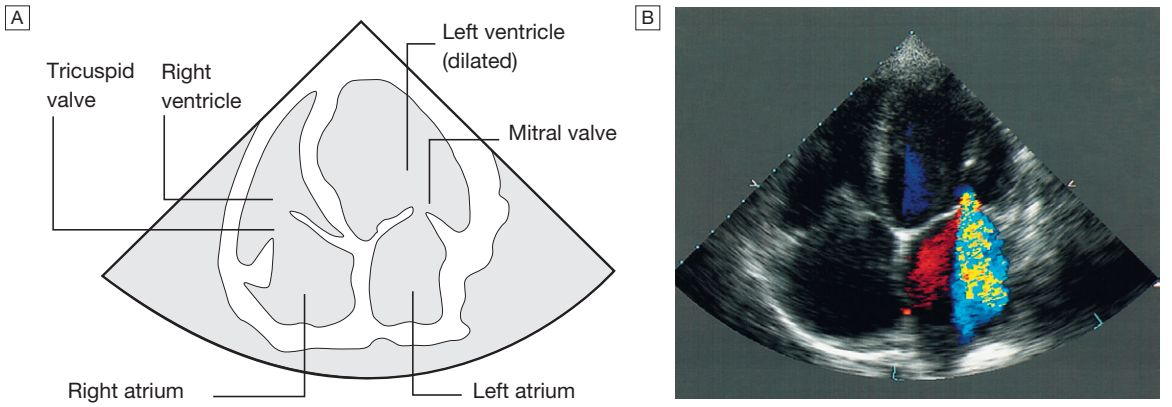

Fig. 18.12 Echocardiographic illustration of the principal cardiac structures in the 'four-chamber' view. A The major chambers and valves. B Colour-flow Doppler has been used to demonstrate mitral regurgitation: a flame-shaped (yellow/blue) turbulent jet into the left atrium.

blood flow is reversed and turbulence is seen, and is also used to detect high pressure gradients associated with stenosed valves. For example, the normal resting systolic flow velocity across the aortic valve is approximately 1 m/sec; in the presence of aortic stenosis, this is increased as blood accelerates through the narrow orifice. In severe aortic stenosis, the peak aortic velocity may be increased to 5 m/sec (see Fig. 18.11). An estimate of the pressure gradient across a valve or lesion is given by the modified Bernoulli equation:

$$\text{Pressure gradient (mmHg)} = 4 \times (\text{peak velocity in m/sec})^2$$

Advanced techniques include three-dimensional echocardiography, intravascular ultrasound (defines vessel wall abnormalities and guides coronary intervention), intracardiac ultrasound (provides high-resolution images) and tissue Doppler imaging (quantifies myocardial contractility and diastolic function).

Transoesophageal echocardiography

Transthoracic echocardiography sometimes produces poor images, especially if the patient is overweight or has obstructive airways disease. Some structures are difficult to visualise in transthoracic views, such as the left atrial appendage, pulmonary veins, thoracic aorta and interatrial septum. Transoesophageal echocardiography (TOE) uses an endoscope-like ultrasound probe which is passed into the oesophagus under light sedation and positioned behind the LA. This produces high-resolution images, which makes the technique particularly valuable for investigating patients with prosthetic (especially mitral) valve dysfunction, congenital abnormalities (e.g. atrial septal defect), aortic dissection, infective endocarditis (vegetations that are too small to be detected by transthoracic echocardiography) and systemic embolism (intracardiac thrombus or masses).

Stress echocardiography

Stress echocardiography is used to investigate patients with suspected coronary artery disease who are unsuitable for exercise stress testing, such as those with mobility problems or pre-existing bundle branch block. A two-dimensional echo is performed before and after infusion of a moderate to high dose of an inotrope, such as dobutamine. Myocardial segments with poor perfusion become ischaemic and contract poorly under stress, showing as a wall motion abnormality on the scan. Stress echocardiography is sometimes used to examine myocardial viability in patients with impaired left ventricular function. Low-dose dobutamine can induce contraction in 'hibernating' myocardium; such patients may benefit from bypass surgery or percutaneous coronary intervention.

Computed tomographic imaging

Computed tomography (CT) is useful for imaging the cardiac chambers, great vessels, pericardium, and mediastinal structures and masses. Multidetector scanners can acquire up to 320 slices per rotation, allowing very high-resolution imaging. CT is often performed using a timed injection of X-ray contrast to produce clear images of blood vessels and associated pathologies. Contrast scans are very useful for imaging the aorta in suspected aortic dissection (see Fig. 18.82, p. 607), and the pulmonary arteries and branches in suspected pulmonary embolism (p. 721).

Some centres use cardiac CT scans for quantification of coronary artery calcification, which may serve as an index of cardiovascular risk. However, modern multidetector scanning allows non-invasive coronary angiography (Fig. 18.13) with a spatial resolution approaching that of conventional coronary arteriography and at a lower radiation dose. CT coronary angiography is particularly useful in the initial elective assessment of patients with chest pain and a low or intermediate likelihood of disease, since its negative predictive value is very high: that is, excluding the presence of coronary artery disease. Modern volume scanners are also able to assess myocardial perfusion, often at the same sitting.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) requires no ionising radiation and can be used to generate cross-sectional images of the heart, lungs and mediastinal structures. It provides better differentiation of soft tissue structures than CT but is poor at demonstrating calcification. MRI scans need to be 'gated' to the ECG, allowing the scanner to produce moving images of the heart and mediastinal structures throughout the cardiac cycle. MRI is very

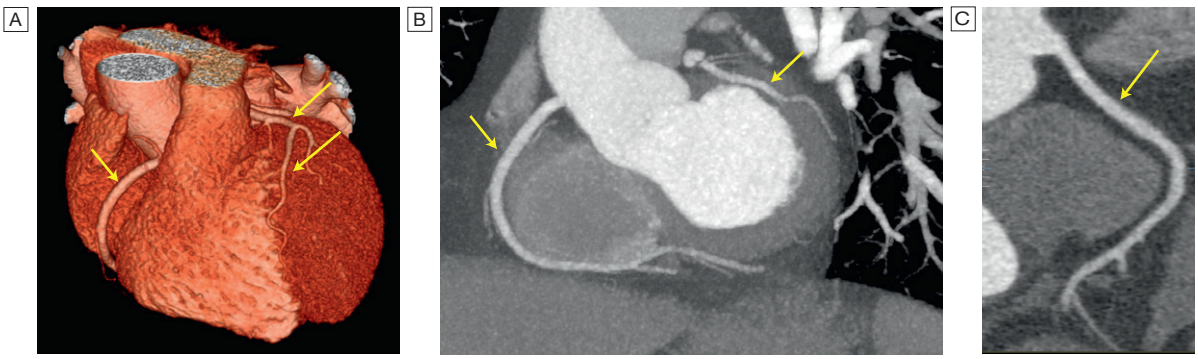

Fig. 18.13 Computed tomography coronary angiography demonstrating normal coronary arteries (arrows).

useful for imaging the aorta, including suspected dissection (see Fig. 18.81, p. 606), and can define the anatomy of the heart and great vessels in patients with congenital heart disease. It is also useful for detecting infiltrative conditions affecting the heart.

Physiological data can be obtained from the signal returned from moving blood, which allows quantification of blood flow across regurgitant or stenotic valves. It is also possible to analyse regional wall motion in patients with suspected coronary disease or cardiomyopathy. The RV is difficult to assess using echocardiography because of its retrosternal position but is readily visualised with MRI.

MRI can also be employed to assess myocardial perfusion and viability. When a contrast agent, such as gadolinium, is injected, areas of myocardial hypoperfusion can be identified with better spatial resolution than nuclear medicine techniques. Later redistribution of this contrast, so-called delayed enhancement, can be used to identify myocardial scarring and fibrosis (Fig. 18.14). This can help in selecting patients for revascularisation procedures, or in identifying those with myocardial infiltration such as that seen with sarcoid heart disease and right ventricular dysplasia.

Cardiac catheterisation

This involves passage of a preshaped catheter via a vein or artery into the heart under X-ray guidance, which allows the measurement of pressure and oxygen saturation in the cardiac chambers and great vessels, and the performance of angiograms by injecting contrast media into a chamber or blood vessel.

Left heart catheterisation involves accessing the arterial circulation, usually via the radial artery, to allow catheterisation of the aorta, LV and coronary arteries. Coronary angiography is the most widely performed procedure, in which the left and right coronary arteries are selectively cannulated and imaged, providing information about the extent and severity of coronary stenoses, thrombus and calcification (Fig. 18.15). This permits

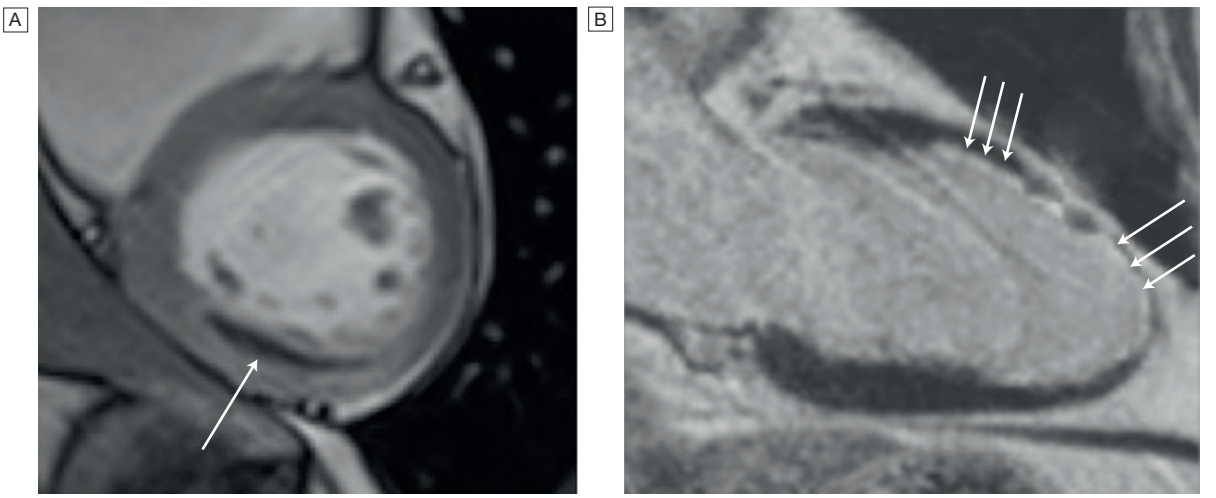

Fig. 18.14 Cardiac magnetic resonance imaging. A Recent inferior myocardial infarction with black area of microvascular obstruction (arrow). B Old anterior myocardial infarction with large area of subendocardial delayed gadolinium enhancement (white area, arrows).

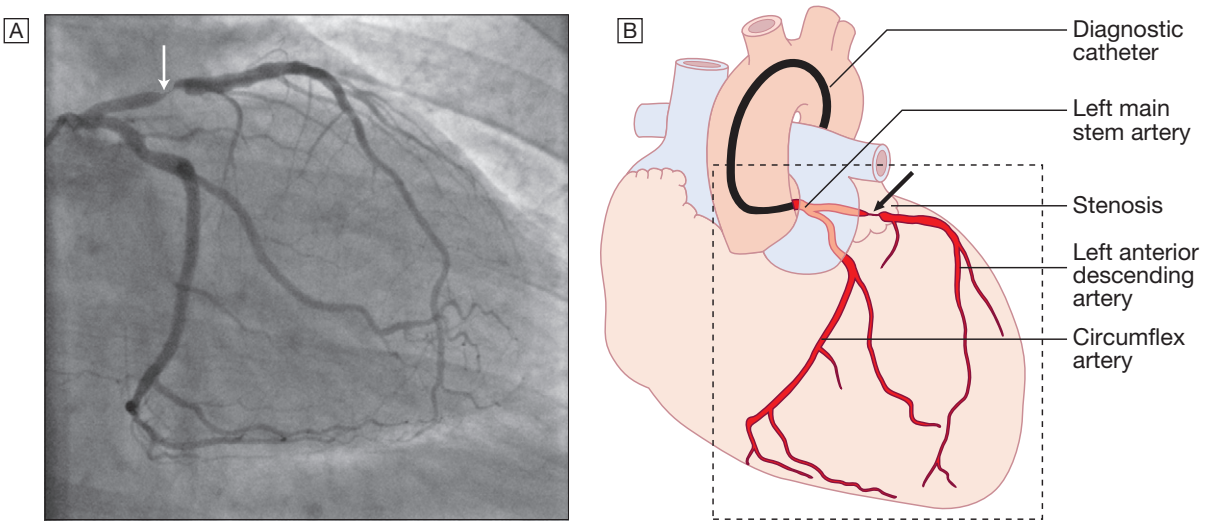

Fig. 18.15 The left anterior descending and circumflex coronary arteries with a stenosis in the left anterior descending vessel. A Coronary artery angiogram. B Schematic of the vessels and branches.

planning of percutaneous coronary intervention and coronary artery bypass graft surgery. Left ventriculography can be performed during the procedure to determine the size and function of the LV and to demonstrate mitral regurgitation. Aortography defines the size of the aortic root and thoracic aorta, and can help quantify aortic regurgitation. Left heart catheterisation is a day-case procedure and is relatively safe, with serious complications occurring in fewer than 1 in 1000 cases.

Right heart catheterisation is used to assess right heart and pulmonary artery pressures, and to detect intracardiac shunts by measuring oxygen saturations in different chambers. For example, a step up in oxygen saturation from 65% in the RA to 80% in the pulmonary artery is indicative of a large left-to-right shunt that might be due to a ventricular septal defect. Cardiac output can also be measured using thermodilution techniques. Left atrial pressure can be measured directly by puncturing the interatrial septum from the RA with a special catheter. For most purposes, however, a satisfactory approximation to left atrial pressure can be obtained by 'wedging' an end-hole or balloon catheter in a branch of the pulmonary artery. Swan–Ganz balloon catheters are often used to monitor pulmonary 'wedge' pressure as a guide to left heart filling pressure in critically ill patients (p. 186).

Electrophysiology study

Patients with known or suspected arrhythmia are investigated by percutaneous placement of electrode catheters into the heart via the femoral and neck veins. Electrophysiology study (EPS) is most commonly performed to evaluate patients for catheter ablation, normally done during the same procedure. It is occasionally used for risk stratification of patients suspected of being at risk of ventricular arrhythmias.

Radionuclide imaging

The availability of gamma-emitting radionuclides with a short half-life has made it possible to study cardiac function non-invasively. Two techniques are available, although their use is declining due to the availability of equivalent or superior imaging techniques that have lower or no exposure to ionising radiation.

Blood pool imaging

The isotope is injected intravenously and mixes with the circulating blood. A gamma camera detects the amount of radiation-emitting blood in the heart at different phases of the cardiac cycle, thereby permitting the calculation of ventricular ejection fractions. It also allows the assessment of the size and 'shape' of the cardiac chambers.

Myocardial perfusion imaging

This technique involves obtaining scintiscans of the myocardium at rest and during stress after the administration of an intravenous radioactive isotope, such as ^{99}technetium tetrofosmin (see Fig. 18.65, p. 585). More sophisticated quantitative information is obtained with positron emission tomography (PET), which can also be used to assess myocardial metabolism, but this is only available in a few centres.

PRESENTING PROBLEMS IN CARDIOVASCULAR DISEASE

Cardiovascular disease gives rise to a relatively limited range of symptoms. Differential diagnosis depends on careful analysis of the factors that provoke symptoms, the subtle differences in how they are described by the patient, the clinical findings and appropriate investigations. A close relationship between symptoms and exercise is the hallmark of heart disease. The New York Heart Association (NYHA) functional classification is used to grade disability (Box 18.5).

Chest pain

Chest pain is a common presentation of cardiac disease but can also be a manifestation of anxiety or disease of the respiratory, musculoskeletal or gastrointestinal systems (see Box 18.6 below). Some patients deny 'pain' in favour of 'discomfort' but the significance remains the same.

Characteristics of cardiac pain

Several key characteristics help to distinguish cardiac pain from that of other causes (Fig. 18.16). Diagnosis may be difficult and it is helpful to classify pain as typical, atypical or non-cardiac chest pain, based on the balance of evidence (Fig. 18.17).

- *Site*. Cardiac pain is typically located in the centre of the chest because of the derivation of the nerve supply to the heart and mediastinum.

18.5 New York Heart Association (NYHA) functional classification

• **Class I**	No limitation during ordinary activity
• **Class II**	Slight limitation during ordinary activity
• **Class III**	Marked limitation of normal activities without symptoms at rest
• **Class IV**	Unable to undertake physical activity without symptoms; symptoms may be present at rest

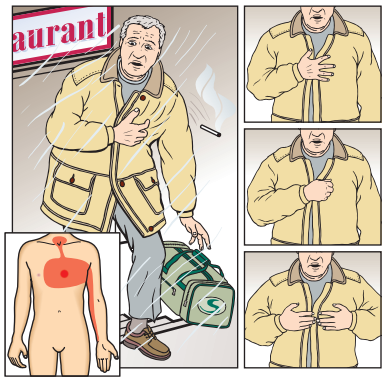

Fig. 18.16 Typical ischaemic cardiac pain. Characteristic hand gestures used to describe cardiac pain. Typical radiation of pain is shown in the schematic.

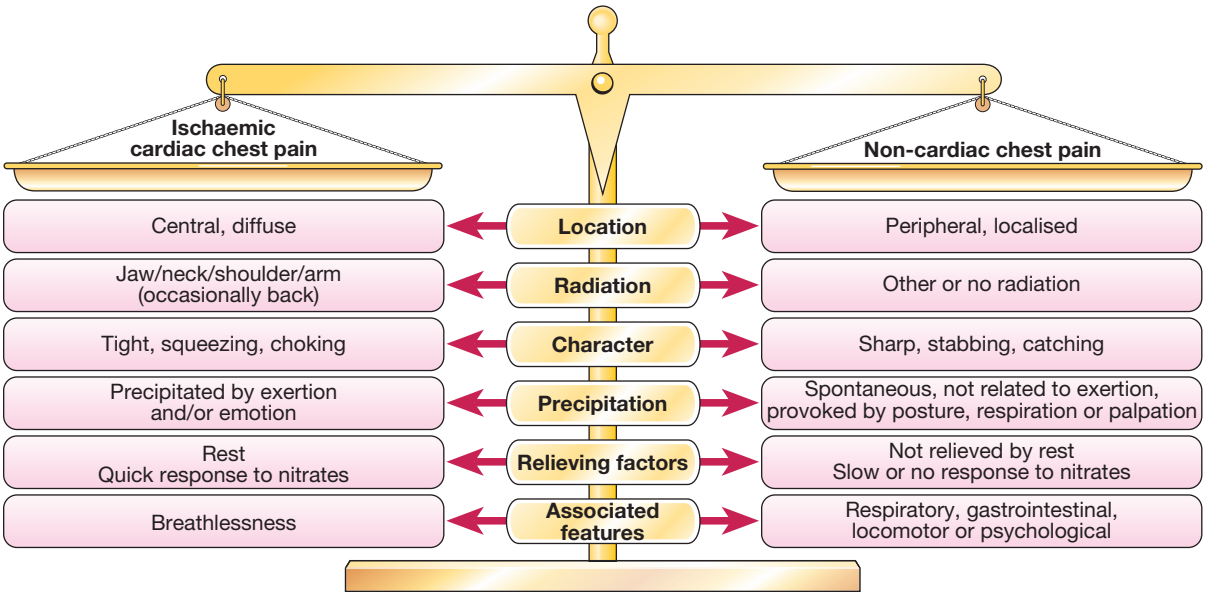

Fig. 18.17 Identifying ischaemic cardiac pain: the 'balance' of evidence.

- *Radiation*. Ischaemic cardiac pain may radiate to the neck, jaw, and upper or even lower arms. Occasionally, cardiac pain may be experienced only at the sites of radiation or in the back. Pain situated over the left anterior chest and radiating laterally is unlikely to be due to cardiac ischaemia and may have many causes, including pleural or lung disorders, musculoskeletal problems and anxiety.
- *Character*. Cardiac pain is typically dull, constricting, choking or 'heavy', and is usually described as squeezing, crushing, burning or aching but not sharp, stabbing, pricking or knife-like. The sensation can be described as breathlessness. Patients often emphasise that it is a discomfort rather than a pain. They typically use characteristic hand gestures (e.g. open hand or clenched fist) when describing ischaemic pain (see Fig. 18.16).
- *Provocation*. Anginal pain occurs during (not after) exertion and is promptly relieved (in less than 5 minutes) by rest. The pain may also be precipitated or exacerbated by emotion but tends to occur more readily during exertion, after a large meal or in a cold wind. In crescendo or unstable angina, similar pain may be precipitated by minimal exertion or at rest. The increase in venous return or preload induced by lying down may also be sufficient to provoke pain in vulnerable patients (decubitus angina). The pain of MI may be preceded by a period of stable or unstable angina but often occurs de novo. In contrast, pleural or pericardial pain is usually described as a 'sharp' or 'catching' sensation that is exacerbated by breathing, coughing or movement. Pain associated with a specific movement (bending, stretching, turning) is likely to be musculoskeletal in origin.
- *Onset*. The pain of MI typically takes several minutes or even longer to develop; similarly, angina builds up gradually in proportion to the intensity of exertion. Pain that occurs after rather than during exertion is usually musculoskeletal or psychological in origin. The pain of aortic dissection, massive pulmonary embolism or pneumothorax is usually very sudden or instantaneous in onset.
- *Associated features*. The pain of MI, massive pulmonary embolism or aortic dissection is often accompanied by autonomic disturbance, including sweating, nausea and vomiting. Breathlessness, due to pulmonary congestion arising from transient ischaemic left ventricular dysfunction, is often a prominent and occasionally the dominant feature of MI or angina (angina equivalent). Breathlessness may also accompany any of the respiratory causes of chest pain and can be associated with cough, wheeze or other respiratory symptoms. Gastrointestinal disorders, such as gastro-oesophageal reflux, peptic ulceration or biliary colic, may present with chest pain but effort-related 'indigestion' is usually due to heart disease.

Differential diagnosis of chest pain

Common causes of chest pain are listed in Box 18.6.

Psychological aspects of chest pain

Emotional distress is a common cause of atypical or non-cardiac chest pain. This diagnosis should be considered if there are features of anxiety and the pain lacks a predictable relationship with exercise. However, the prospect of heart disease is a frightening experience, particularly when it has been responsible for the death of a close friend or relative; psychological and organic features therefore often coexist. Anxiety may amplify the effects of organic disease and can create a very confusing picture. Patients who believe they are suffering from heart disease are sometimes afraid to take exercise and this may make it difficult to establish their true effort tolerance; assessment may also be complicated by the impact of physical deconditioning.

Myocarditis and pericarditis

Pain is characteristically felt retrosternally, to the left of the sternum, or in the left or right shoulder, and typically varies in intensity with movement and the phase of respiration. The pain is described as 'sharp' and may 'catch' the patient during inspiration, coughing or lying flat; there may be a history of a prodromal viral illness.

Mitral valve prolapse

Sharp left-sided chest pain that is suggestive of a musculoskeletal problem may be a feature of mitral valve prolapse (p. 618).

Aortic dissection

This pain is severe, sharp and tearing, is often felt in or penetrating through to the back, and is typically very abrupt in onset (p. 605). The pain follows the path of the dissection.

Oesophageal pain

This can mimic the pain of angina very closely, is sometimes precipitated by exercise and may be relieved by nitrates. However, it is usually possible to elicit a history relating chest pain to supine posture or eating, drinking or oesophageal reflux. It often radiates to the interscapular region and dysphagia may be present.

Bronchospasm

Patients with reversible airways obstruction, such as asthma, may describe exertional chest tightness that is relieved by rest. This may be difficult to distinguish from ischaemic chest tightness. Bronchospasm may be associated with wheeze, atopy and cough (p. 654).

Musculoskeletal chest pain

This is a common problem that is very variable in site and intensity but does not usually fall into any of the patterns described above. The pain may vary with posture or movement of the upper body and is sometimes accompanied by local tenderness over a rib or costal cartilage. There are numerous causes, including arthritis, costochondritis, intercostal muscle injury and Coxsackie viral infection (epidemic myalgia or Bornholm disease). Many minor soft tissue injuries are related to everyday activities, such as driving, manual work and sport. The differential diagnosis of peripheral or pleural chest pain is discussed on page 658.

18.6 Common causes of chest pain

Anxiety/emotion

Cardiac
- Myocardial ischaemia (angina)
- MI
- Pericarditis
- Mitral valve prolapse

Aortic
- Aortic dissection
- Aortic aneurysm

Oesophageal
- Oesophagitis
- Oesophageal spasm
- Mallory–Weiss syndrome

Lungs/pleura
- Bronchospasm
- Pulmonary infarct
- Pneumonia
- Tracheitis
- Pneumothorax
- Pulmonary embolism
- Malignancy
- Tuberculosis
- Connective tissue disorders (rare)

Musculoskeletal
- Osteoarthritis
- Rib fracture/injury
- Costochondritis (Tietze's syndrome)
- Intercostal muscle injury
- Epidemic myalgia (Bornholm disease)

Neurological
- Prolapsed intervertebral disc
- Herpes zoster
- Thoracic outlet syndrome

Initial evaluation of suspected cardiac pain

A careful history is crucial in determining whether pain is cardiac or not. Although the physical findings and subsequent investigations may help to confirm the diagnosis, they are of more value in determining the nature and extent of any underlying heart disease, the risk of a serious adverse event, and the best course of management.

Stable angina

Effort-related chest pain is the hallmark of angina pectoris or 'choking in the chest' (Fig. 18.18). The reproducibility, predictability and relationship to physical exertion (and occasionally emotion) of the chest pain are

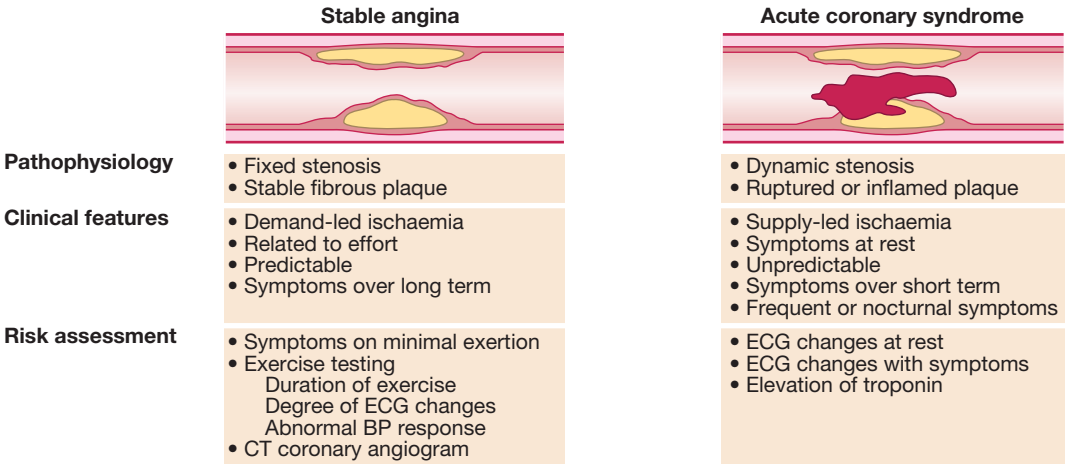

Fig. 18.18 Pathophysiology, clinical features and risk assessment of patients with stable or unstable coronary heart disease.

the most important features. The duration of symptoms should be noted because patients with recent-onset angina are at greater risk than those with long-standing and unchanged symptoms.

Physical examination is often normal but may reveal evidence of risk factors (e.g. xanthoma indicating hyperlipidaemia), left ventricular dysfunction (e.g. dyskinetic apex beat, gallop rhythm), other manifestations of arterial disease (e.g. bruits, signs of peripheral vascular disease) and unrelated conditions that may exacerbate angina (e.g. anaemia, thyroid disease). Stable angina is usually a symptom of coronary artery disease but may be a manifestation of other forms of heart disease, particularly aortic valve disease and hypertrophic cardiomyopathy. In patients with angina in whom a murmur is found, echocardiography should be performed.

A full blood count, fasting blood glucose, lipids, thyroid function tests and a 12-lead ECG are the most important baseline investigations. Exercise testing may confirm the diagnosis and also identify high-risk patients

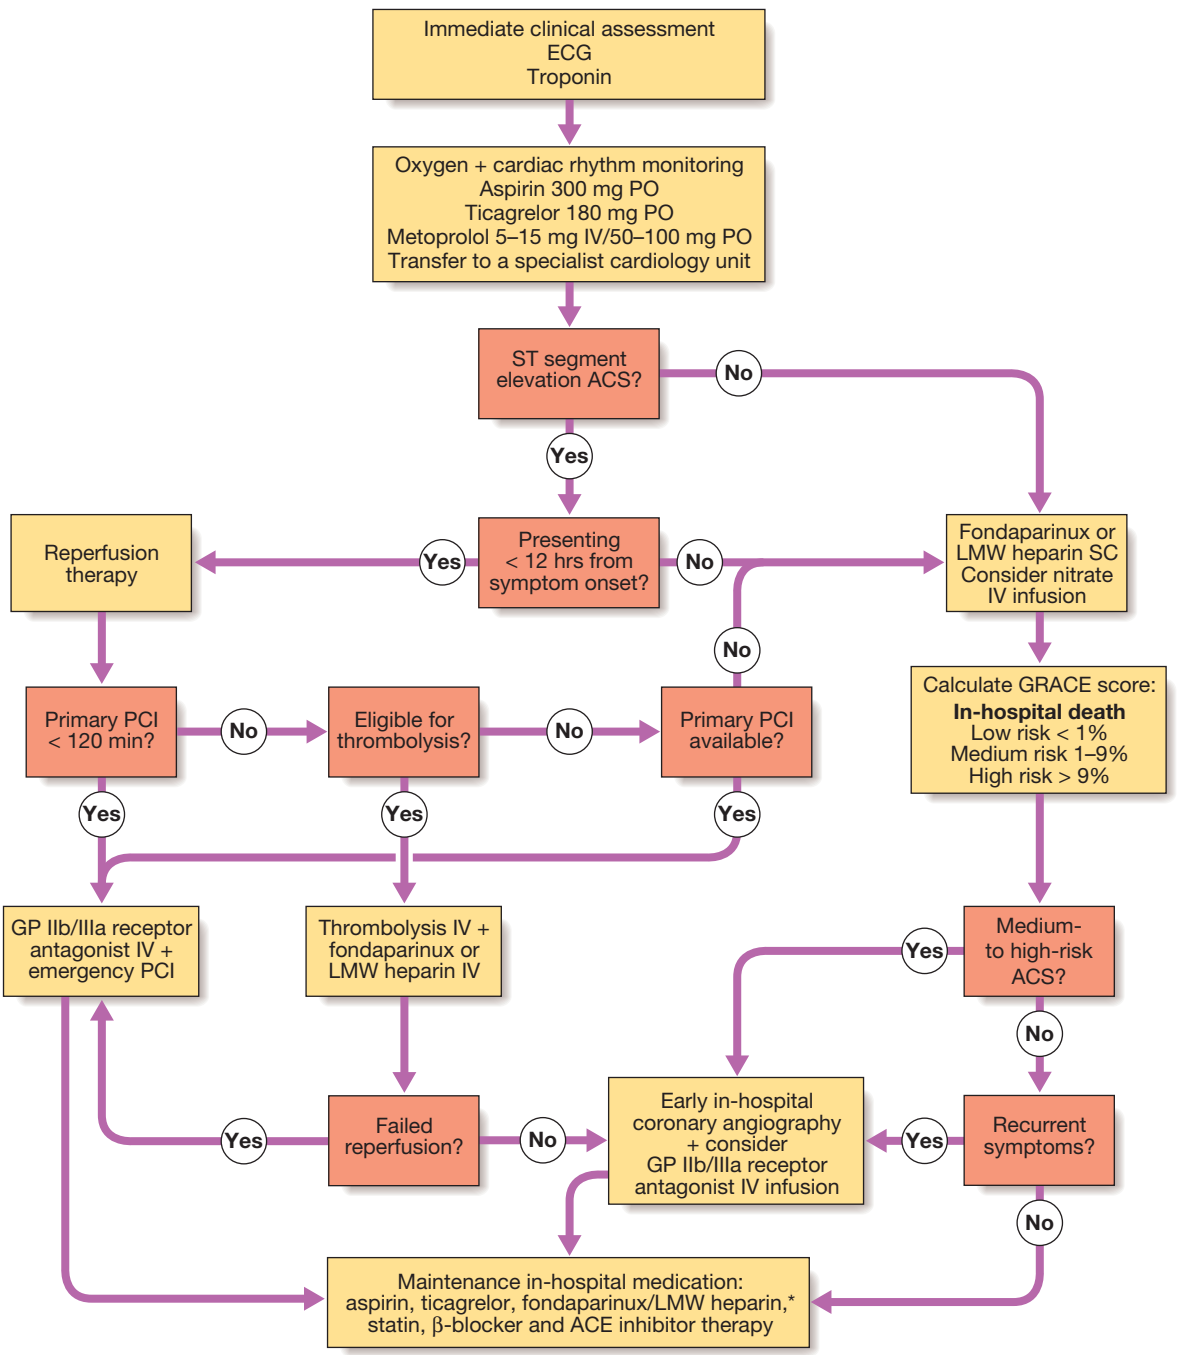

Fig. 18.19 Summary of treatment for acute coronary syndrome (ACS). *Not required following PCI. Amended from SIGN 93. For details of the GRACE score, see Figure 18.70, p. 591 (ACE = angiotensin-converting enzyme; GP = glycoprotein; LMW = low molecular weight; PCI = percutaneous coronary intervention). From SIGN 93 – see p. 641.

who require further investigation and treatment (p. 534). CT coronary angiography is very useful to exclude the presence of coronary artery disease where doubt exists.

Acute coronary syndromes

Prolonged, severe cardiac chest pain may be due to unstable angina (which comprises recent-onset limiting angina, rapidly worsening or crescendo angina, and angina at rest) or acute MI; these are known collectively as the acute coronary syndromes. Although there may be a history of antecedent chronic stable angina, an episode of chest pain at rest is often the first presentation of coronary artery disease. Diagnosis depends on analysis of the character of the pain and its associated features. Physical examination may reveal signs of important comorbidity, such as peripheral or cerebrovascular disease, autonomic disturbance (pallor or sweating) and complications (arrhythmia or heart failure).

Patients presenting with symptoms consistent with an acute coronary syndrome require urgent evaluation because there is a high risk of avoidable complications, such as sudden death and MI. Signs of haemodynamic compromise (hypotension, pulmonary oedema), ECG changes (ST segment elevation or depression) and biochemical markers of cardiac damage, such as elevated troponin I or T, are powerful indicators of short-term risk. A 12-lead ECG is mandatory and is the most useful method of initial triage (Fig. 18.19). The release of markers such as creatine kinase, troponin and myoglobin is relatively slow (p. 593) but can help guide immediate management and treatment.

If the diagnosis is unclear, patients with a suspected acute coronary syndrome should be observed in hospital. Repeated ECG recordings are valuable, particularly if obtained during an episode of pain. Plasma troponin concentrations should be measured at presentation and, if normal, repeated 6–12 hours after the onset of symptoms or hospital admission. New ECG changes or an elevated plasma troponin concentration confirm the diagnosis of an acute coronary syndrome. The subsequent management is described on page 593.

If the pain has not recurred, troponin concentrations are not elevated and there are no new ECG changes, the patient may be discharged from hospital. At this stage, an exercise test or CT coronary angiogram may help diagnose underlying coronary artery disease.

Breathlessness (dyspnoea)

Dyspnoea of cardiac origin may vary in severity from an uncomfortable awareness of breathing to a frightening sensation of 'fighting for breath'. The sensation of dyspnoea originates in the cerebral cortex and is described in detail on page 655.

There are several causes of cardiac dyspnoea: acute left heart failure, chronic heart failure, arrhythmia and angina equivalent (Box 18.7). The assessment and treatment of heart failure is described on pages 548–553, and arrhythmias on pages 562–571.

18.7 Some causes of dyspnoea

Acute dyspnoea	Chronic exertional dyspnoea
Cardiovascular system	
*Acute pulmonary oedema	*Congestive cardiac failure Myocardial ischaemia
Respiratory system	
*Acute severe asthma *Acute exacerbation of COPD *Pneumothorax *Pneumonia *Pulmonary embolus ARDS Inhaled foreign body (especially in a child) Lobar collapse Laryngeal oedema (e.g. anaphylaxis)	*COPD *Chronic asthma Chronic pulmonary thromboembolism Bronchial carcinoma Interstitial lung diseases: sarcoidosis, fibrosing alveolitis, extrinsic allergic alveolitis, pneumoconiosis Lymphatic carcinomatosis Large pleural effusion(s)
Others	
Metabolic acidosis (e.g. diabetic ketoacidosis, lactic acidosis, uraemia, overdose of salicylates, ethylene glycol poisoning) Hyperventilation	Severe anaemia Obesity

*Common cause. (ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)

Acute left heart failure

Acute left heart failure may be triggered by a major event, such as MI, in a previously healthy heart, or by a relatively minor event, such as the onset of atrial fibrillation, in a diseased heart. An increase in the left ventricular diastolic pressure causes the pressure in the LA, pulmonary veins and pulmonary capillaries to rise. When the hydrostatic pressure of the pulmonary capillaries exceeds the oncotic pressure of plasma (about 25–30 mmHg), fluid moves from the capillaries into alveoli. This stimulates respiration through a series of autonomic reflexes, producing rapid shallow respiration. Congestion of the bronchial mucosa may cause wheeze (cardiac asthma).

Acute pulmonary oedema is a terrifying experience because of the sensation of 'fighting for breath'. Sitting upright or standing may provide some relief by helping to reduce congestion at the apices of the lungs. The patient may be unable to speak and is typically distressed, agitated, sweaty and pale. Respiration is rapid, with recruitment of accessory muscles, coughing and wheezing. Sputum may be profuse, frothy and blood-streaked or pink. Extensive crepitations and rhonchi are usually audible in the chest and there may also be signs of right heart failure.

Chronic heart failure

Chronic heart failure is the most common cardiac cause of chronic dyspnoea. Symptoms may first present on moderate exertion, such as walking up a steep hill, and may be described as a difficulty in 'catching my breath'. As heart failure progresses, the dyspnoea is provoked by less exertion and, ultimately, the patient may be breathless walking from room to room, washing, dressing or trying to hold a conversation. Other symptoms may include:

- *Orthopnoea*. Lying down increases the venous return to the heart and provokes breathlessness. Patients may prop themselves up with pillows to prevent this.

- *Paroxysmal nocturnal dyspnoea*. In patients with severe heart failure, fluid shifts from the interstitial tissues of the peripheries into the circulation within 1–2 hours of lying down. Pulmonary oedema supervenes, causing the patient to wake and sit upright, profoundly breathless.
- *Cheyne–Stokes respiration*. This cyclical pattern of respiration is due to impaired responsiveness of the respiratory centre to carbon dioxide and occurs in severe left ventricular failure. The pattern of slowly diminishing respiration, leading to apnoea, followed by progressively increasing respiration and hyperventilation, may be accompanied by a sensation of breathlessness and panic during the period of hyperventilation. The Cheyne–Stokes cycle length is a function of the circulation time. The condition can also occur in diffuse cerebral atherosclerosis, stroke or head injury, and may be exaggerated by sleep, barbiturates and opiates.

Arrhythmia

Any arrhythmia may cause breathlessness but usually only does so if the heart is structurally abnormal, such as with the onset of atrial fibrillation in a patient with mitral stenosis.

Angina equivalent

Breathlessness is a common feature of angina. Patients will sometimes describe chest tightness as 'breathlessness'. However, myocardial ischaemia may also induce true breathlessness by provoking transient left ventricular dysfunction or heart failure. When breathlessness is the dominant or sole feature of myocardial ischaemia, it is known as 'angina equivalent'. A history of chest tightness, the close correlation with exercise, and objective evidence of myocardial ischaemia from stress testing may all help to establish the diagnosis.

Acute circulatory failure (cardiogenic shock)

'Shock' is used to describe the clinical syndrome that develops when there is critical impairment of tissue perfusion due to some form of acute circulatory failure. There are numerous causes of shock, described in detail on page 190. The important features and causes (Fig. 18.20) of acute heart failure or cardiogenic shock are described here.

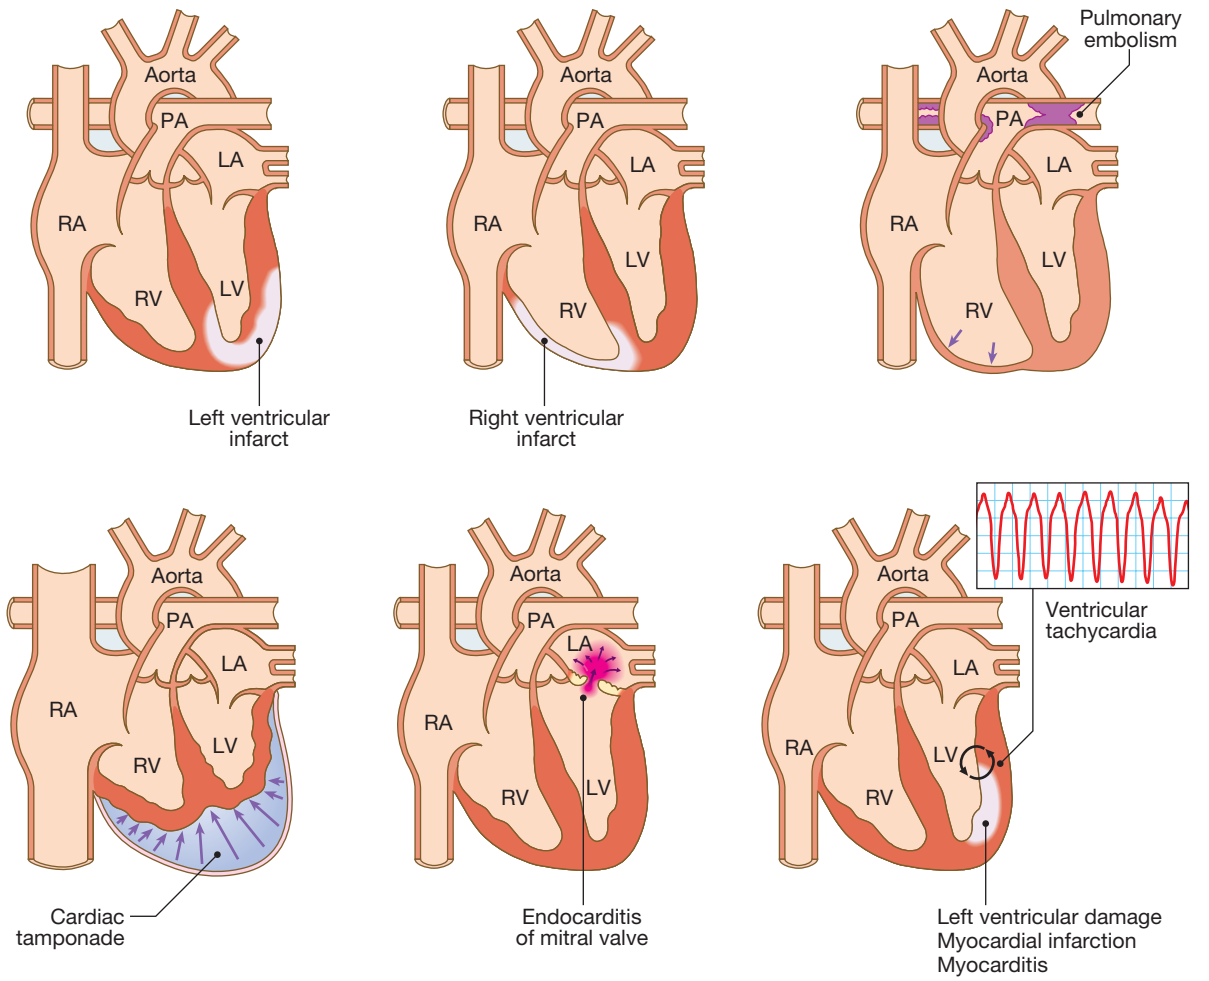

Fig. 18.20 Some common causes of cardiogenic shock.

Myocardial infarction

Shock in acute MI is due to left ventricular dysfunction in more than 70% of cases. However, it may also be due to infarction of the RV and a variety of mechanical complications, including tamponade (due to infarction and rupture of the free wall), an acquired ventricular septal defect (due to infarction and rupture of the septum) and acute mitral regurgitation (due to infarction or rupture of the papillary muscles).

Severe myocardial systolic dysfunction causes a fall in cardiac output, BP and coronary perfusion pressure. Diastolic dysfunction causes a rise in left ventricular end-diastolic pressure, pulmonary congestion and oedema, leading to hypoxaemia that worsens myocardial ischaemia. This is further exacerbated by peripheral vasoconstriction. These factors combine to create the 'downward spiral' of cardiogenic shock (Fig. 18.21).

Hypotension, oliguria, confusion and cold, clammy peripheries are the manifestations of a low cardiac output, whereas breathlessness, hypoxaemia, cyanosis and inspiratory crackles at the lung bases are typical features of pulmonary oedema. A chest X-ray (see Fig. 18.25, p. 550) may reveal signs of pulmonary congestion when clinical examination is normal. If necessary, a Swan–Ganz catheter can be used to measure the pulmonary artery wedge pressure and to guide fluid replacement. The findings can be used to categorise patients with acute MI into four haemodynamic subsets (Box 18.8). Those with cardiogenic shock should be considered for immediate coronary revascularisation.

The viable myocardium surrounding a fresh infarct may contract poorly for a few days and then recover. This phenomenon is known as myocardial stunning and means that acute heart failure should be treated intensively because overall cardiac function may subsequently improve.

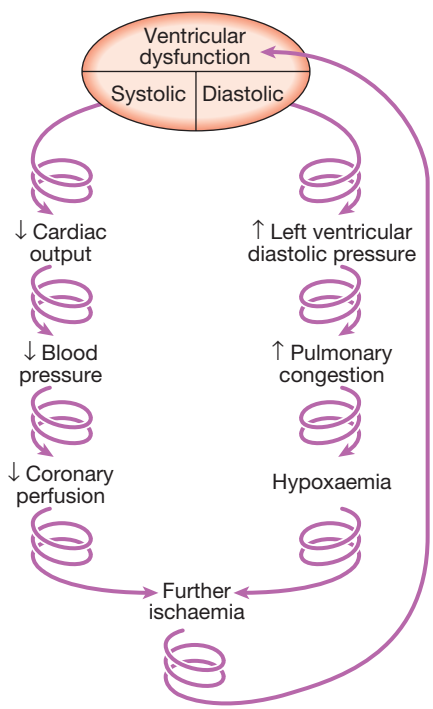

Fig. 18.21 The downward spiral of cardiogenic shock.

18.8 Acute myocardial infarction: haemodynamic subsets

Cardiac output	Pulmonary oedema	
	No	Yes
Normal	Good prognosis and requires no treatment for heart failure	Due to moderate left ventricular dysfunction. Treat with vasodilators and diuretics
Low	Due to right ventricular dysfunction or concomitant hypovolaemia. Give fluid challenge and consider pulmonary artery catheter to guide therapy	Extensive MI and poor prognosis. Consider intra-aortic balloon pump, vasodilators, diuretics and inotropes

Acute massive pulmonary embolism

This may complicate leg or pelvic vein thrombosis and usually presents with sudden collapse. The clinical features and treatment are discussed on page 721. Bedside echocardiography may demonstrate a small, underfilled, vigorous LV with a dilated RV; it is sometimes possible to see thrombus in the right ventricular outflow tract or main pulmonary artery. CT pulmonary angiography usually provides a definitive diagnosis.

Cardiac tamponade

This is due to a collection of fluid or blood in the pericardial sac, compressing the heart; the effusion may be small and is very occasionally less than 100 mL. Sudden deterioration (Box 18.9) may be due to bleeding into the pericardial space. Tamponade may complicate any form of pericarditis but can be caused by malignant disease. Other causes include trauma and rupture of the free wall of the myocardium following MI.

An ECG may show features of the underlying disease, such as pericarditis or acute MI. When there is a large pericardial effusion, the ECG complexes are small and there may be electrical alternans: a changing axis with alternate beats caused by the heart swinging from side to side in the pericardial fluid. A chest X-ray shows an enlarged globular heart but can look normal. Echocardiography is the best way of confirming the diagnosis

18.9 Clinical features of pericardial tamponade

- Dyspnoea
- Collapse
- Tachycardia
- Hypotension
- Gross elevation of the JVP
- Soft heart sounds with an early third heart sound
- Pulsus paradoxus (a large fall in BP during inspiration, when the pulse may be impalpable)
- Kussmaul's sign (a paradoxical rise in the JVP during inspiration)

(JVP = jugular venous pressure)

and helps to identify the optimum site for aspiration of the fluid. Prompt recognition of tamponade is important because the patient usually responds dramatically to percutaneous pericardiocentesis (p. 640) or surgical drainage.

Valvular heart disease

Acute left ventricular failure and shock may be due to the sudden onset of aortic regurgitation, mitral regurgitation or prosthetic valve dysfunction (Box 18.10).

The clinical diagnosis of acute valvular dysfunction is sometimes difficult. Murmurs are often unimpressive because there is usually a tachycardia and a low cardiac output. Transthoracic echocardiography will establish the diagnosis in most cases; however, transoesophageal echocardiography is sometimes required, especially in patients with prosthetic mitral valves.

Patients with acute valve failure usually require cardiac surgery and should be referred for urgent assessment in a cardiac centre.

Aortic dissection may lead to shock by causing aortic regurgitation, coronary dissection, tamponade or blood loss (p. 605).

18.10 Causes of acute valve failure

Aortic regurgitation
• Aortic dissection • Infective endocarditis
Mitral regurgitation
• Papillary muscle rupture due to acute MI • Infective endocarditis • Rupture of chordae due to myxomatous degeneration
Prosthetic valve failure
• Mechanical valves: fracture, jamming, thrombosis, dehiscence • Biological valves: degeneration with cusp tear

Management of shock

This is discussed in detail on page 190.

Heart failure

Heart failure describes the clinical syndrome that develops when the heart cannot maintain adequate output, or can do so only at the expense of elevated ventricular filling pressure. In mild to moderate forms of heart failure, cardiac output is normal at rest and only becomes impaired when the metabolic demand increases during exercise or some other form of stress. In practice, heart failure may be diagnosed when a patient with significant heart disease develops the signs or symptoms of a low cardiac output, pulmonary congestion or systemic venous congestion.

Almost all forms of heart disease can lead to heart failure. An accurate aetiological diagnosis (Box 18.11) is

18.11 Mechanisms of heart failure

Cause	Examples	Features
Reduced ventricular contractility	MI (segmental dysfunction)	In coronary artery disease, 'akinetic' or 'dyskinetic' segments contract poorly and may impede the function of normal segments by distorting their contraction and relaxation patterns
	Myocarditis/cardiomyopathy (global dysfunction)	Progressive ventricular dilatation
Ventricular outflow obstruction (pressure overload)	Hypertension, aortic stenosis (left heart failure) Pulmonary hypertension, pulmonary valve stenosis (right heart failure)	Initially, concentric ventricular hypertrophy allows the ventricle to maintain a normal output by generating a high systolic pressure. Later, secondary changes in the myocardium and increasing obstruction lead to failure with ventricular dilatation and rapid clinical deterioration
Ventricular inflow obstruction	Mitral stenosis, tricuspid stenosis	Small, vigorous ventricle, dilated hypertrophied atrium. Atrial fibrillation is common and often causes marked deterioration because ventricular filling depends heavily on atrial contraction
Ventricular volume overload	Ventricular septal defect Right ventricular volume overload (e.g. atrial septal defect) Increased metabolic demand (high output)	Dilatation and hypertrophy allow the ventricle to generate a high stroke volume and help to maintain a normal cardiac output. However, secondary changes in the myocardium lead to impaired contractility and worsening heart failure
Arrhythmia	Atrial fibrillation	Tachycardia does not allow for adequate filling of the heart, resulting in reduced cardiac output and back pressure
	Tachycardia cardiomyopathy	Incessant tachycardia causes myocardial fatigue
	Complete heart block	Bradycardia limits cardiac output, even if stroke volume is normal
Diastolic dysfunction	Constrictive pericarditis	Marked fluid retention and peripheral oedema, ascites, pleural effusions and elevated jugular veins
	Restrictive cardiomyopathy	Bi-atrial enlargement (restrictive filling pattern and high atrial pressures). Atrial fibrillation may cause deterioration
	Left ventricular hypertrophy and fibrosis	Good systolic function but poor diastolic filling
	Cardiac tamponade	Hypotension, elevated jugular veins, pulsus paradoxus, poor urine output

important because treatment of the underlying cause may reverse heart failure or prevent its progression.

Heart failure is most common in the elderly. The prevalence of heart failure rises from 1% in those aged 50–59 years to over 10% in those aged 80–89 years. In the UK, most patients admitted to hospital with heart failure are more than 70 years old; they remain hospitalised for a week or more and may be left with chronic disability. The most common aetiology is coronary artery disease and myocardial infarction.

Although the outlook depends, to some extent, on the underlying cause of the problem, untreated heart failure carries a poor prognosis; approximately 50% of patients with severe heart failure due to left ventricular dysfunction will die within 2 years, because of either pump failure or malignant ventricular arrhythmias.

Pathophysiology

Cardiac output is determined by preload (the volume and pressure of blood in the ventricles at the end of diastole), afterload (the volume and pressure of blood in the ventricles during systole) and myocardial contractility; this is the basis of Starling's Law (Fig. 18.22).

In patients without valvular disease, the primary abnormality is impairment of ventricular myocardial function, leading to a fall in cardiac output. This can occur because of impaired systolic contraction, impaired diastolic relaxation, or both. This activates counter-regulatory neurohumoral mechanisms that, in normal physiological circumstances, would support cardiac function but, in the setting of impaired ventricular function, can lead to a deleterious increase in both afterload and preload (Fig. 18.23). A vicious circle may be established because any additional fall in cardiac output will cause further neurohumoral activation and increasing peripheral vascular resistance.

Stimulation of the renin–angiotensin–aldosterone system leads to vasoconstriction, sodium and water retention, and sympathetic nervous system activation. This is mediated by angiotensin II, a potent constrictor of arterioles, in both the kidney and the systemic circulation (see Fig. 18.23). Activation of the sympathetic nervous system may initially sustain cardiac output through increased myocardial contractility (inotropy) and heart rate (chronotropy). Prolonged sympathetic stimulation also causes negative effects, including cardiac myocyte apoptosis, hypertrophy and focal myocardial necrosis. Sympathetic stimulation also causes peripheral vasoconstriction and arrhythmias. Sodium and water retention is promoted by the release of aldosterone, endothelin-1 (a potent vasoconstrictor peptide with marked effects on the renal vasculature) and, in severe heart failure, antidiuretic hormone (ADH). Natriuretic peptides are released from the atria in response to atrial stretch, and act as physiological antagonists to the fluid-conserving effect of aldosterone.

After MI, cardiac contractility is impaired and neurohumoral activation causes hypertrophy of non-infarcted segments, with thinning, dilatation and expansion of the

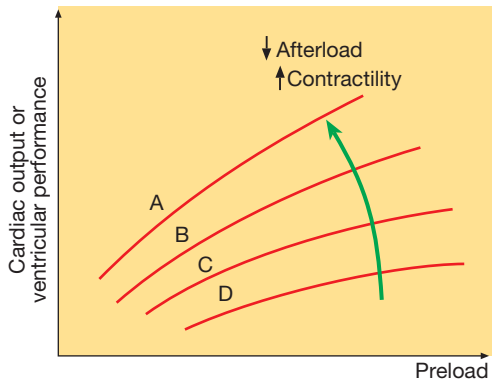

Fig. 18.22 Starling's Law. Normal (A), mild (B), moderate (C) and severe (D) heart failure. Ventricular performance is related to the degree of myocardial stretching. An increase in preload (end-diastolic volume, end-diastolic pressure, filling pressure or atrial pressure) will therefore enhance function; however, overstretching causes marked deterioration. In heart failure, the curve moves to the right and becomes flatter. An increase in myocardial contractility or a reduction in afterload will shift the curve upwards and to the left (green arrow).

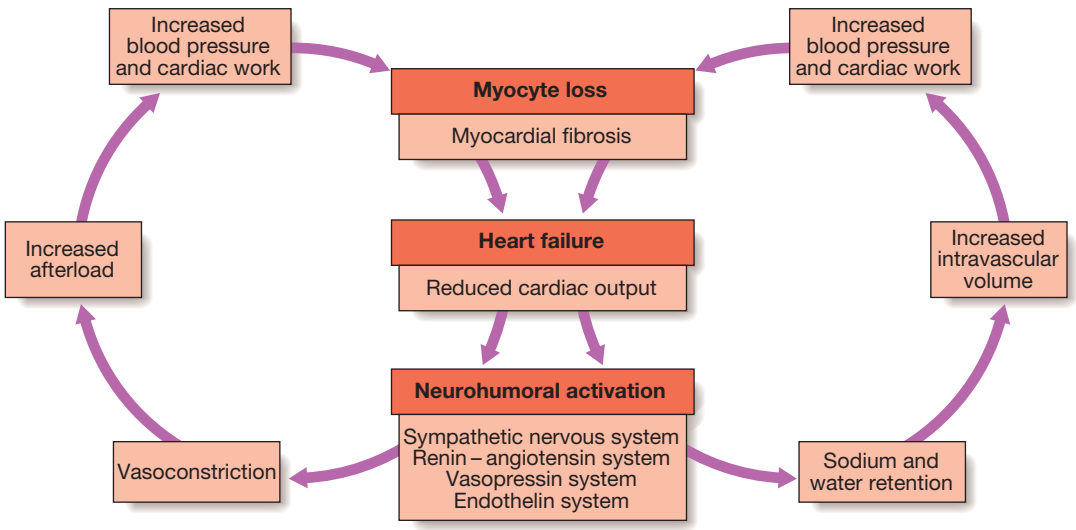

Fig. 18.23 Neurohumoral activation and compensatory mechanisms in heart failure. There is a vicious circle in progressive heart failure.

infarcted segment (remodelling; see Fig. 18.77, p. 597). This leads to further deterioration in ventricular function and worsening heart failure.

Pulmonary and peripheral oedema occurs because of high left and right atrial pressures, respectively; this is compounded by sodium and water retention, caused by impairment of renal perfusion and by secondary hyperaldosteronism.

Types of heart failure

Left, right and biventricular heart failure

The left side of the heart comprises the functional unit of the LA and LV, together with the mitral and aortic valves; the right heart comprises the RA, RV, and tricuspid and pulmonary valves.

- *Left-sided heart failure*. There is a reduction in left ventricular output and an increase in left atrial and pulmonary venous pressure. An acute increase in left atrial pressure causes pulmonary congestion or pulmonary oedema; a more gradual increase in left atrial pressure, as occurs with mitral stenosis, leads to reflex pulmonary vasoconstriction, which protects the patient from pulmonary oedema. This increases pulmonary vascular resistance and causes pulmonary hypertension, which can, in turn, impair right ventricular function.
- *Right-sided heart failure*. There is a reduction in right ventricular output and an increase in right atrial and systemic venous pressure. Causes of isolated right heart failure include chronic lung disease (cor pulmonale), pulmonary embolism and pulmonary valvular stenosis.
- *Biventricular heart failure*. Failure of the left and right heart may develop because the disease process, such as dilated cardiomyopathy or ischaemic heart disease, affects both ventricles or because disease of the left heart leads to chronic elevation of the left atrial pressure, pulmonary hypertension and right heart failure.

Diastolic and systolic dysfunction

Heart failure may develop as a result of impaired myocardial contraction (systolic dysfunction) but can also be due to poor ventricular filling and high filling pressures stemming from abnormal ventricular relaxation (diastolic dysfunction). The latter is caused by a stiff, non-compliant ventricle and is commonly found in patients with left ventricular hypertrophy. Systolic and diastolic dysfunction often coexist, particularly in patients with coronary artery disease.

High-output failure

A large arteriovenous shunt, beri-beri (p. 128), severe anaemia or thyrotoxicosis can occasionally cause heart failure due to an excessively high cardiac output.

Acute and chronic heart failure

Heart failure may develop suddenly, as in MI, or gradually, as in progressive valvular heart disease. When there is gradual impairment of cardiac function, several compensatory changes may take place.

The term 'compensated heart failure' is sometimes used to describe the condition of those with impaired cardiac function, in whom adaptive changes have prevented the development of overt heart failure. A minor event, such as an intercurrent infection or development of atrial fibrillation, may precipitate overt or acute heart failure (Box 18.12). Acute left heart failure occurs, either de novo or as an acute decompensated episode, on a background of chronic heart failure: so-called acute-on-chronic heart failure.

18.12 Factors that may precipitate or aggravate heart failure in pre-existing heart disease

- Myocardial ischaemia or infarction
- Intercurrent illness, e.g. infection
- Arrhythmia, e.g. atrial fibrillation
- Inappropriate reduction of therapy
- Administration of a drug with negative inotropic (β-blocker) or fluid-retaining properties (NSAIDs, corticosteroids)
- Pulmonary embolism
- Conditions associated with increased metabolic demand, e.g. pregnancy, thyrotoxicosis, anaemia
- IV fluid overload, e.g. post-operative IV infusion

(NSAIDs = non-steroidal anti-inflammatory drugs)

Clinical assessment

Acute left heart failure

Acute de novo left ventricular failure presents with a sudden onset of dyspnoea at rest that rapidly progresses to acute respiratory distress, orthopnoea and prostration. The precipitant, such as acute MI, is often apparent from the history.

The patient appears agitated, pale and clammy. The peripheries are cool to the touch and the pulse is rapid. Inappropriate bradycardia or excessive tachycardia should be identified promptly, as this may be the precipitant for the acute episode of heart failure. The BP is usually high because of sympathetic nervous system activation, but may be normal or low if the patient is in cardiogenic shock.

The jugular venous pressure (JVP) is usually elevated, particularly with associated fluid overload or right heart failure. In acute de novo heart failure, there has been no time for ventricular dilatation and the apex is not displaced. A 'gallop' rhythm, with a third heart sound, is heard quite early in the development of acute left-sided heart failure. A new systolic murmur may signify acute mitral regurgitation or ventricular septal rupture. Auscultatory findings in pulmonary oedema are crepitations at the lung bases, or throughout the lungs if pulmonary oedema is severe. Expiratory wheeze often accompanies this.

Acute-on-chronic heart failure will have additional features of long-standing heart failure (see below). Potential precipitants, such as an upper respiratory tract infection or inappropriate cessation of diuretic medication, should be identified.

Chronic heart failure

Patients with chronic heart failure commonly follow a relapsing and remitting course, with periods of stability and episodes of decompensation, leading to worsening symptoms that may necessitate hospitalisation. The clinical picture depends on the nature of the underlying heart disease, the type of heart failure that it has evoked, and the neurohumoral changes that have developed (see Box 18.11 and Fig. 18.24).

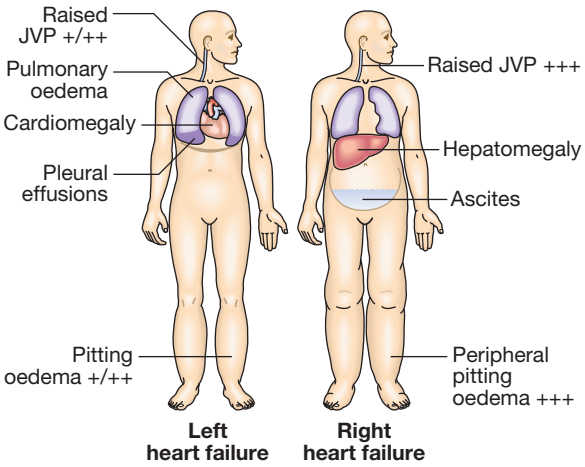

Fig. 18.24 Clinical features of left and right heart failure. (JVP = jugular venous pressure)

18.13 Differential diagnosis of peripheral oedema

- Cardiac failure: right or combined left and right heart failure, pericardial constriction, cardiomyopathy
- Chronic venous insufficiency: varicose veins
- Hypoalbuminaemia: nephrotic syndrome, liver disease, protein-losing enteropathy; often widespread, can affect arms and face
- Drugs:
  - Sodium retention: fludrocortisone, NSAIDs
  - Increasing capillary permeability: nifedipine, amlodipine
- Idiopathic: women > men
- Chronic lymphatic obstruction

Low cardiac output causes fatigue, listlessness and a poor effort tolerance; the peripheries are cold and the BP is low. To maintain perfusion of vital organs, blood flow is diverted away from skeletal muscle and this may contribute to fatigue and weakness. Poor renal perfusion leads to oliguria and uraemia.

Pulmonary oedema due to left heart failure presents as above and with inspiratory crepitations over the lung bases. In contrast, right heart failure produces a high JVP with hepatic congestion and dependent peripheral oedema. In ambulant patients, the oedema affects the ankles, whereas, in bed-bound patients, it collects around the thighs and sacrum. Ascites or pleural effusion may occur (see Fig. 18.24). Heart failure is not the only cause of oedema (Box 18.13).

Chronic heart failure is sometimes associated with marked weight loss (cardiac cachexia), caused by a combination of anorexia and impaired absorption due to gastrointestinal congestion, poor tissue perfusion due to a low cardiac output, and skeletal muscle atrophy due to immobility.

Complications

In advanced heart failure, the following may occur:

- *Renal failure* is caused by poor renal perfusion due to low cardiac output and may be exacerbated by diuretic therapy, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers.
- *Hypokalaemia* may be the result of treatment with potassium-losing diuretics or hyperaldosteronism caused by activation of the renin–angiotensin system and impaired aldosterone metabolism due to hepatic congestion. Most of the body's potassium is intracellular and there may be substantial depletion of potassium stores, even when the plasma concentration is in the reference range.
- *Hyperkalaemia* may be due to the effects of drugs which promote renal resorption of potassium, in particular the combination of ACE inhibitors (or angiotensin receptor blockers) and mineralocorticoid receptor antagonists. These effects are amplified if there is renal dysfunction due to low cardiac output or atherosclerotic renal vascular disease.
- *Hyponatraemia* is a feature of severe heart failure and is a poor prognostic sign. It may be caused by diuretic therapy, inappropriate water retention due to high ADH secretion, or failure of the cell membrane ion pump.
- *Impaired liver function* is caused by hepatic venous congestion and poor arterial perfusion, which frequently cause mild jaundice and abnormal liver function tests; reduced synthesis of clotting factors can make anticoagulant control difficult.
- *Thromboembolism*. Deep vein thrombosis and pulmonary embolism may occur due to the effects of a low cardiac output and enforced immobility. Systemic emboli occur in patients with atrial fibrillation or flutter, or with intracardiac thrombus complicating conditions such as mitral stenosis, MI or left ventricular aneurysm.
- *Atrial and ventricular arrhythmias* are very common and may be related to electrolyte changes (e.g. hypokalaemia, hypomagnesaemia), the underlying cardiac disease, and the pro-arrhythmic effects of sympathetic activation. Atrial fibrillation occurs in approximately 20% of patients with heart failure and causes further impairment of cardiac function. Sudden death occurs in up to 50% of patients with heart failure and is often due to a ventricular arrhythmia. Frequent ventricular ectopic beats and runs of non-sustained ventricular tachycardia are common findings in patients with heart failure and are associated with an adverse prognosis.

Investigations

Serum urea, creatinine and electrolytes, haemoglobin, thyroid function, ECG and chest X-ray may help to establish the nature and severity of the underlying heart disease and detect any complications. Brain natriuretic peptide (BNP) is elevated in heart failure and is a marker of risk; it is useful in the investigation of patients with breathlessness or peripheral oedema.

Echocardiography is very useful and should be considered in all patients with heart failure in order to:

- determine the aetiology
- detect hitherto unsuspected valvular heart disease, such as occult mitral stenosis, and other conditions that may be amenable to specific remedies
- identify patients who will benefit from long-term drug therapy, e.g. ACE inhibitors (see below).

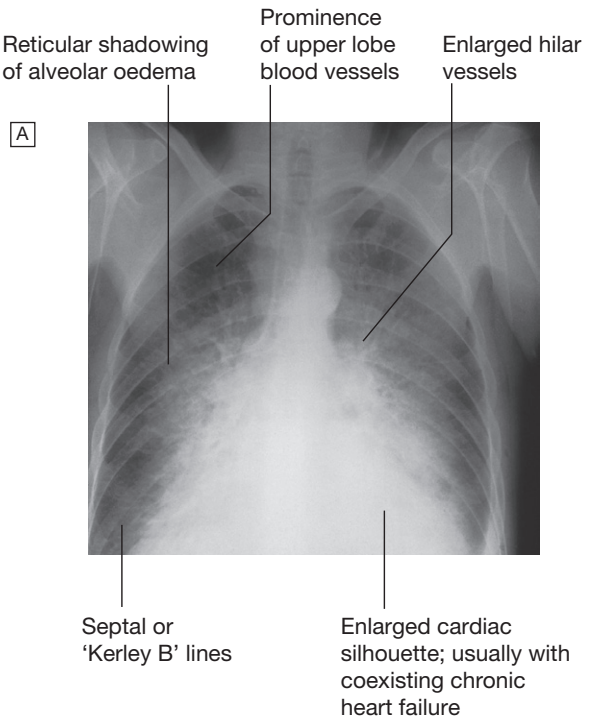

Fig. 18.25 Radiological features of heart failure. A Chest X-ray of a patient with pulmonary oedema. B Enlargement of lung base showing septal or 'Kerley B' lines (arrow).

Chest X-ray

High pulmonary venous pressure in left-sided heart failure first shows on the chest X-ray (Fig. 18.25) as an abnormal distension of the upper lobe pulmonary veins (with the patient in the erect position). The vascularity of the lung fields becomes more prominent, and the right and left pulmonary arteries dilate. Subsequently, interstitial oedema causes thickened interlobular septa and dilated lymphatics. These are evident as horizontal lines in the costophrenic angles (septal or 'Kerley B' lines). More advanced changes due to alveolar oedema cause a hazy opacification spreading from the hilar regions, and pleural effusions.

Management of acute pulmonary oedema

This is an acute medical emergency:

- Sit the patient up to reduce pulmonary congestion.
- Give oxygen (high-flow, high-concentration). Non-invasive positive pressure ventilation (continuous positive airways pressure (CPAP) of 5–10 mmHg) by a tight-fitting facemask results in a more rapid clinical improvement.
- Administer nitrates, such as IV glyceryl trinitrate (10–200 µg/min or buccal glyceryl trinitrate 2–5 mg, titrated upwards every 10 minutes), until clinical improvement occurs or systolic BP falls to less than 110 mmHg.
- Administer a loop diuretic, such as furosemide (50–100 mg IV).

The patient should initially be kept rested, with continuous monitoring of cardiac rhythm, BP and pulse oximetry. Intravenous opiates must be used sparingly in distressed patients, as they may cause respiratory depression and exacerbation of hypoxaemia and hypercapnia.

If these measures prove ineffective, inotropic agents may be required to augment cardiac output, particularly in hypotensive patients. Insertion of an intra-aortic balloon pump may be beneficial in patients with acute cardiogenic pulmonary oedema and shock.

Management of chronic heart failure

General measures

Education of patients and their relatives about the causes and treatment of heart failure can help adherence to a management plan (Box 18.14). Some patients may need to weigh themselves daily, as a measure of fluid load, and adjust their diuretic therapy accordingly. Treatment of the underlying cause of heart failure (e.g. coronary artery disease) is important to prevent its progression.

Drug therapy

Cardiac function can be improved by increasing contractility, optimising preload or decreasing afterload (see Fig. 18.23). Drugs that reduce preload are appropriate in patients with high end-diastolic filling pressures and evidence of pulmonary or systemic venous congestion. Those that reduce afterload or increase myocardial

18.14 General measures for the management of heart failure

Education
• Explanation of nature of disease, treatment and self-help strategies
Diet
• Good general nutrition and weight reduction for the obese • Avoidance of high-salt foods and added salt, especially for patients with severe congestive heart failure
Alcohol
• Moderation or elimination of alcohol consumption. Alcohol-induced cardiomyopathy requires abstinence
Smoking
• Cessation
Exercise
• Regular moderate aerobic exercise within limits of symptoms
Vaccination
• Consider influenza and pneumococcal vaccination

contractility are more useful in patients with signs and symptoms of a low cardiac output.

Diuretic therapy

In heart failure, diuretics produce an increase in urinary sodium and water excretion, leading to reduction in blood and plasma volume (p. 434). Diuretic therapy reduces preload and improves pulmonary and systemic venous congestion. It may also reduce afterload and ventricular volume, leading to a fall in ventricular wall tension and increased cardiac efficiency.

Although a fall in preload (ventricular filling pressure) tends to reduce cardiac output, the 'Starling curve' in heart failure is flat, so there may be a substantial and beneficial fall in filling pressure with little change in cardiac output (see Figs 18.22 and 18.26). Nevertheless, excessive diuretic therapy may cause an undesirable fall in cardiac output, especially in patients with a marked diastolic component to their heart failure. This leads to hypotension, lethargy and renal failure.

In some patients with severe chronic heart failure, particularly if there is associated renal impairment, oedema may persist, despite oral loop diuretic therapy. In such patients, an intravenous infusion of furosemide (5–10 mg/hr) may initiate a diuresis. Combining a loop diuretic with a thiazide diuretic (e.g. bendroflumethiazide 5 mg daily) may prove effective, but this can cause an excessive diuresis.

18.15 Congestive cardiac failure in old age

- **Incidence**: rises with age and affects 5–10% of those in their eighties.
- **Common causes**: coronary artery disease, hypertension and calcific degenerative valvular disease.
- **Diastolic dysfunction**: often prominent, particularly in those with a history of hypertension.
- **ACE inhibitors**: improve symptoms and mortality but are more frequently associated with postural hypotension and renal impairment than in younger patients.
- **Loop diuretics**: usually required but may be poorly tolerated in those with urinary incontinence and men with prostate enlargement.

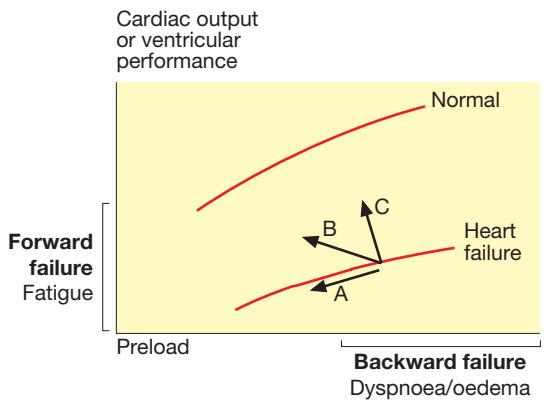

Fig. 18.26 The effect of treatment on ventricular performance curves in heart failure. Diuretics and venodilators (A), angiotensin-converting enzyme (ACE) inhibitors and mixed vasodilators (B), and positive inotropic agents (C).

Mineralocorticoid receptor antagonists, such as spironolactone and eplerenone, are potassium-sparing diuretics that are of particular benefit in patients with heart failure with severe left ventricular systolic dysfunction. They may cause hyperkalaemia, particularly when used with an ACE inhibitor. They improve long-term clinical outcome in patients with severe heart failure or heart failure following acute MI.

Angiotensin-converting enzyme inhibition therapy

Angiotensin-converting enzyme (ACE) inhibition therapy interrupts the vicious circle of neurohumoral activation that is characteristic of moderate and severe heart failure by preventing the conversion of angiotensin I to angiotensin II, thereby preventing peripheral vasoconstriction, activation of the sympathetic nervous system (Fig. 18.27), and salt and water retention due to aldosterone release. These drugs also prevent the undesirable activation of the renin–angiotensin system caused by diuretic therapy.

In moderate and severe heart failure, ACE inhibitors can produce a substantial improvement in effort tolerance and in mortality. They can also improve outcome and prevent the onset of overt heart failure in patients with poor residual left ventricular function following MI (Box 18.16).

ACE inhibitors can cause symptomatic hypotension and impairment of renal function, especially in patients with bilateral renal artery stenosis or those with pre-existing renal disease. An increase in serum potassium concentration may occur that can offset hypokalaemia associated with loop diuretic therapy. Short-acting ACE inhibitors can cause marked falls in BP, particularly in the elderly or when started in the presence of hypotension, hypovolaemia or hyponatraemia. In stable patients without hypotension (systolic BP over 100 mmHg), ACE inhibitors can usually be safely started in the community. However, in other patients, it is usually advisable to withhold diuretics for 24 hours before starting treatment with a small dose of a long-acting agent, preferably given at night (Box 18.17). Renal function and serum potassium must be monitored and should be checked 1–2 weeks after starting therapy.

EBM 18.16 ACE inhibitors and treatment of chronic heart failure

'ACE inhibitors in chronic heart failure due to ventricular dysfunction reduce mortality and re-admission rates; average NNT_B for 3 years to prevent 1 death = 26 and for the combined endpoint of death or re-admission = 19.'

- Flather M, et al. Lancet 2000; 355:1575–1581.

For further information: www.sign.ac.uk/guidelines/fulltext/95/contents.html

Angiotensin receptor blocker therapy

Angiotensin receptor blockers (ARBs; see Box 18.17) act by blocking the action of angiotensin II on the heart, peripheral vasculature and kidney. In heart failure, they produce beneficial haemodynamic changes that are similar to the effects of ACE inhibitors (see Fig. 18.27) but are generally better tolerated. They have comparable effects on mortality and are a useful alternative for patients who cannot tolerate ACE inhibitors (Box 18.18).

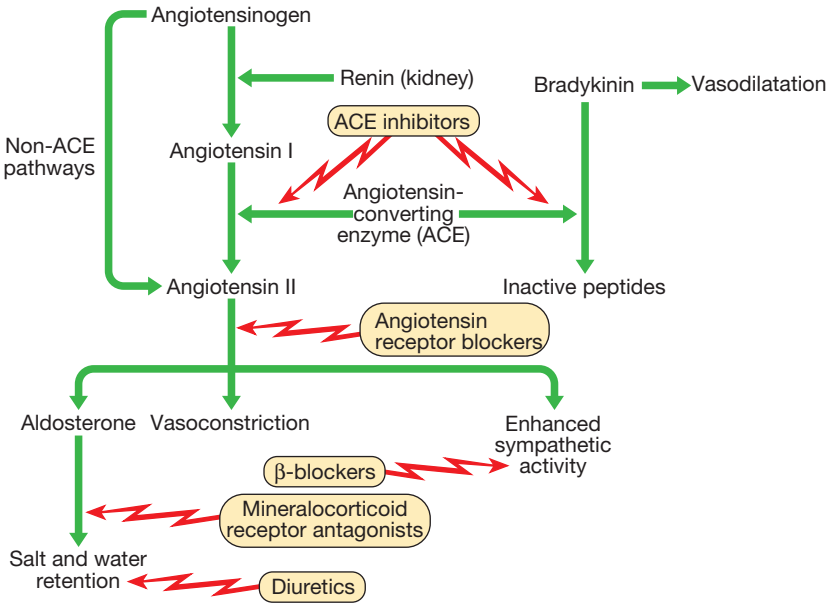

Fig. 18.27 Neurohumoral activation and sites of action of drugs used in the treatment of heart failure.

18.17 ACE inhibitor and angiotensin receptor blocker (ARB) dosages in heart failure

	Starting dose	Target dose
ACE inhibitors		
Enalapril	2.5 mg twice daily	10 mg twice daily
Lisinopril	2.5 mg daily	20 mg daily
Ramipril	1.25 mg daily	10 mg daily
Angiotensin receptor blockers		
Losartan	25 mg daily	100 mg daily
Candesartan	4 mg daily	32 mg daily
Valsartan	40 mg daily	160 mg daily

EBM 18.18 Angiotensin receptor blockers (ARBs) and chronic heart failure

'Compared with ACE inhibitors, ARBs are better tolerated and have similar efficacy in reducing cardiovascular events. ARBs reduce cardiovascular morbidity and mortality in patients with symptomatic heart failure who are intolerant of ACE inhibitors. NNT_B for 5 years to prevent 1 death or hospitalisation for heart failure = 8. The addition of an ARB to an ACE inhibitor produces further additional benefit. NNT_B for 5 years to prevent 1 death or hospitalisation for heart failure = 16.'

- Granger CB, et al. Lancet 2003; 362:772–776.
- McMurray JJV, et al. Lancet 2003; 362:767–771.

Unfortunately, they share all the more serious adverse effects of ACE inhibitors, including renal dysfunction and hyperkalaemia. ARBs are normally used as an alternative to ACE inhibitors, but the two can be combined in patients with resistant or recurrent heart failure.

Vasodilator therapy

These drugs are valuable in chronic heart failure, when ACE inhibitor or ARB drugs are contraindicated (e.g. in severe renal failure). Venodilators, such as nitrates, reduce preload, and arterial dilators, such as hydralazine, reduce afterload (see Fig. 18.26). Their use is limited by pharmacological tolerance and hypotension.

EBM 18.19 Beta-blockers and treatment of chronic heart failure

'Adding oral β-blockers gradually in small incremental doses to standard therapy, including ACE inhibitors, in people with heart failure reduces the rate of death or hospital admission. NNT_B for 1 year to prevent 1 death = 21.'

- Lechat P, et al. Circulation 1998; 98:1184–1191.
- Shibata MC, et al. Eur J Heart Fail 2001; 34:351–357.

For further information: www.escardio.org

Beta-adrenoceptor blocker therapy

Beta-blockade helps to counteract the deleterious effects of enhanced sympathetic stimulation and reduces the risk of arrhythmias and sudden death. When initiated in standard doses, they may precipitate acute-on-chronic heart failure, but when given in small incremental doses (e.g. bisoprolol started at a dose of 1.25 mg daily, and increased gradually over a 12-week period to a target maintenance dose of 10 mg daily), they can increase ejection fraction, improve symptoms, reduce the frequency of hospitalisation and reduce mortality in patients with chronic heart failure (Box 18.19). Beta-blockers are more effective at reducing mortality than ACE inhibitors: relative risk reduction of 33% versus 20%, respectively.

Ivabradine

Ivabradine acts on the I_f inward current in the SA node, resulting in reduction of heart rate. It reduces hospital admission and mortality rates in patients with heart failure due to moderate or severe left ventricular systolic impairment. In trials, its effects were most marked in patients with a relatively high heart rate (over 77/min), so ivabradine is best suited to patients who cannot take β-blockers or in whom the heart rate remains high despite β-blockade. It is ineffective in patients in atrial fibrillation.

Digoxin

Digoxin (p. 576) can be used to provide rate control in patients with heart failure and atrial fibrillation. In patients with severe heart failure (NYHA class III–IV, see Box 18.5, p. 539), digoxin reduces the likelihood of hospitalisation for heart failure, although it has no effect on long-term survival.

Amiodarone

This is a potent anti-arrhythmic drug (p. 576) that has little negative inotropic effect and may be valuable in patients with poor left ventricular function. It is only effective in the treatment of symptomatic arrhythmias, and should not be used as a preventative agent in asymptomatic patients.

Implantable cardiac defibrillators and resynchronisation therapy

Patients with symptomatic ventricular arrhythmias and heart failure have a very poor prognosis. Irrespective of their response to anti-arrhythmic drug therapy, all should be considered for implantation of a cardiac defibrillator because it improves survival (p. 579). In patients with marked intraventricular conduction delay, prolonged depolarisation may lead to uncoordinated left ventricular contraction. When this is associated with severe symptomatic heart failure, cardiac resynchronisation therapy should be considered. Here, both the LV and RV are paced simultaneously (Fig. 18.28) to generate a more coordinated left ventricular contraction and improve cardiac output. This is associated with improved symptoms and survival.

Coronary revascularisation

Coronary artery bypass surgery or percutaneous coronary intervention may improve function in areas of the myocardium that are 'hibernating' because of inadequate blood supply, and can be used to treat carefully selected patients with heart failure and coronary artery disease. If necessary, 'hibernating' myocardium can be identified by stress echocardiography and specialised nuclear or MR imaging.

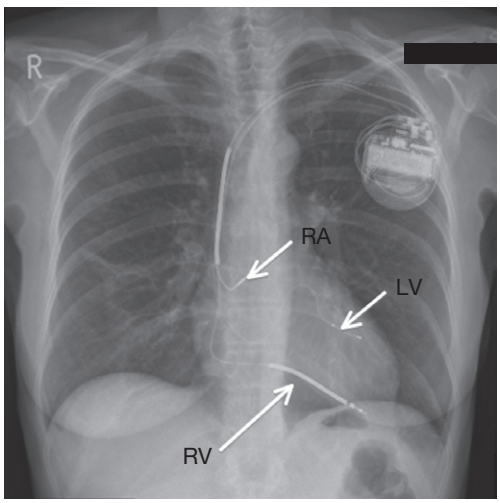

Fig. 18.28 Chest X-ray of a biventricular pacemaker and defibrillator (cardiac resynchronisation therapy). The right ventricular lead (RV) is in position in the ventricular apex and is used for both pacing and defibrillation. The left ventricular lead (LV) is placed via the coronary sinus, and the right atrial lead (RA) is placed in the right atrial appendage; both are used for pacing only.

Heart transplantation

Cardiac transplantation is an established and successful treatment for patients with intractable heart failure. Coronary artery disease and dilated cardiomyopathy are the most common indications. The introduction of ciclosporin for immunosuppression (p. 96) has improved survival, which is around 80% at 1 year. The use of transplantation is limited by the efficacy of modern drug and device therapies, as well as the availability of donor hearts, so it is generally reserved for young patients with severe symptoms despite optimal therapy.

Conventional heart transplantation is contraindicated in patients with pulmonary vascular disease due to long-standing left heart failure, complex congenital heart disease (e.g. Eisenmenger's syndrome) or primary pulmonary hypertension because the RV of the donor heart may fail in the face of high pulmonary vascular resistance. However, heart–lung transplantation can be successful in patients with Eisenmenger's syndrome. Lung transplantation has been used for primary pulmonary hypertension.

Although cardiac transplantation usually produces a dramatic improvement in the recipient's quality of life, serious complications may occur:

- *Rejection*. In spite of routine therapy with ciclosporin A, azathioprine and corticosteroids, episodes of rejection are common and may present with heart failure, arrhythmias or subtle ECG changes; cardiac biopsy is often used to confirm the diagnosis before starting treatment with high-dose corticosteroids.
- *Accelerated atherosclerosis*. Recurrent heart failure is often due to progressive atherosclerosis in the coronary arteries of the donor heart. This is not confined to patients who underwent transplantation for coronary artery disease and is probably a manifestation of chronic rejection. Angina is rare because the heart has been denervated.
- *Infection*. Opportunistic infection with organisms such as cytomegalovirus or *Aspergillus* remains a major cause of death in transplant recipients.

Ventricular assist devices

Because of the limited supply of donor organs, ventricular assist devices (VADs) have been employed as:

- a bridge to cardiac transplantation
- potential long-term therapy
- short-term restoration therapy following a potentially reversible insult, e.g. viral myocarditis.

VADs assist cardiac output by using a roller, centrifugal or pulsatile pump that, in some cases, is implantable and portable. They withdraw blood through cannulae inserted in the atria or ventricular apex and pump it into the pulmonary artery or aorta. They are designed not only to unload the ventricles but also to provide support to the pulmonary and systemic circulations. Their more widespread application is limited by high complication rates (haemorrhage, systemic embolism, infection, neurological and renal sequelae), although some improvements in survival and quality of life have been demonstrated in patients with severe heart failure.

Syncope and presyncope

The term 'syncope' refers to sudden loss of consciousness due to reduced cerebral perfusion. 'Presyncope' refers to lightheadedness in which the individual thinks he or she may black out. Syncope affects around 20% of the population at some time and accounts for more than 5% of hospital admissions. Dizziness and presyncope are very common in old age (p. 173). Symptoms are disabling, undermine confidence and independence, and can affect an individual's ability to work or to drive. There are three principal mechanisms that underlie recurrent presyncope or syncope:

- *cardiac syncope* due to mechanical cardiac dysfunction or arrhythmia
- *neurocardiogenic syncope*, in which an abnormal autonomic reflex causes bradycardia and/or hypotension
- *postural hypotension*, in which physiological peripheral vasoconstriction on standing is impaired, lead to hypotension.

Loss of consciousness can also be caused by non-cardiac pathology, such as epilepsy, cerebrovascular ischaemia or hypoglycaemia (Fig. 18.29).

Differential diagnosis

History-taking, from the patient or a witness, is the key to establishing a diagnosis. Attention should be paid to potential triggers (e.g. medication, exertion, posture), the victim's appearance (e.g. colour, seizure activity), the duration of the episode and the speed of recovery (Box 18.20). Cardiac syncope is usually sudden but can be associated with premonitory lightheadedness, palpitation or chest discomfort. The blackout is usually brief and recovery rapid. Neurocardiogenic syncope will often be associated with a situational trigger, and the patient may experience flushing, nausea and malaise for several minutes afterwards. Patients with seizures do not exhibit pallor, may have abnormal movements, usually take more than 5 minutes to recover and are often confused. A history of rotational vertigo is suggestive of a labyrinthine or vestibular disorder (p. 1167). The pattern and description of the patient's symptoms should indicate the probable mechanism and help to determine subsequent investigations (Fig. 18.30). Postural hypotension is normally obvious from the history, with presyncope or, less commonly, syncope, occurring within a few seconds of standing.

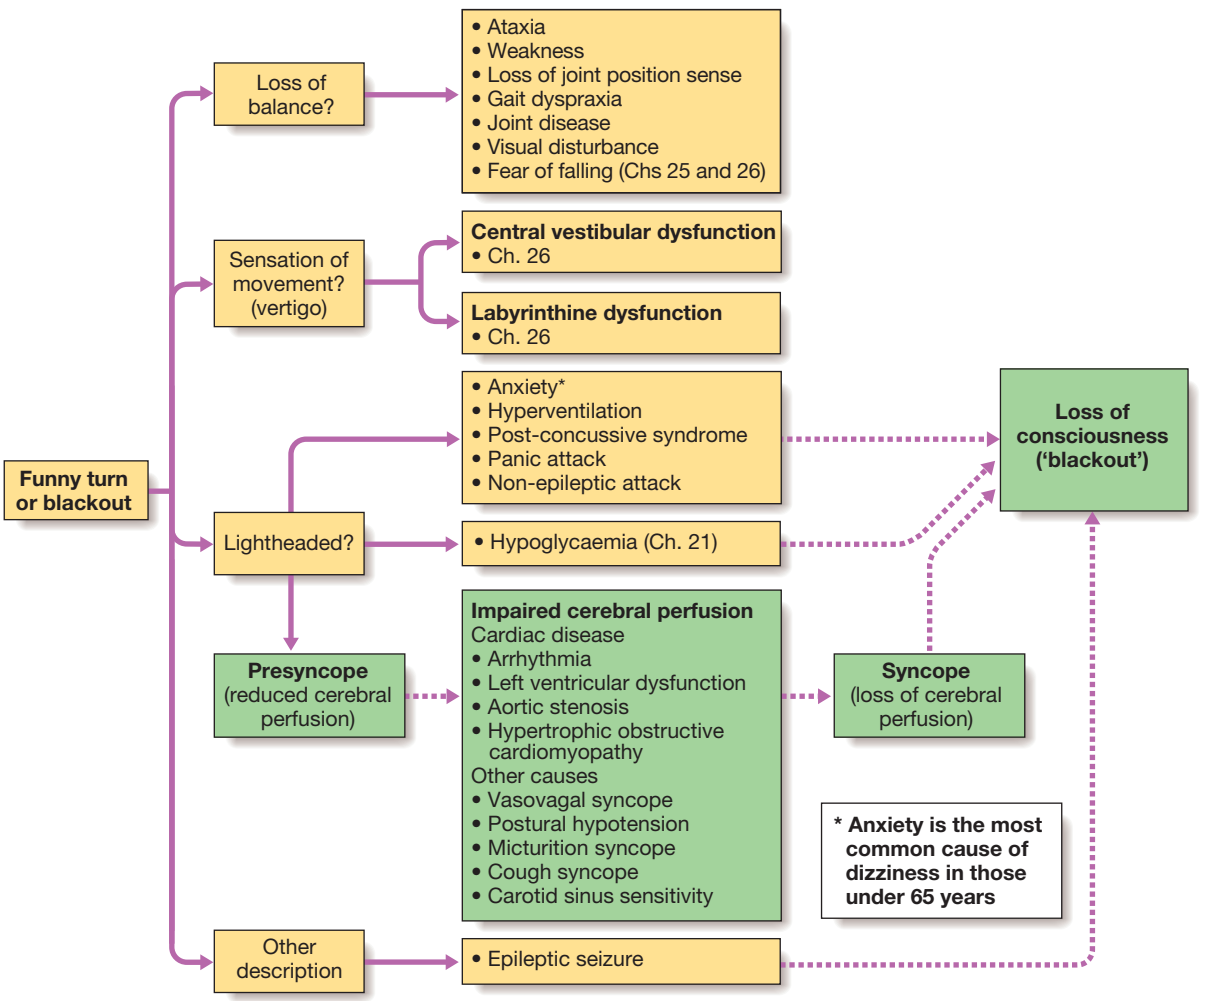

Fig. 18.29 The differential diagnosis of syncope and presyncope.

18.20 Typical features of cardiac syncope, vasovagal syncope and seizures

	Cardiac syncope	Neurocardiogenic syncope	Seizures
Premonitory symptoms	Often none Lightheadedness Palpitation Chest pain Breathlessness	Nausea Lightheadedness Sweating	Confusion Hyperexcitability Olfactory hallucinations 'Aura'
Unconscious period	Extreme 'death-like' pallor	Pallor	Prolonged (> 1 min) unconsciousness Motor seizure activity* Tongue-biting Urinary incontinence
Recovery	Rapid recovery (< 1 min) Flushing	Slow Nausea Lightheadedness	Prolonged confusion (> 5 mins) Headache Focal neurological signs

***N.B.** Cardiac syncope can also cause convulsions by inducing cerebral anoxia.

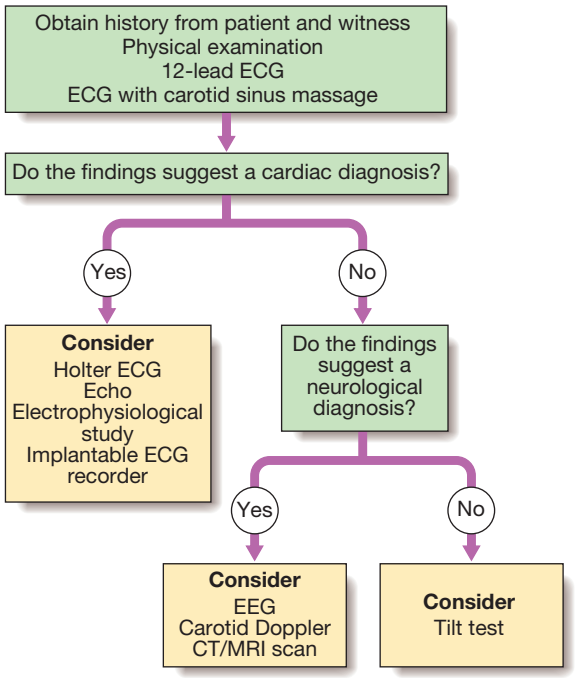

Fig. 18.30 A simple guide to the investigation and diagnosis of recurrent presyncope and syncope.

Cardiac syncope

Arrhythmia

Lightheadedness may occur with many arrhythmias, but blackouts (Stokes–Adams attacks, p. 572) are usually due to profound bradycardia or malignant ventricular tachyarrhythmias. The 12-lead ECG may show evidence of conducting system disease (e.g. sinus bradycardia, atrioventricular block, bundle branch block or axis deviation), which would predispose a patient to bradycardia, but the key to establishing a diagnosis is to obtain an ECG recording *while symptoms are present*. Since minor rhythm disturbances are common, especially in old age, symptoms must occur at the same time as a recorded arrhythmia before a diagnosis can be made. Ambulatory ECG recordings are helpful only if symptoms occur several times per week. Patient-activated ECG recorders are useful for examining the rhythm in patients with recurrent dizziness but are not useful in assessing sudden blackouts. When these investigations fail to establish a cause in patients with presyncope or syncope, an implantable ECG recorder can be sited subcutaneously over the upper left chest. This device continuously records the cardiac rhythm and will activate automatically if extreme bradycardia or tachycardia occurs. The ECG memory can also be tagged by the patient, using a hand-held activator. Stored ECGs can be accessed by the implanting centre, using a telemetry device in a clinic, or using a home monitoring system via an online link.

Structural heart disease

Severe aortic stenosis and hypertrophic obstructive cardiomyopathy can lead to lightheadedness or syncope on exertion. This is caused by profound hypotension due to a fall in cardiac output, or failure to increase output during exertion, coupled with exercise-induced peripheral vasodilatation. Severe coronary artery disease can produce the same symptoms because of ischaemic left ventricular dysfunction. Exertional arrhythmias also occur in these patients.

Neurocardiogenic syncope

This encompasses a family of syndromes in which bradycardia and/or hypotension occur because of a series of abnormal autonomic reflexes. The two main conditions are hypersensitive carotid sinus syndrome and malignant vasovagal syncope.

Situational syncope

This is the collective name given to some variants of neurocardiogenic syncope that occur in the presence of identifiable triggers (e.g. cough syncope, micturition syncope).

Vasovagal syncope

This is normally triggered by a reduction in venous return due to prolonged standing, excessive heat or a large meal. It is mediated by the Bezold–Jarisch reflex, in which a combination of sympathetic activation, and

reduced venous return due to an impaired vasoconstrictor response to standing, leads to vigorous contraction of relatively under-filled ventricles. This stimulates ventricular mechanoreceptors, producing parasympathetic (vagal) activation and sympathetic withdrawal, causing bradycardia, vasodilatation or both. Head-up tilt-table testing is a provocation test used to establish the diagnosis, and involves positioning the patient supine on a padded table that is then tilted to an angle of 60–70° for up to 45 minutes, while the ECG and BP responses are monitored. A positive test is characterised by bradycardia (cardio-inhibitory response) and/or hypotension (vasodepressor response) associated with typical symptoms. Initial management involves lifestyle modification (salt supplementation and avoiding prolonged standing, dehydration or missing meals). In resistant cases, drug therapy can be tried, although efficacy is inconsistent in clinical trials. Fludrocortisone (causes sodium and water retention and expands plasma volume), disopyramide (a vagolytic agent) or midodrine (a vasoconstrictor α-adrenoceptor agonist) may be helpful. Beta-blockers (inhibit the initial sympathetic activation) are seldom effective and are rarely used. In patients with resistant vasovagal syncope in which bradycardia is the predominant response, a dual-chamber pacemaker can be useful. Patients with a urinary sodium excretion of less than 170 mmol/day may respond to salt loading.

Hypersensitive carotid sinus syndrome

Hypersensitive carotid sinus syndrome (HCSS) causes presyncope or syncope because of reflex bradycardia and vasodilatation. Carotid baroreceptors are involved in BP regulation and are activated by increased BP, resulting in a vagal discharge that causes a compensatory drop in BP. In HCSS, the baroreceptor is sensitive to external pressure (e.g. during neck movement or if a tight collar is worn), so that pressure over the carotid artery causes an inappropriate and intense vagal discharge. The diagnosis can be established by monitoring the ECG and BP during carotid sinus pressure. This manœuvre should not be attempted in patients with a carotid bruit or with a history of cerebrovascular disease because of the risk of embolic stroke. A positive cardio-inhibitory response is defined as a sinus pause of 3 seconds or more; a positive vasodepressor response is defined as a fall in systolic BP of more than 50 mmHg. Carotid sinus pressure will produce positive findings in about 10% of elderly individuals but less than 25% of these experience spontaneous syncope. Symptoms should not therefore be attributed to HCSS unless they are reproduced by carotid sinus pressure. Dual-chamber pacemaker implantation usually prevents syncope in patients with the more common cardio-inhibitory response.

Postural hypotension

This is caused by a failure of normal postural compensatory mechanisms. Relative hypovolaemia (often due to excessive diuretic therapy), sympathetic degeneration (diabetes mellitus, Parkinson's disease, ageing) and drug therapy (vasodilators, antidepressants) can all cause or aggravate the problem. Treatment is often ineffective; however, withdrawing unnecessary medication and advising the patient to wear graduated elastic stockings and to get up slowly may be helpful. Fludrocortisone, which can expand blood volume through sodium and water retention, may be of value.

Palpitation

Palpitation is a very common and sometimes frightening symptom. Patients use the term to describe many sensations, including an unusually erratic, fast, slow or forceful heart beat, or even chest pain or breathlessness. Initial evaluation should concentrate on determining its likely mechanism, and whether or not there is significant underlying heart disease.

A detailed description of the sensation is essential and patients should be asked to describe their symptoms clearly, or to demonstrate the sensation of rhythm by tapping with their hand. A provisional diagnosis can usually be made on the basis of a thorough history (Box 18.21 and Fig. 18.31). The diagnosis should be confirmed by an ECG recording during an episode using an ambulatory ECG monitor or a patient-activated ECG recorder.

18.21 How to evaluate palpitation

- Is the palpitation continuous or intermittent?
- Is the heart beat regular or irregular?
- What is the approximate heart rate?
- Do symptoms occur in discrete attacks?
  Is the onset abrupt? How do attacks terminate?
- Are there any associated symptoms?
  e.g. Chest pain, lightheadedness, polyuria (a feature of supraventricular tachycardia, p. 567)
- Are there any precipitating factors, e.g. exercise, alcohol?
- Is there a history of structural heart disease, e.g. coronary artery disease, valvular heart disease?

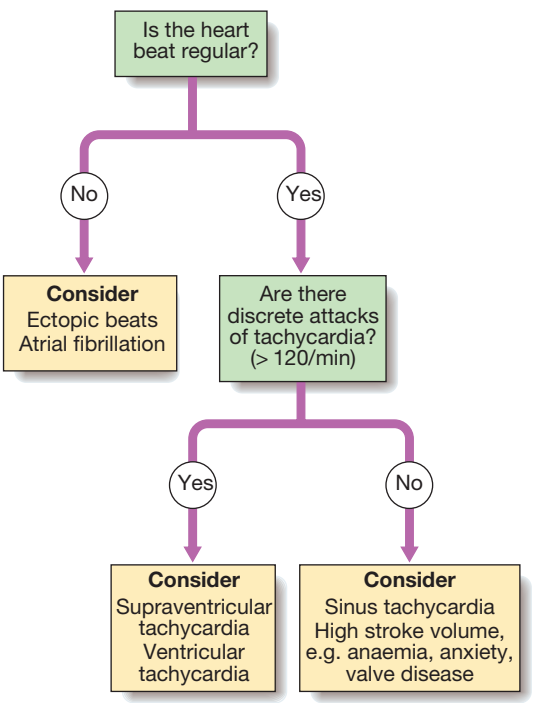

Fig. 18.31 A simple approach to the diagnosis of palpitation.

Recurrent but short-lived bouts of an irregular heart beat are usually due to atrial or ventricular extrasystoles (ectopic beats). Some patients will describe the experience as a 'flip' or a 'jolt' in the chest, while others report dropped or missed beats. Extrasystoles are often more frequent during periods of stress or debility; they can be triggered by alcohol or nicotine.

Episodes of a pounding, forceful and relatively fast (90–120 /min) heart beat are a common manifestation of anxiety. These may also reflect a hyperdynamic circulation, such as anaemia, pregnancy and thyrotoxicosis, and can occur in some forms of valve disease (e.g. aortic regurgitation). Discrete bouts of a very rapid (over 120/min) heart beat are more likely to be due to a paroxysmal tachyarrhythmia. Supraventricular and ventricular tachycardias may present in this way. In contrast, episodes of atrial fibrillation typically present with irregular and usually rapid palpitation.

Palpitation is usually benign and, even if the patient's symptoms are due to an arrhythmia, the outlook is good if there is no underlying structural heart disease. Most cases are due to an awareness of the normal heart beat, a sinus tachycardia or benign extrasystoles, in which case an explanation and reassurance may be all that is required. Palpitation associated with presyncope or syncope may reflect more serious structural or electrical disease and should be investigated without delay.

The diagnosis and management of individual arrhythmias are considered on pages 562–579.

Cardiac arrest and sudden cardiac death

Cardiac arrest describes the sudden and complete loss of cardiac output due to asystole, ventricular tachycardia or fibrillation, or loss of mechanical cardiac contraction (pulseless electrical activity). The clinical diagnosis is based on the victim being unconscious and pulseless; breathing may take some time to stop completely after cardiac arrest. Death is virtually inevitable, unless effective treatment is given promptly.

18.22 Causes of sudden arrhythmic death

Coronary artery disease (85%)

- Myocardial ischaemia
- Acute MI
- Prior MI with myocardial scarring

Structural heart disease (10%)

- Aortic stenosis (p. 620)
- Hypertrophic cardiomyopathy (p. 637)
- Dilated cardiomyopathy (p. 636)
- Arrhythmogenic right ventricular dysplasia (p. 638)
- Congenital heart disease (p. 629)

No structural heart disease (5%)

- Long QT syndrome (p. 570)
- Brugada syndrome (p. 571)
- Wolff–Parkinson–White syndrome (p. 568)
- Adverse drug reactions (torsades de pointes, p. 570)
- Severe electrolyte abnormalities

Sudden cardiac death is usually caused by a catastrophic arrhythmia and accounts for 25–30% of deaths from cardiovascular disease, claiming an estimated 70 000–90 000 lives each year in the UK. Many of these deaths are potentially preventable. Arrhythmias complicate many types of heart disease and can sometimes occur in the absence of recognisable structural abnormalities (causes are listed in Box 18.22). Sudden death less often occurs because of an acute mechanical catastrophe such as cardiac rupture or aortic dissection (pp. 597 and 605).

Coronary artery disease is the most common condition leading to cardiac arrest. Ventricular fibrillation or ventricular tachycardia is common in the first few hours of MI and many victims die before medical help is sought. Up to one-third of people developing MI die before reaching hospital, emphasising the importance of educating the public to recognise symptoms and to seek medical help quickly. Acute myocardial ischaemia (in the absence of infarction) can also cause these arrhythmias, although less commonly. Patients with a history of previous MI may be at risk of sudden arrhythmic death, especially if there is extensive left ventricular scarring and impairment, or if there is ongoing myocardial ischaemia. In these patients, the risk is reduced by the treatment of heart failure with β-blockers and ACE inhibitors, and by coronary revascularisation. For some patients, the risk of sudden death is reduced by the implantation of a cardiac defibrillator (p. 579).

Aetiology of cardiac arrest

Cardiac arrest may be caused by ventricular fibrillation, pulseless ventricular tachycardia, asystole or pulseless electrical activity.

Ventricular fibrillation and pulseless ventricular tachycardia

These are the most common and most easily treatable cardiac arrest rhythms. Ventricular fibrillation produces rapid, ineffective, uncoordinated movement of the ventricles, which therefore produces no pulse. The ECG (Fig. 18.32) shows rapid, bizarre and irregular ventricular complexes. Ventricular tachycardia (p. 569) can cause cardiac arrest if the ventricular rate is so rapid that effective mechanical contraction and relaxation cannot occur, especially in the presence of severe left ventricular impairment. It may degenerate into ventricular fibrillation. Defibrillation will restore cardiac output in more than 80% of patients, if delivered immediately. However, the chances of survival fall by at least 10% with each minute's delay, and by more if basic life support is not given (see below); thus provision of these is the key to survival.

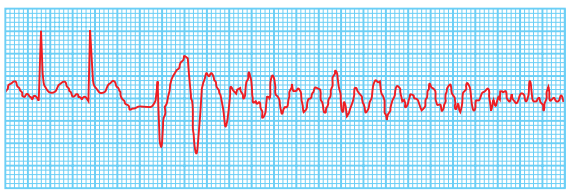

Fig. 18.32 Ventricular fibrillation. A bizarre chaotic rhythm, initiated in this case by two ventricular ectopic beats in rapid succession.

Asystole

This occurs when there is no electrical activity within the ventricles and is usually due to failure of the conducting tissue or massive ventricular damage complicating MI. A precordial thump, external cardiac massage, or administration of intravenous atropine or adrenaline (epinephrine) may restore cardiac activity. When due to conducting tissue failure, permanent pacemaker implantation will be required if the individual survives.

Pulseless electrical activity

This occurs when there is no effective cardiac output despite the presence of organised electrical activity. It may be caused by reversible conditions, such as hypovolaemia, cardiac tamponade or tension pneumothorax (see Fig. 18.35 below), but is often due to a catastrophic event, such as cardiac rupture or massive pulmonary embolism, and therefore carries an extremely poor prognosis.

Management of cardiac arrest

The Chain of Survival

This term refers to the sequence of events that is necessary to maximise the chances of a cardiac arrest victim surviving (Fig. 18.33). Survival is most likely if all links in the chain are strong: that is, if the arrest is witnessed, help is called immediately, basic life support is administered by a trained individual, the emergency medical services respond promptly, and defibrillation is achieved within a few minutes. Good training in both basic and advanced life support is essential and should be maintained by regular refresher courses. In recent years, public access defibrillation has been introduced in places of high population density, particularly where traffic congestion may impede the response of emergency services, such as railway stations, airports and sports stadia. Designated individuals can respond to a cardiac arrest using basic life support and an automated external defibrillator.

Basic life support

Basic life support (BLS) encompasses manœuvres that aim to maintain a low level of circulation until more definitive treatment with advanced life support can be given. The ABCDE approach to management of the collapsed patient should be followed: prompt assessment and restoration of the Airway, maintenance of ventilation using rescue Breathing ('mouth-to-mouth' breathing), maintenance of the Circulation using chest compressions; Disability, in resuscitated patients, refers to assessment of neurological status, and Exposure entails removal of clothes to enable defibrillation, auscultation of the chest, and assessment for a rash caused by anaphylaxis, injuries or so on (Fig. 18.34). Chest compression-only ('hands-only') CPR is easier for members of the public to learn and administer, and is now advocated in public education campaigns.

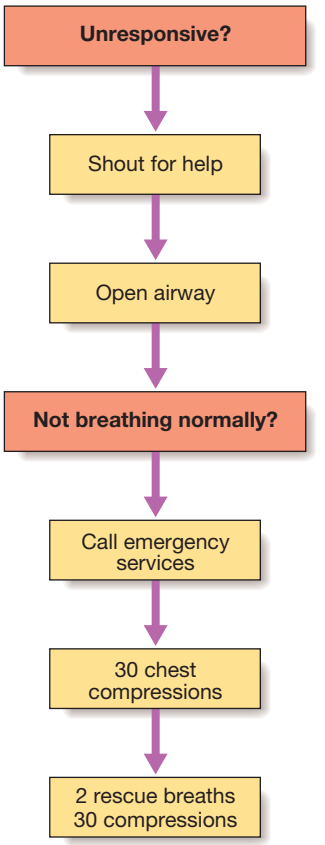

Fig. 18.34 Algorithm for adult basic life support. For further information see www.resus.org.uk. From Resuscitation Council (UK) guidelines – see p. 641.

Advanced life support (ALS)

ALS (Fig. 18.35) aims to restore normal cardiac rhythm by defibrillation when the cause of cardiac arrest is due to a tachyarrhythmia, or to restore cardiac output by correcting other reversible causes of cardiac arrest. ALS can also involve administration of intravenous drugs to

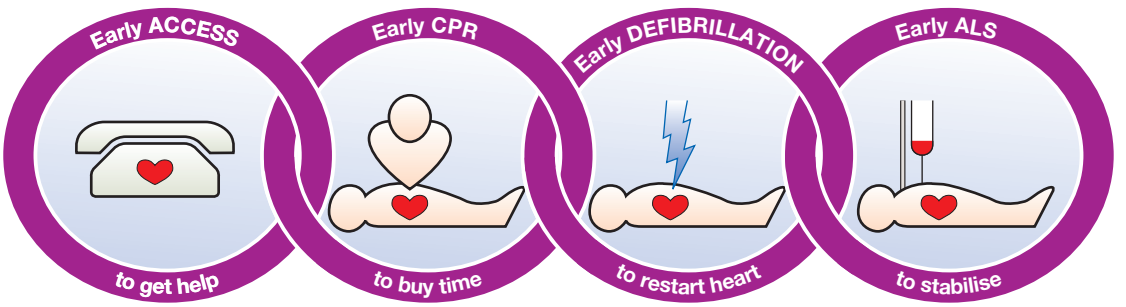

Fig. 18.33 The Chain of Survival in cardiac arrest. (ALS = advanced life support; CPR = cardiopulmonary resuscitation)

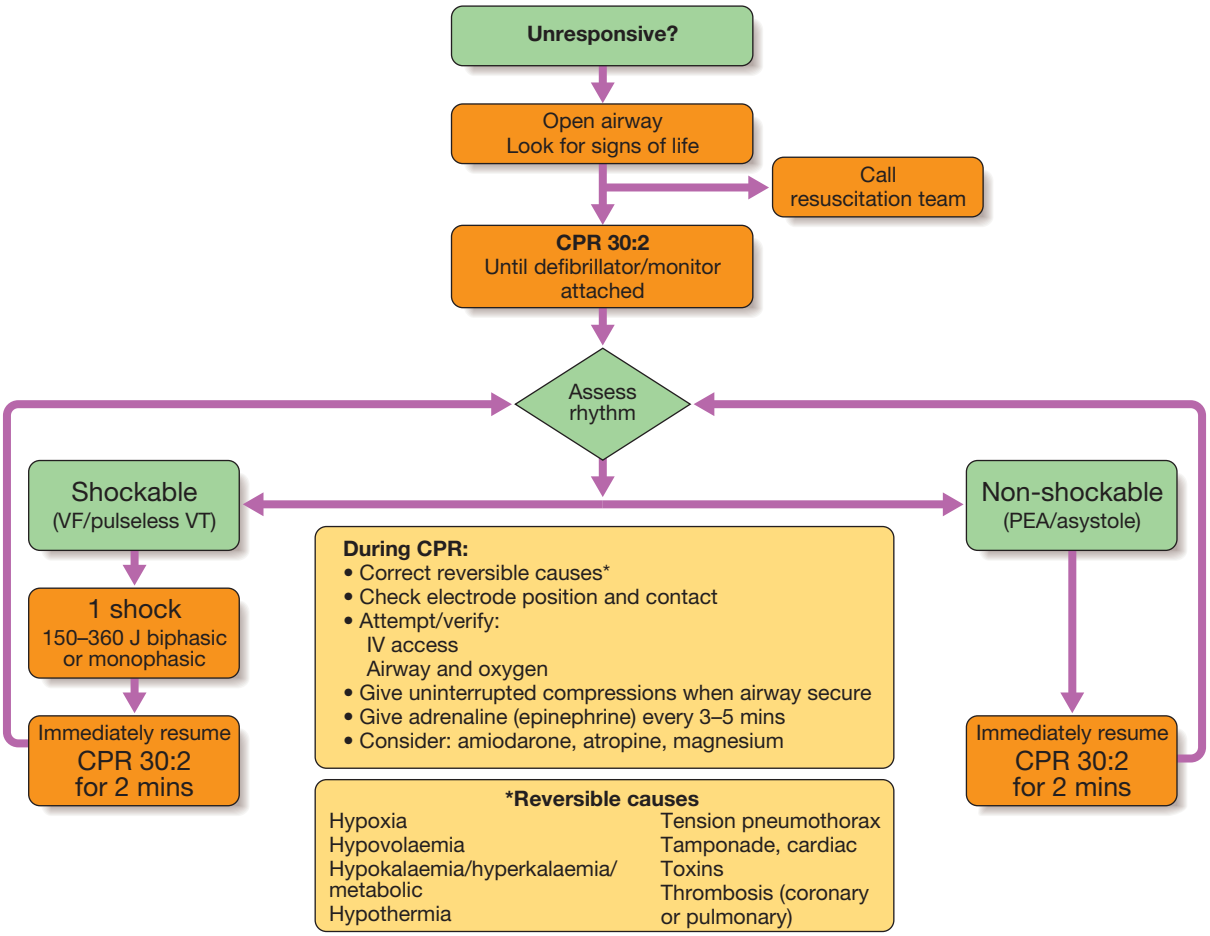

Fig. 18.35 Algorithm for adult advanced life support. For further information see www.resus.org.uk (CPR = cardiopulmonary resuscitation: PEA = pulseless electrical activity; VF = ventricular fibrillation; VT = pulseless ventricular tachycardia) From Resuscitation Council (UK) guidelines – see p. 641.

support the circulation, and endotracheal intubation to ventilate the lungs.

If cardiac arrest is witnessed, a precordial thump may sometimes convert ventricular fibrillation or tachycardia to normal rhythm, but this is futile if cardiac arrest has lasted longer than a few seconds. The priority is to assess the patient's cardiac rhythm by attaching a defibrillator or monitor. Ventricular fibrillation or pulseless ventricular tachycardia is treated with immediate defibrillation. Defibrillation is more likely to be effective if a biphasic shock defibrillator is used, where the polarity of the shock is reversed midway through its delivery. Defibrillation is usually administered using a 150-Joule biphasic shock, and CPR resumed immediately for 2 minutes without attempting to confirm restoration of a pulse, because restoration of mechanical cardiac output rarely occurs immediately after successful defibrillation. If, after 2 minutes, a pulse is not restored, a further biphasic shock of 150–200 joules is given. Thereafter, additional biphasic shocks of 150–200 joules are given every 2 minutes after each cycle of cardiopulmonary resuscitation (CPR). During resuscitation, adrenaline (epinephrine, 1 mg IV) should be given every 3–5 minutes and consideration given to the use of intravenous amiodarone, especially if ventricular fibrillation or ventricular tachycardia re-initiates after successful defibrillation.

Ventricular fibrillation of low amplitude, or 'fine VF', may mimic asystole. If asystole cannot be confidently diagnosed, the patient should be treated for VF and defibrillated. If an electrical rhythm is observed that would be expected to produce a cardiac output, 'pulseless electrical activity' is present. Pulseless electrical activity is treated by continuing CPR and adrenaline (epinephrine) administration whilst seeking such causes. Asystole is treated similarly, with the additional support of atropine and sometimes external or transvenous pacing in an attempt to generate an electrical rhythm.

There are many potentially reversible causes of cardiac arrest and the main causes can be easily remembered as a list of four Hs and four Ts (see Fig. 18.35).

Survivors of cardiac arrest

Patients who survive a cardiac arrest caused by acute MI need no specific treatment beyond that given to those recovering from an uncomplicated infarct, since their prognosis is similar (p. 599). Those with reversible causes, such as exercise-induced ischaemia or aortic stenosis, should have the underlying cause treated if possible. Survivors of ventricular tachycardia or ventricular

fibrillation arrest in whom no reversible cause can be identified may be at risk of another episode, and should be considered for an implantable cardiac defibrillator (p. 579) and anti-arrhythmic drug therapy.

Abnormal heart sounds and murmurs

The first indication of heart disease may be the discovery of an abnormal sound on auscultation (Box 18.23). This may be incidental – for example, during a routine childhood examination – or may be prompted by symptoms of heart disease. Clinical evaluation is helpful, and is supported by more detailed evaluation of the abnormal sound or murmur using echocardiography.

Is the sound cardiac?

Additional heart sounds and murmurs demonstrate a consistent relationship to a specific part of the cardiac cycle but extracardiac sounds (e.g. pleural rub or venous hum) do not. Pericardial friction produces a characteristic scratching noise (a pericardial 'rub'), which may have two components corresponding to atrial and ventricular systole, and may vary with posture and respiration.

Is the sound pathological?

Pathological sounds and murmurs are the product of turbulent blood flow or rapid ventricular filling due to abnormal loading conditions. Some added sounds are physiological but may also occur in pathological conditions; for example, a third sound is common in young people and in pregnancy but is also a feature of heart failure (see Box 18.23). Similarly, a systolic murmur due to turbulence across the right ventricular outflow tract may occur in hyperdynamic states (e.g. anaemia, pregnancy), but may also be due to pulmonary stenosis or an intracardiac shunt leading to volume overload of the RV (e.g. atrial septal defect).

Benign murmurs do not occur in diastole (Box 18.24), and systolic murmurs that radiate or are associated with a thrill are almost always pathological.

Auscultatory evaluation of a heart murmur

Timing, intensity, location, radiation and quality are all useful clues to the origin and nature of a heart murmur (Box 18.25). Radiation of a murmur is determined by the direction of turbulent blood flow and is only detectable when there is a high-velocity jet, such as in mitral regurgitation (radiation from apex to axilla) or aortic stenosis (radiation from base to neck). Similarly, the pitch and quality of the sound can help to distinguish the murmur,

18.24 Features of a benign or innocent heart murmur

- Soft
- Mid-systolic
- Heard at left sternal edge
- No radiation
- No other cardiac abnormalities

18.23 Normal and abnormal heart sounds

Sound	Timing	Characteristics	Mechanisms	Variable features
First heart sound (S1)	Onset of systole	Usually single or narrowly split	Closure of mitral and tricuspid valves	Loud: hyperdynamic circulation (anaemia, pregnancy, thyrotoxicosis); mitral stenosis Soft: heart failure; mitral regurgitation
Second heart sound (S2)	End of systole	Split on inspiration Single on expiration (p. 532)	Closure of aortic and pulmonary valve A_2 first P_2 second	Fixed wide splitting with atrial septal defect Wide but variable splitting with delayed right heart emptying (e.g. right bundle branch block) Reversed splitting due to delayed left heart emptying (e.g. left bundle branch block)
Third heart sound (S3)	Early in diastole, just after S2	Low pitch, often heard as 'gallop'	From ventricular wall due to abrupt cessation of rapid filling	Physiological: young people, pregnancy Pathological: heart failure, mitral regurgitation
Fourth heart sound (S4)	End of diastole, just before S1	Low pitch	Ventricular origin (stiff ventricle and augmented atrial contraction) related to atrial filling	Absent in atrial fibrillation A feature of severe left ventricular hypertrophy (e.g. hypertrophic cardiomyopathy)
Systolic clicks	Early or mid-systole	Brief, high-intensity sound	Valvular aortic stenosis Valvular pulmonary stenosis Floppy mitral valve Prosthetic heart sounds from opening and closing of normally functioning mechanical valves	Click may be lost when stenotic valve becomes thickened or calcified Prosthetic clicks lost when valve obstructed by thrombus or vegetations
Opening snap (OS)	Early in diastole	High pitch, brief duration	Opening of stenosed leaflets of mitral valve Prosthetic heart sounds	Moves closer to S2 as mitral stenosis becomes more severe. May be absent in calcific mitral stenosis

18.25 How to assess a heart murmur

When does it occur?	Time the murmur using heart sounds, carotid pulse and the apex beat. Is it systolic or diastolic? Does the murmur extend throughout systole or diastole or is it confined to a shorter part of the cardiac cycle?
How loud is it? (intensity)	Grade 1: very soft (only audible in ideal conditions) Grade 2: soft Grade 3: moderate Grade 4: loud with associated thrill Grade 5: very loud Grade 6: heard without stethoscope N.B. Diastolic murmurs are sometimes graded 1–4
Where is it heard best? (location)	Listen over the apex and base of the heart, including the aortic and pulmonary areas
Where does it radiate?	Listen at the neck, axilla or back
What does it sound like? (pitch and quality)	Pitch is determined by flow (high pitch indicates high-velocity flow) Is the intensity constant or variable?

such as the 'blowing' murmur of mitral regurgitation or the 'rasping' murmur of aortic stenosis.

The position of a murmur in relation to the cardiac cycle is crucial and should be assessed by timing it with the heart sounds, carotid pulse and apex beat (Figs 18.36 and 18.37).

Systolic murmurs

Ejection systolic murmurs are associated with ventricular outflow tract obstruction and occur in mid-systole with a crescendo–decrescendo pattern, reflecting the changing velocity of blood flow (Box 18.26). Pansystolic murmurs maintain a constant intensity and extend from the first heart sound throughout systole to the second heart sound, sometimes obscuring it. They occur when blood leaks from a ventricle into a low-pressure chamber at an even or constant velocity. Mitral regurgitation, tricuspid regurgitation and ventricular septal defect are the only causes of a pansystolic murmur. Late systolic murmurs are unusual but may occur in mitral valve prolapse, if the mitral regurgitation is confined to late systole, and hypertrophic obstructive cardiomyopathy, if dynamic obstruction occurs late in systole.

Diastolic murmurs

These are due to accelerated or turbulent flow across the mitral or tricuspid valves. They are low-pitched noises that are often difficult to hear and should be evaluated with the bell of the stethoscope. A mid-diastolic murmur may be due to mitral stenosis (located at the apex and axilla), tricuspid stenosis (located at the left sternal edge), increased flow across the mitral valve (e.g. the to-and-fro murmur of severe mitral regurgitation) or increased flow across the tricuspid valve (e.g. left-to-right shunt through a large atrial septal defect). Early diastolic murmurs have a soft, blowing quality with a

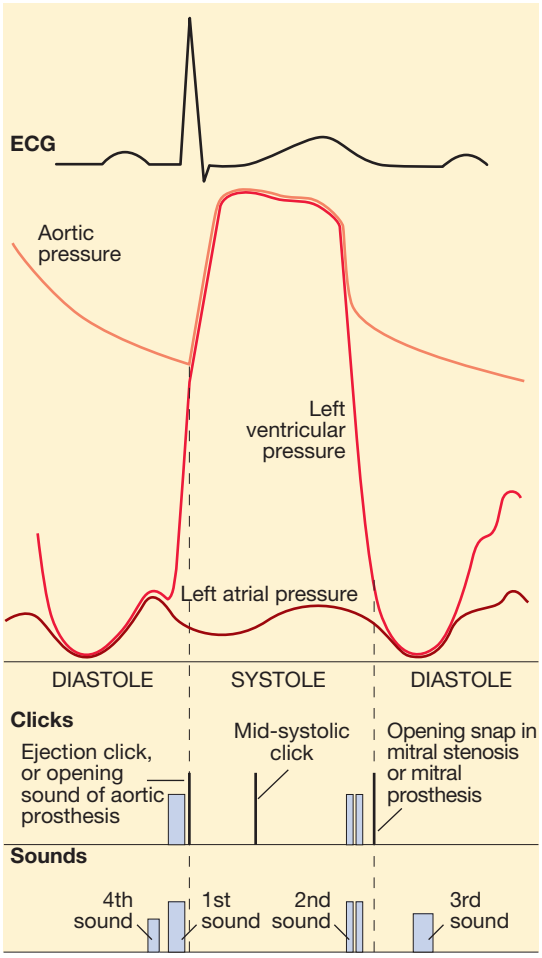

Fig. 18.36 The relationship of the cardiac cycle to the ECG, the left ventricular pressure wave and the position of heart sounds.

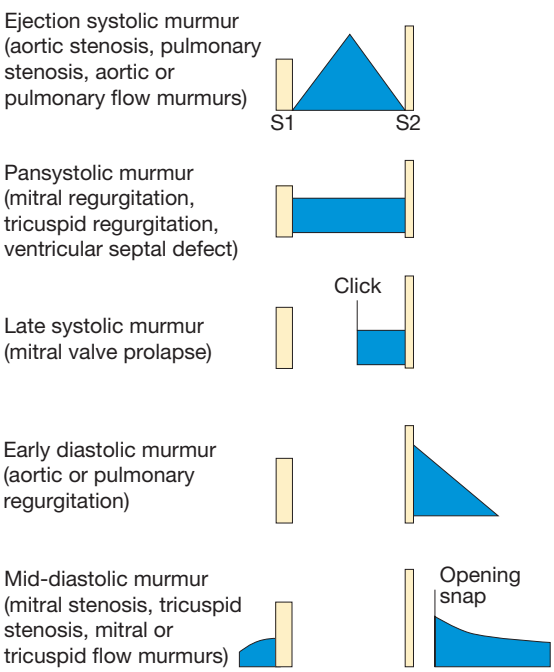

Fig. 18.37 The timing and pattern of cardiac murmurs.

18.26 Features of some common systolic murmurs

Condition	Timing and duration	Quality	Location and radiation	Associated features
Aortic stenosis	Mid-systolic	Loud, rasping	Base and left sternal edge, radiating to suprasternal notch and carotids	Single second heart sound Ejection click (in young patients) Slow rising pulse Left ventricular hypertrophy (pressure overload)
Mitral regurgitation	Pansystolic	Blowing	Apex, radiating to axilla	Soft first heart sound Third heart sound Left ventricular hypertrophy (volume overload)
Ventricular septal defect (VSD)	Pansystolic	Harsh	Lower left sternal edge, radiating to whole precordium	Thrill Biventricular hypertrophy
Benign	Mid-systolic	Soft	Left sternal edge, no radiation	No other signs of heart disease

decrescendo pattern and should be evaluated with the diaphragm of the stethoscope. They are due to regurgitation across the aortic or pulmonary valves and are best heard at the left sternal edge, with the patient sitting forwards in held expiration.

Continuous murmurs

These result from a combination of systolic and diastolic flow (e.g. persistent ductus arteriosus), and must be distinguished from extracardiac noises such as bruits from arterial shunts, venous hums (high rates of venous flow in children) and pericardial friction rubs.

The characteristics of specific valve defects and congenital anomalies are described on pages 613 and 629.

DISORDERS OF HEART RATE, RHYTHM AND CONDUCTION

The heart beat is normally initiated by an electrical discharge from the sinoatrial (sinus) node. The atria and ventricles then depolarise sequentially as electrical depolarisation passes through specialised conducting tissues (see Fig. 18.4, p. 529). The sinus node acts as a pacemaker and its intrinsic rate is regulated by the autonomic nervous system; vagal activity decreases the heart rate, and sympathetic activity increases it via cardiac sympathetic nerves and circulating catecholamines.

If the sinus rate becomes unduly slow, another, more distal part of the conducting system may assume the role of pacemaker. This is known as an escape rhythm and may arise in the atrioventricular (AV) node or His bundle (junctional rhythm) or the ventricles (idioventricular rhythm).

A cardiac arrhythmia is a disturbance of the electrical rhythm of the heart. Arrhythmias are often a manifestation of structural heart disease but may also occur because of abnormal conduction or depolarisation in an otherwise healthy heart. A heart rate of more than 100/min is called a tachycardia, and a heart rate of less than 60/min is called a bradycardia.

There are three main mechanisms of tachycardia:

- *Increased automaticity.* The tachycardia is produced by repeated spontaneous depolarisation of an ectopic focus, often in response to catecholamines.
- *Re-entry.* The tachycardia is initiated by an ectopic beat and sustained by a re-entry circuit (Fig. 18.38). Most tachyarrhythmias are due to re-entry.
- *Triggered activity.* This can cause ventricular arrhythmias in patients with coronary artery disease. It is a form of secondary depolarisation arising from an incompletely repolarised cell membrane.

Bradycardia may be due to:

- *Reduced automaticity*, e.g. sinus bradycardia.
- *Blocked or abnormally slow conduction*, e.g. AV block.

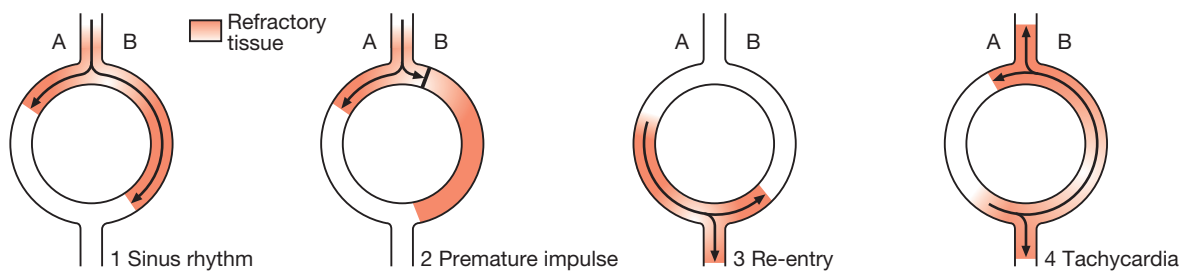

Fig. 18.38 The mechanism of re-entry. Re-entry can occur when there are two alternative pathways with different conducting properties (e.g. the AV node and an accessory pathway, or an area of normal and an area of ischaemic tissue). Here, pathway A conducts slowly and recovers quickly, while pathway B conducts rapidly and recovers slowly. (1) In sinus rhythm, each impulse passes down both pathways before entering a common distal pathway. (2) As the pathways recover at different rates, a premature impulse may find pathway A open and B closed. (3) Pathway B may recover while the premature impulse is travelling selectively down pathway A. The impulse can then travel retrogradely up pathway B, setting up a closed loop or re-entry circuit. (4) This may initiate a tachycardia that continues until the circuit is interrupted by a change in conduction rates or electrical depolarisation.

An arrhythmia may be 'supraventricular' (sinus, atrial or junctional) or ventricular in origin. Supraventricular rhythms usually produce narrow QRS complexes because the ventricles are depolarised in their normal sequence via the AV node and bundle of His. In contrast, ventricular rhythms produce broad, bizarre QRS complexes because the ventricles are activated in an abnormal sequence. Occasionally, however, a supraventricular rhythm can produce broad or wide QRS complexes due to coexisting bundle branch block or the presence of an additional atrioventricular connection (accessory pathway, see below).

Bradycardias cause symptoms that reflect low cardiac output: fatigue, lightheadedness and syncope. Tachycardias cause rapid palpitation, dizziness, chest discomfort or breathlessness. Extreme tachycardias can cause syncope because the heart is unable to contract or relax properly at extreme rates. Extreme bradycardias or tachycardias can precipitate sudden death or cardiac arrest.

Sinoatrial nodal rhythms

Sinus arrhythmia

Phasic alteration of the heart rate during respiration (the sinus rate increases during inspiration and slows during expiration) is a consequence of normal parasympathetic nervous system activity and can be pronounced in children. Absence of this normal variation in heart rate with breathing or with changes in posture may be a feature of autonomic neuropathy (p. 831).

Sinus bradycardia

A sinus rate of less than 60/min may occur in healthy people at rest and is a common finding in athletes. Some pathological causes are listed in Box 18.27. Asymptomatic sinus bradycardia requires no treatment. Symptomatic acute sinus bradycardia usually responds to intravenous atropine 0.6–1.2 mg. Patients with recurrent or persistent symptomatic sinus bradycardia should be considered for pacemaker implantation.

18.27 Some pathological causes of sinus bradycardia and tachycardia

Sinus bradycardia

- MI
- Sinus node disease (sick sinus syndrome)
- Hypothermia
- Hypothyroidism
- Cholestatic jaundice
- Raised intracranial pressure
- Drugs, e.g. β-blockers, digoxin, verapamil

Sinus tachycardia

- Anxiety
- Fever
- Anaemia
- Heart failure
- Thyrotoxicosis
- Phaeochromocytoma
- Drugs, e.g. β-agonists (bronchodilators)

Sinus tachycardia

This is defined as a sinus rate of more than 100/min, and is usually due to an increase in sympathetic activity associated with exercise, emotion, pregnancy or pathology (see Box 18.27). Young adults can produce a rapid sinus rate, up to 200/min, during intense exercise.

Sinoatrial disease (sick sinus syndrome)

Sinoatrial disease can occur at any age but is most common in older people. The underlying pathology involves fibrosis, degenerative changes or ischaemia of the SA (sinus) node. The condition is characterised by a variety of arrhythmias (Box 18.28) and may present with palpitation, dizzy spells or syncope, due to intermittent tachycardia, bradycardia, or pauses with no atrial or ventricular activity (SA block or sinus arrest) (Fig. 18.39).

18.28 Common features of sinoatrial disease

- Sinus bradycardia
- Sinoatrial block (sinus arrest)
- Paroxysmal atrial fibrillation
- Paroxysmal atrial tachycardia
- Atrioventricular block

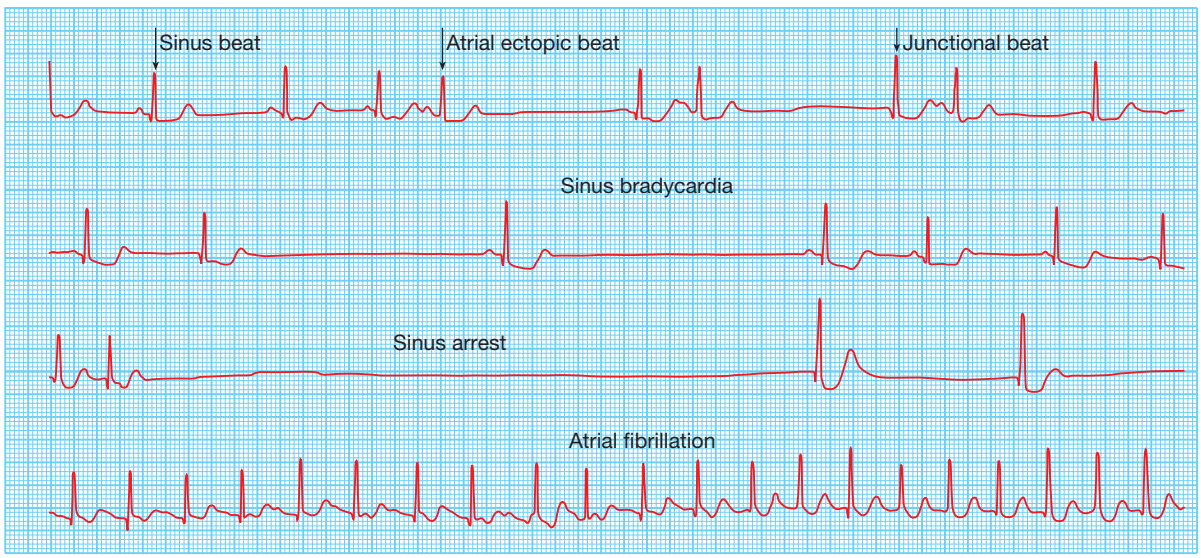

Fig. 18.39 Sinoatrial disease (sick sinus syndrome). A continuous rhythm strip from a 24-hour ECG tape recording illustrating periods of sinus rhythm, atrial ectopics, junctional beats, sinus bradycardia, sinus arrest and paroxysmal atrial fibrillation.

A permanent pacemaker may benefit patients with troublesome symptoms due to spontaneous bradycardias, or those with symptomatic bradycardias induced by drugs required to prevent tachyarrhythmias. Atrial pacing may prevent episodes of atrial fibrillation. Pacing improves symptoms but not prognosis, and is not indicated in patients who are asymptomatic.

Atrial tachyarrhythmias

Atrial ectopic beats (extrasystoles, premature beats)

These usually cause no symptoms but can give the sensation of a missed beat or an abnormally strong beat. The ECG (Fig. 18.40) shows a premature but otherwise normal QRS complex; if visible, the preceding P wave has a different morphology because the atria activate from an abnormal site. In most cases, these are of no consequence, although very frequent atrial ectopic beats may herald the onset of atrial fibrillation. Treatment is rarely necessary but β-blockers can be used if symptoms are intrusive.

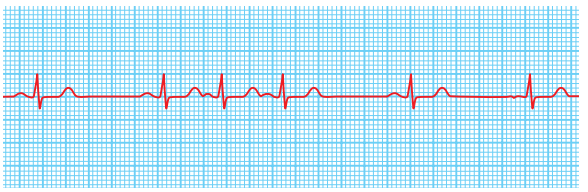

Fig. 18.40 Atrial ectopic beats. The first, second and fifth complexes are normal sinus beats. The third, fourth and sixth complexes are atrial ectopic beats with identical QRS complexes and abnormal (sometimes barely visible) P waves.

Atrial tachycardia

Atrial tachycardia may be a manifestation of increased atrial automaticity, sinoatrial disease or digoxin toxicity. It produces a narrow-complex tachycardia with abnormal P-wave morphology, sometimes associated with AV block if the atrial rate is rapid. It may respond to β-blockers, which reduce automaticity, or class I or III anti-arrhythmic drugs (see Box 18.38, p. 575). The ventricular response in rapid atrial tachycardias may be controlled by AV node-blocking drugs. Catheter ablation (p. 577) can be used to target the ectopic site and should be offered as an alternative to anti-arrhythmic drugs in patients with recurrent atrial tachycardia.

Atrial flutter

Atrial flutter is characterised by a large (macro) re-entry circuit, usually within the right atrium encircling the tricuspid annulus. The atrial rate is approximately 300/min, and is usually associated with 2:1, 3:1 or 4:1 AV block (with corresponding heart rates of 150, 100 or 75/min). Rarely, in young patients, every beat is conducted, producing a rate of 300/min and, potentially, haemodynamic compromise. The ECG shows saw-toothed flutter waves (Fig. 18.41). When there is regular 2:1 AV block, it may be difficult to identify flutter waves that are buried in QRS complexes and T waves. Atrial flutter should always be suspected when there is a narrow-complex tachycardia of 150/min. Carotid sinus pressure or intravenous adenosine may help to establish the diagnosis by temporarily increasing the degree of AV block and revealing flutter waves (Fig. 18.42).

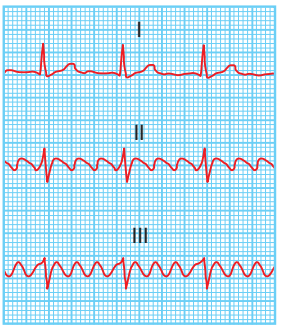

Fig. 18.41 Atrial flutter. Simultaneous recording showing atrial flutter with 3:1 AV block; flutter waves are only visible in leads II and III.

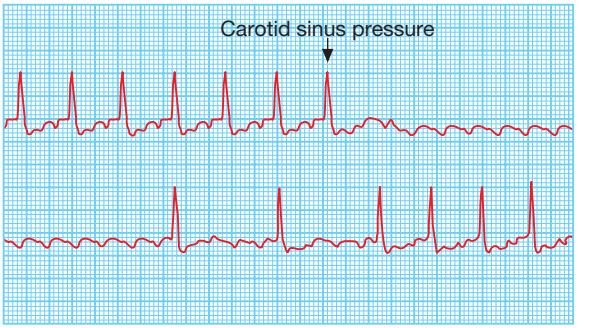

Fig. 18.42 Carotid sinus pressure in atrial flutter: continuous trace. The diagnosis of atrial flutter with 2:1 block was established when carotid sinus pressure produced temporary AV block, revealing the flutter waves.

Management

Digoxin, β-blockers or verapamil can control the ventricular rate (pp. 574–576). However, in many cases, it may be preferable to try to restore sinus rhythm by direct current (DC) cardioversion or by using intravenous amiodarone. Beta-blockers or amiodarone can also be used to prevent recurrent episodes of atrial flutter. Although flecainide can also be used for acute treatment or prophylaxis, it should be avoided because there is a risk of slowing the flutter circuit and facilitating 1:1 AV nodal conduction. This can cause a paradoxical tachycardia and haemodynamic compromise. If used, it should always be prescribed along with an AV node-blocking drug, such as a β-blocker. Catheter ablation offers a 90% chance of complete cure and is the treatment of choice for patients with persistent symptoms.

Atrial fibrillation

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia, with an overall prevalence of 0.5% in the adult population of the UK. The prevalence rises with age, affecting 1% of those aged 60–64 years, increasing to 9% of those aged over 80 years. AF is a complex arrhythmia characterised by both abnormal automatic firing and the presence of multiple interacting re-entry

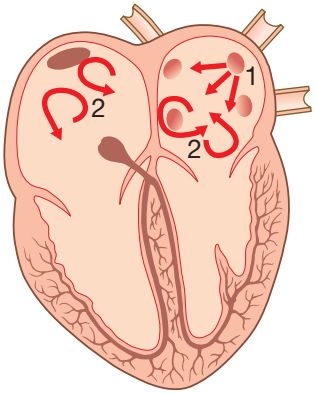

Fig. 18.43 Mechanisms initiating atrial fibrillation. (1) Ectopic beats, often arising from the pulmonary veins, trigger atrial fibrillation. (2) Re-entry within the atria maintains atrial fibrillation, with multiple interacting re-entry circuits operating simultaneously.

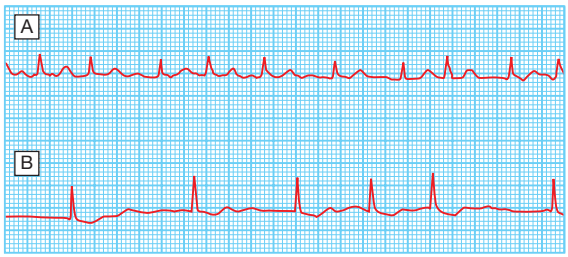

Fig. 18.44 Two examples of atrial fibrillation. The QRS complexes are irregular and there are no P waves. **A** There is usually a fast ventricular rate, e.g. between 120 and 160/min, at the onset of atrial fibrillation. **B** In chronic atrial fibrillation, the ventricular rate may be much slower, due to the effects of medication and AV nodal fatigue.

circuits looping around the atria. Episodes of atrial fibrillation are initiated by rapid bursts of ectopic beats arising from conducting tissue in the pulmonary veins or from diseased atrial tissue. AF becomes sustained because of re-entrant conduction within the atria or sometimes because of continuous ectopic firing (Fig. 18.43). Re-entry is more likely to occur in atria that are enlarged, or in which conduction is slow (as is the case in many forms of heart disease). During episodes of AF, the atria beat rapidly but in an uncoordinated and ineffective manner. The ventricles are activated irregularly at a rate determined by conduction through the AV node. This produces the characteristic 'irregularly irregular' pulse. The ECG (Fig. 18.44) shows normal but irregular QRS complexes; there are no P waves but the baseline may show irregular fibrillation waves.

AF can be classified as paroxysmal (intermittent episodes which self-terminate within 7 days), persistent (prolonged episodes that can be terminated by electrical or chemical cardioversion) or permanent. In patients with AF seen for the first time, it can be difficult to identify which of these is present. Unfortunately for many patients, paroxysmal AF will become permanent as the underlying disease process that predisposes to AF progresses. Electrophysiological changes occur in the atria within a few hours of the onset of AF that tend to maintain fibrillation: electrical remodelling. When AF persists for a period of months, structural remodelling occurs, with atrial fibrosis and dilatation that further predispose to AF. Thus early treatment of AF will prevent re-initiation of the arrhythmia.

18.29 Common causes of atrial fibrillation

- Coronary artery disease (including acute MI)
- Valvular heart disease, especially rheumatic mitral valve disease
- Hypertension
- Sinoatrial disease
- Hyperthyroidism
- Alcohol
- Cardiomyopathy
- Congenital heart disease
- Chest infection
- Pulmonary embolism
- Pericardial disease
- Idiopathic (lone atrial fibrillation)

AF may be the first manifestation of many forms of heart disease (Box 18.29), particularly those that are associated with enlargement or dilatation of the atria. Alcohol excess, hyperthyroidism and chronic lung disease are also common causes of AF, although multiple aetiological factors often coexist, such as the combination of alcohol, hypertension and coronary artery disease. About 50% of all patients with paroxysmal AF and 20% of patients with persistent or permanent AF have structurally normal hearts; this is known as 'lone atrial fibrillation'.

AF can cause palpitation, breathlessness and fatigue. In patients with poor ventricular function or valve disease, it may precipitate or aggravate cardiac failure because of loss of atrial function and heart rate control. A fall in BP may cause lightheadedness, and chest pain may occur with underlying coronary artery disease. In older patients, AF may not be associated with a rapid ventricular rate and is thus often asymptomatic, in which case it is usually discovered as a result of a routine examination or ECG.

AF is associated with significant morbidity and a twofold increase in mortality (mainly because of its association with other underlying heart disease). By far the most disabling consequence is its association with stroke and systemic embolism. Careful assessment, risk stratification and therapy can markedly improve prognosis.

Management

Assessment of patients with newly diagnosed AF includes a full history, physical examination, 12-lead ECG, echocardiogram and thyroid function tests. Additional investigations may be needed to determine the nature and extent of any underlying heart disease. Biochemical evidence of hyperthyroidism is found in a small minority of patients with otherwise unexplained AF.

When AF complicates an acute illness (e.g. chest infection, pulmonary embolism), effective treatment of the primary disorder will often restore sinus rhythm. Otherwise, the main objectives are restoration of sinus rhythm (when possible), prevention of recurrent AF, optimisation of the heart rate during periods of AF, reduction of the risk of thromboembolism, and treatment of underlying cardiac disease.

Paroxysmal atrial fibrillation

Occasional attacks that are well tolerated do not necessarily require treatment. Beta-blockers are normally

used as first-line therapy if symptoms are troublesome, and are particularly useful for treating patients with AF associated with coronary artery disease, hypertension and cardiac failure. Beta-blockers reduce the ectopic firing that normally initiates AF. Class Ic drugs (see Box 18.38, p. 575), such as propafenone or flecainide, are also effective at preventing episodes but should not be given to patients with coronary artery disease or left ventricular dysfunction. Flecainide is usually prescribed along with a rate limiting β-blocker because it occasionally precipitates atrial flutter. Class III drugs can also be used; amiodarone is the most effective agent for preventing AF but its side-effects restrict its use to patients in whom other measures fail. Dronedarone is an effective alternative, but is contraindicated in patients with heart failure or significant left ventricular impairment. Digoxin and verapamil are not effective drugs for preventing paroxysms of AF, although they do limit the heart rate when AF occurs by blocking the AV node. In patients with AF in whom anti-arrhythmic drug therapy is ineffective or causes side-effects, catheter ablation can be considered. Ablation is used to disconnect the pulmonary veins from the LA electrically, preventing ectopic triggering of AF. In addition, lines of conduction block can be created within the atria to prevent re-entry. Ablation prevents AF in approximately 75% of patients with prior drug-resistant episodes, although a repeat procedure is sometimes required before this is achieved. Ablation for AF is an attractive treatment for patients in whom drugs are ineffective or poorly tolerated but it is associated with a risk of cardiac tamponade, stroke and other complications.

18.30 Atrial fibrillation in old age

- **Prevalence**: rises with age, reaching 9% in those over 80 yrs of age.
- **Symptoms**: sometimes asymptomatic but often accompanied by diastolic heart failure.
- **Hyperthyroidism**: atrial fibrillation may emerge as the dominant feature of otherwise silent or occult hyperthyroidism.
- **Cardioversion**: followed by high rates (~70% at 1 yr) of recurrent atrial fibrillation.
- **Stroke**: atrial fibrillation is an important cause of cerebral embolism, found in 15% of all stroke patients and 2–8% of those with transient ischaemic attacks (TIAs).
- **Anticoagulation**: although the risk of thromboembolism rises, the hazards of anticoagulation also become greater with age because of increased comorbidity, particularly cognitive impairment and falls.
- **Target INR**: if anticoagulation is recommended in those over 75 yrs, care should be taken to maintain an INR below 3.0 because of the increased risk of intracranial haemorrhage.
- **Direct thrombin (e.g. dabigatran) and factor Xa (e.g. rivaroxaban) inhibitors**: alternatives to warfarin. No blood monitoring is required, there are fewer drug interactions, and fixed dosing may aid compliance. Dabigatran dose is reduced from 150 mg twice daily to 110 mg twice daily in the over-eighties or if creatinine clearance is less than 30 mL/min. Rivaroxaban dose is reduced from 20 mg once daily to 15 mg once daily if creatinine clearance is 30–49 mL/min, and contraindicated if below 30 mL/min.

Persistent and permanent atrial fibrillation

There are two options for treating persistent AF:

- *rhythm control:* attempting to restore and maintain sinus rhythm
- *rate control:* accepting that AF will be permanent and using treatments to control the ventricular rate and to prevent embolic complications.

Rhythm control. An attempt to restore sinus rhythm is particularly appropriate if the arrhythmia causes troublesome symptoms and if there is a modifiable or treatable underlying cause. Electrical cardioversion (p. 577) is initially successful in three-quarters of patients but relapse is frequent (25–50% at 1 month and 70–90% at 1 year). Attempts to restore and maintain sinus rhythm are most successful if AF has been present for less than 3 months, the patient is young and there is no important structural heart disease.

Immediate cardioversion, after administration of intravenous heparin, is appropriate if AF has been present for under 48 hours. In stable patients with no history of structural heart disease, intravenous flecainide (2 mg/kg over 30 mins, maximum dose 150 mg) can be used for pharmacological cardioversion and will restore sinus rhythm in 75% of patients within 8 hours. In patients with structural or ischaemic heart disease, intravenous amiodarone can be given via a central venous catheter. Electrical cardioversion, using a DC shock, is an alternative and is often effective when drugs fail. In other situations, DC cardioversion should be deferred until the patient has been established on warfarin, with an international normalised ratio (INR) of more than 2.0 for a minimum of 4 weeks, and any underlying problems, such as hypertension or alcohol excess, have been eliminated. Anticoagulation should be maintained for at least 3 months following successful cardioversion. If AF recurs, further cardioversion may be appropriate but consideration should be given to pretreatment with amiodarone to reduce the risk of recurrence. Catheter ablation is sometimes used to help restore and maintain sinus rhythm in resistant cases, but is a less effective treatment than for paroxysmal AF.

Rate control. If sinus rhythm cannot be restored, treatment should be directed at maintaining an appropriate heart rate. Digoxin, β-blockers and rate-limiting calcium antagonists, such as verapamil or diltiazem (pp. 574–576), reduce the ventricular rate by increasing the degree of AV block. This alone may produce a striking improvement in cardiac function, particularly in patients with mitral stenosis. Beta-blockers and rate-limiting calcium antagonists are more effective than digoxin at controlling the heart rate during exercise and have additional benefits in patients with hypertension or structural heart disease. Combination therapy (e.g. digoxin and atenolol) is often advisable but rate-limiting calcium channel antagonists should not be used with β-blockers because of the risk of bradycardia.

In exceptional cases, poorly controlled and symptomatic AF can be treated by deliberately inducing complete AV nodal block with catheter ablation; a permanent pacemaker must be implanted beforehand. This is known as the 'pace and ablate' strategy.

Prevention of thromboembolism

Loss of atrial contraction and left atrial dilatation cause stasis of blood in the LA and may lead to thrombus

18.31 CHA_2DS_2-VAS_c stroke risk scoring system for non-valvular atrial fibrillation

	Parameter	Score
C	Congestive heart failure	1 point
H	Hypertension history	1 point
A_2	Age ≥ 75 yrs	2 points
D	Diabetes mellitus	1 point
S_2	Previous stroke or TIA	2 points
V	Vascular disease	1 point
A	Age 65–74 yrs	1 point
S_c	Sex category female	1 point
	Maximum total score	9 points

Annual stroke risk
0 points = 0% (no prophylaxis required)
1 point = 1.3% (oral anticoagulant or aspirin recommended)
2+ points = > 2.2% (oral anticoagulant recommended)

European Society of Cardiology Clinical Practice Guidelines: Atrial Fibrillation (Management of) 2010 and Focused Update (2012). Eur Heart J 2012; 33:2719–2747.

formation in the left atrial appendage. This predisposes patients to stroke and other forms of systemic embolism. The annual risk of stroke in patients with AF (Box 18.31) is influenced by many factors, and in each patient a decision has to be made about the risk of stroke versus the risk of anticoagulation.

Several large randomised trials have shown that treatment with adjusted-dose warfarin (target INR 2.0–3.0) reduces the risk of stroke by about two-thirds, at the cost of an annual risk of bleeding of 1–1.5%, whereas treatment with aspirin reduces the risk of stroke by only one-fifth, is associated with significant bleeding risk and, although still included in European guidelines, has a very limited role. Warfarin is thus indicated for patients with AF who have specific risk factors for stroke. In intermittent AF, the risk of stroke is only loosely related to the frequency and duration of AF episodes, so stroke prevention guidelines do not distinguish between those with paroxysmal, persistent and permanent AF.

An assessment of the risk of embolism helps to define the possible benefits of antithrombotic therapy (see Box 18.31), which must be balanced against its potential hazards. Risk stratification is based on clinical factors using the CHA_2DS_2-VAS_C scoring system. Echocardiographic assessment (e.g. left atrial size) is of limited value in predicting stroke risk and is mainly used to identify associated structural disease. Oral anticoagulation is indicated in patients at moderate or high risk of stroke, unless there is an unacceptable bleeding risk. The choice of oral anticoagulant is widening (Box 18.32). Until recently, warfarin was the treatment of choice, mandating regular blood testing, with a target INR of 2.0–3.0. The direct thrombin inhibitor, dabigatran, is the first novel oral anticoagulant drug shown to be as effective and safe as warfarin at stroke prevention in AF. No blood monitoring is required and there are few drug interactions. For all anticoagulant drugs, comorbid conditions that may be complicated by bleeding, such as peptic ulcer, uncontrolled hypertension, alcohol misuse, frequent falls, poor drug compliance and potential drug interactions, are all relative contraindications. In warfarin-treated patients, anticoagulation can be reversed by administering vitamin K or clotting factors, but there are no current antidotes for the direct thrombin inhibitors. Young patients (under 65 years) with no evidence of structural heart disease have a very low risk of stroke and may not require oral anticoagulation.

EBM 18.32 Anticoagulation in atrial fibrillation

'Anticoagulation with warfarin reduces the risk of ischaemic stroke in non-rheumatic atrial fibrillation by about 62% (absolute risk reduction 2.7% for primary prevention and 8.4% for secondary prevention).

Newer anticoagulants, such as the direct thrombin inhibitor, dabigatran, and the factor Xa inhibitors, apixaban and rivaroxaban, appear to have better efficacy and safety profiles than warfarin. They are most effective in patients who have poorly controlled anticoagulation with warfarin or those who are unable to take warfarin.'

'Supraventricular' tachycardias

The term 'supraventricular tachycardia' (SVT) is commonly used to describe regular tachycardias that have a similar appearance on ECG. These are usually associated with a narrow QRS complex and are characterised by a re-entry circuit or automatic focus involving the atria. The term SVT is misleading, as, in many cases, the ventricles also form part of the re-entry circuit, such as in patients with AV re-entrant tachycardia.

Atrioventricular nodal re-entrant tachycardia

Atrioventricular nodal re-entrant tachycardia (AVNRT) is due to re-entry in a circuit involving the AV node and its two right atrial input pathways: a superior 'fast' pathway and an inferior 'slow' pathway (see Fig. 18.46A below). This produces a regular tachycardia with a rate of 120–240/min. It tends to occur in the absence of structural heart disease and episodes may last from a few seconds to many hours. The patient is usually aware of a rapid, very forceful, regular heart beat and may experience chest discomfort, lightheadedness or breathlessness. Polyuria, mainly due to the release of atrial natriuretic peptide, is sometimes a feature. The ECG (Fig. 18.45) usually shows a tachycardia with normal

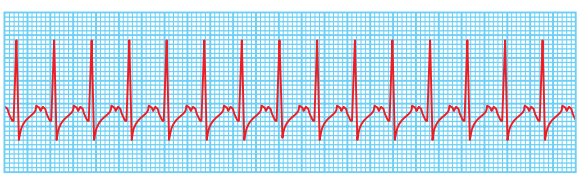

Fig. 18.45 Supraventricular tachycardia. The rate is 180/min and the QRS complexes are normal.

QRS complexes but occasionally there may be rate-dependent bundle branch block.

Management

Treatment is not always necessary. However, an episode may be terminated by carotid sinus pressure or by the Valsalva manœuvre. Adenosine (3–12 mg rapidly IV in incremental doses until tachycardia stops) or verapamil (5 mg IV over 1 min) will restore sinus rhythm in most cases. Intravenous β-blocker or flecainide can also be used. In rare cases, when there is severe haemodynamic compromise, the tachycardia should be terminated by DC cardioversion (p. 577).

In patients with recurrent SVT, catheter ablation (p. 577) is the most effective therapy and will permanently prevent SVT in more than 90% of cases. Alternatively, prophylaxis with oral β-blocker, verapamil or flecainide may be used but commits predominantly young patients to long-term drug therapy and can create difficulty in female patients, as these drugs are normally avoided during pregnancy.

Wolff–Parkinson–White syndrome and atrioventricular re-entrant tachycardia

Here, an abnormal band of conducting tissue connects the atria and ventricles. This 'accessory pathway' comprises rapidly conducting fibres which resemble Purkinje tissue, in that they conduct very rapidly and are rich in sodium channels. In around half of cases, this pathway only conducts in the retrograde direction (from ventricles to atria) and thus does not alter the appearance of the ECG in sinus rhythm. This is known as a concealed accessory pathway. In the rest, the pathway also conducts antegradely (from atria to ventricles) so AV conduction in sinus rhythm is mediated via both the AV node and the accessory pathway, distorting the QRS complex. Premature ventricular activation via the pathway shortens the PR interval and produces a 'slurred' initial deflection of the QRS complex, called a delta wave (Fig. 18.46B). This is known as a manifest accessory pathway. As the AV node and accessory pathway have different conduction speeds and refractory periods, a re-entry circuit can develop, causing tachycardia (Fig. 18.46C); when associated with symptoms, the condition is known as Wolff–Parkinson–White syndrome. The ECG during this tachycardia is almost indistinguishable from that of AVNRT (Fig. 18.46A). Carotid sinus pressure or intravenous adenosine can terminate the tachycardia. If atrial fibrillation occurs, it may produce a dangerously rapid ventricular rate because the accessory pathway lacks the rate-limiting properties of the AV node (Fig. 18.46D). This is known as pre-excited atrial fibrillation and may cause collapse, syncope and even death. It should be treated as an emergency, usually with DC cardioversion.

Catheter ablation is first-line treatment in symptomatic patients and is nearly always curative. Alternatively, prophylactic anti-arrhythmic drugs, such as

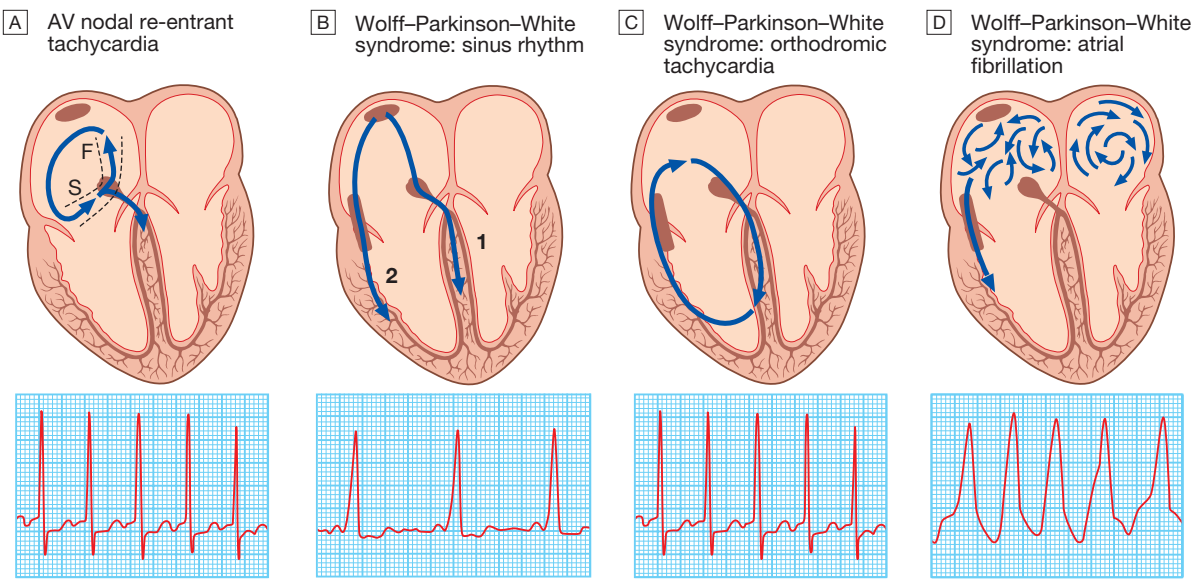

Fig. 18.46 AV nodal re-entrant tachycardia (AVNRT) and Wolff–Parkinson–White (WPW) syndrome. A AV node re-entrant tachycardia. The mechanism of AVNRT occurs via two right atrial AV nodal input pathways: the slow (S) and fast (F) pathways. Antegrade conduction occurs via the slow pathway; the wavefront enters the AV node and passes into the ventricles, at the same time re-entering the atria via the fast pathway.

In WPW syndrome, there is a strip of accessory conducting tissue that allows electricity to bypass the AV node and spread from the atria to the ventricles rapidly and without delay. When the ventricles are depolarised through the AV node, the ECG is normal, but when the ventricles are depolarised through the accessory conducting tissue, the ECG shows a very short PR interval and a broad QRS complex. B Sinus rhythm. In sinus rhythm, the ventricles are depolarised through (1) the AV node and (2) the accessory pathway, producing an ECG with a short PR interval and broadened QRS complexes; the characteristic slurring of the upstroke of the QRS complex is known as a delta wave. The degree of pre-excitation (the proportion of activation passing down the accessory pathway) and therefore the ECG appearances may vary a lot, and at times the ECG can look normal. C Orthodromic tachycardia. This is the most common form of tachycardia in WPW. The re-entry circuit passes antegradely through the AV node and retrogradely through the accessory pathway. The ventricles are therefore depolarised in the normal way, producing a narrow-complex tachycardia that is indistinguishable from other forms of SVT. D Atrial fibrillation. In this rhythm, the ventricles are largely depolarised through the accessory pathway, producing an irregular broad-complex tachycardia which is often more rapid than the example shown.

flecainide or propafenone (p. 574), can be used to slow conduction in, and prolong the refractory period of, the accessory pathway. Long-term drug therapy is not the preferred treatment for most patients and amiodarone should not be used, as its side-effect profile cannot be justified and ablation is safer and more effective. Digoxin and verapamil shorten the refractory period of the accessory pathway and should not be used.

Ventricular tachyarrhythmias

Ventricular ectopic beats (extrasystoles, premature beats)

QRS complexes in sinus rhythm are normally narrow because the ventricles are activated rapidly and simultaneously via the His–Purkinje system. The complexes of ventricular ectopic beats (VEBs) are premature, broad and bizarre because the ventricles are activated sequentially rather than simultaneously. The complexes may be unifocal (identical beats arising from a single ectopic focus) or multifocal (varying morphology with multiple foci, Fig. 18.47). 'Couplet' and 'triplet' are the terms used to describe two or three successive ectopic beats. A run of alternating sinus and ventricular ectopic beats is known as ventricular 'bigeminy'. Ectopic beats produce a low stroke volume because left ventricular contraction occurs before filling is complete. The pulse is therefore irregular, with weak or missed beats (see Fig. 18.47). Patients are usually asymptomatic but may complain of an irregular heart beat, missed beats or abnormally strong beats (due to the increased output of the post-ectopic sinus beat). The significance of VEBs depends on the presence or absence of underlying heart disease.

Ventricular ectopic beats in otherwise healthy subjects

VEBs are frequently found in healthy people and their prevalence increases with age. Ectopic beats in patients with otherwise normal hearts are more prominent at rest and disappear with exercise. Treatment is not necessary, unless the patient is highly symptomatic, in which case β-blockers or, in some situations, catheter ablation can be used. VEBs are sometimes a manifestation of otherwise subclinical heart disease, such as coronary artery disease or cardiomyopathy. There is no evidence that anti-arrhythmic therapy improves prognosis but the discovery of very frequent VEBs should prompt investigations, such as an echocardiogram (looking for structural heart disease) and an exercise stress test (to detect underlying ischaemic heart disease).

Ventricular ectopic beats associated with heart disease

Frequent VEBs often occur during acute MI but need no treatment. Persistent, frequent (over 10/hr) VEBs in patients who have survived the acute phase of MI indicate a poorer long-term outcome. Other than β-blockers, anti-arrhythmic drugs do not improve and may even worsen prognosis.

VEBs are common in patients with heart failure of any cause, including cardiomyopathy. While they are associated with an adverse prognosis, this is not improved by anti-arrhythmic drugs. Effective treatment of the heart failure may suppress the ectopic beats.

VEBs are also a feature of digoxin toxicity, and may occur as 'escape beats' in patients with bradycardia. Treatment is that of the underlying condition.

Ventricular tachycardia

Ventricular tachycardia (VT) occurs most commonly in the settings of acute MI, chronic coronary artery disease, and cardiomyopathy. It occurs when there is extensive ventricular disease, such as impaired left ventricular function or a left ventricular aneurysm. In these settings, VT may cause haemodynamic compromise or degenerate into ventricular fibrillation (p. 557). It is caused by abnormal automaticity or triggered activity in ischaemic tissue, or by re-entry within scarred ventricular tissue. Patients may complain of palpitation or symptoms of low cardiac output, e.g. dizziness, dyspnoea or syncope. The ECG shows tachycardia and broad, abnormal QRS complexes with a rate of more than 120/min (Fig. 18.48). VT may be difficult to distinguish from SVT with bundle branch block or pre-excitation (WPW syndrome). Features in favour of a diagnosis of VT are listed in Box 18.33. A 12-lead ECG (Fig. 18.49) or electrophysiology

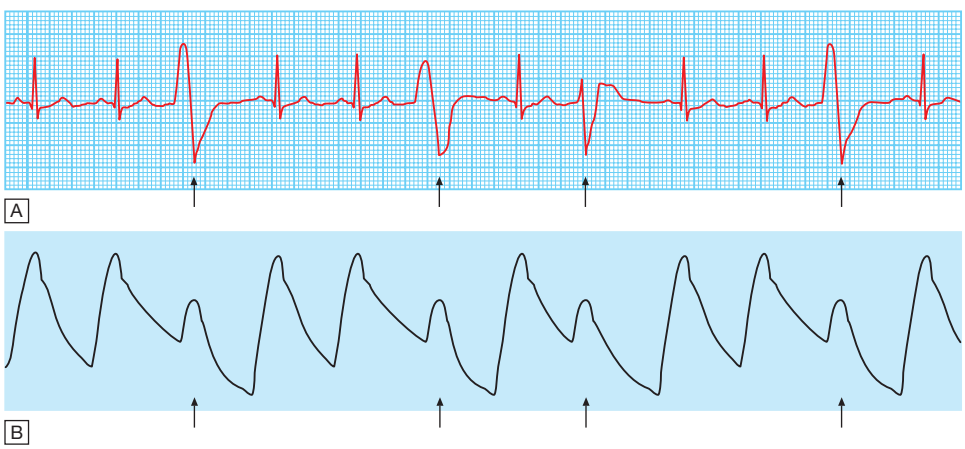

Fig. 18.47 Ventricular ectopic beats. A There are broad, bizarre QRS complexes (arrows) with no preceding P wave in between normal sinus beats. Their configuration varies, so these are multifocal ectopics. B A simultaneous arterial pressure trace is shown. The ectopic beats result in a weaker pulse (arrows), which may be perceived as a 'dropped beat'.

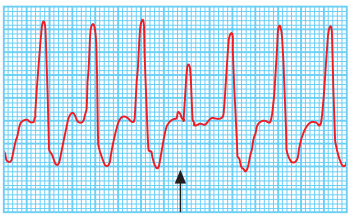

Fig. 18.48 Ventricular tachycardia: fusion beat (arrow). In ventricular tachycardia, there is independent atrial and ventricular activity. Occasionally, a P wave is conducted to the ventricles through the AV node, producing a normal sinus beat in the middle of the tachycardia (a capture beat); more commonly, however, the conducted impulse fuses with an impulse from the tachycardia (a fusion beat). This can only occur when there is AV dissociation and is therefore diagnostic of ventricular tachycardia.

18.33 Features more in keeping with ventricular tachycardia

- History of MI
- AV dissociation (pathognomonic)
- Capture/fusion beats (pathognomonic; see Fig. 18.48)
- Extreme left axis deviation
- Very broad QRS complexes (> 140 ms)
- No response to carotid sinus massage or IV adenosine

study (p. 539) may help establish the diagnosis. When there is doubt, it is safer to manage the problem as VT.

Patients recovering from MI sometimes have periods of idioventricular rhythm ('slow' VT) at a rate only slightly above the preceding sinus rate and below 120/min. These episodes often reflect reperfusion of the infarct territory and may be a good sign. They are usually self-limiting and asymptomatic, and do not require treatment. Other forms of sustained VT will require treatment, often as an emergency.

VT occasionally occurs in patients with otherwise healthy hearts ('normal heart VT'), usually because of abnormal automaticity in the right ventricular outflow tract or one of the fascicles of the left bundle branch. The prognosis is good and catheter ablation can be curative.

Management

Prompt action to restore sinus rhythm is required and should usually be followed by prophylactic therapy. Synchronised DC cardioversion is the treatment of choice if systolic BP is less than 90 mmHg. If the arrhythmia is well tolerated, intravenous amiodarone may be given as a bolus, followed by a continuous infusion (p. 576). Intravenous lidocaine can be used but may depress left ventricular function, causing hypotension or acute heart failure. Hypokalaemia, hypomagnesaemia, acidosis and hypoxaemia should be corrected.

Beta-blockers are effective at preventing VT by reducing ventricular automaticity. Amiodarone can be added if additional control is needed. Class Ic anti-arrhythmic drugs should not be used for prevention of VT in patients with coronary artery disease or heart failure because they depress myocardial function and can be pro-arrhythmic (increase the likelihood of a dangerous arrhythmia). In patients at high risk of arrhythmic death (e.g. those with poor left ventricular function, or where VT is associated with haemodynamic compromise), the use of an implantable cardiac defibrillator is recommended (p. 579). Rarely, surgery (e.g. aneurysm resection) or catheter ablation can be used to interrupt the arrhythmia focus or circuit in patients with VT associated with a myocardial infarct scar.

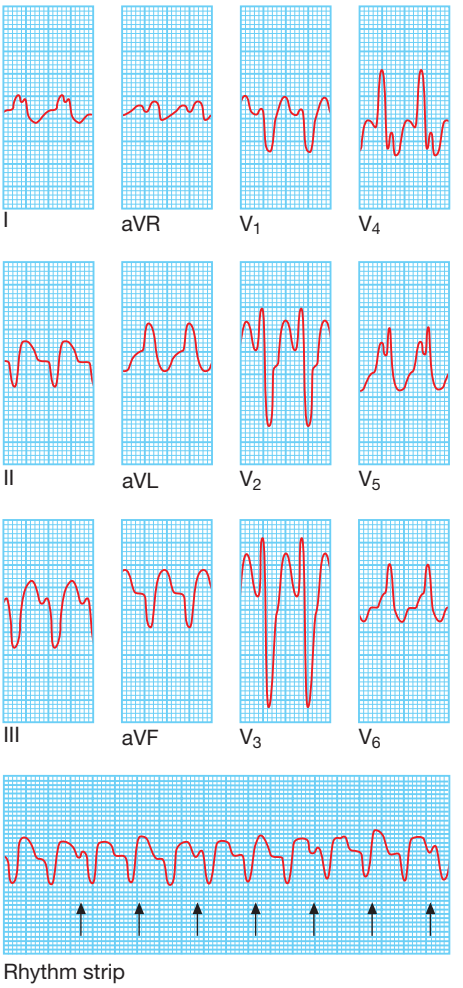

Fig. 18.49 Ventricular tachycardia: 12–lead ECG. There are typically very broad QRS complexes and marked left axis deviation. There is also AV dissociation; some P waves are visible and others are buried in the QRS complexes (arrows).

Torsades de pointes (ventricular tachycardia)

This form of polymorphic VT is a complication of prolonged ventricular repolarisation (prolonged QT interval). The ECG shows rapid irregular complexes that oscillate from an upright to an inverted position and seem to twist around the baseline as the mean QRS axis changes (Fig. 18.50). The arrhythmia is usually non-sustained and repetitive, but may degenerate into ventricular fibrillation. During periods of sinus rhythm, the ECG will usually show a prolonged QT interval (> 0.43 s in men, > 0.45 s in women when corrected to a heart rate of 60/min).

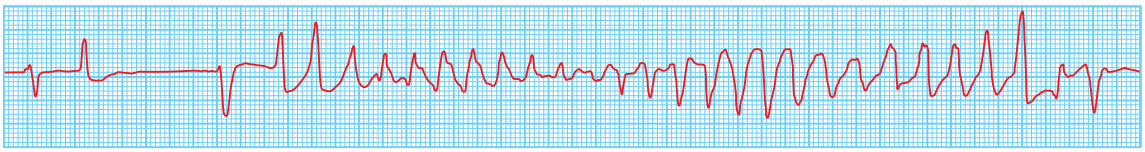

Fig. 18.50 Torsades de pointes. A bradycardia with a long QT interval is followed by polymorphic ventricular tachycardia that is triggered by an R on T ectopic.

18.34 Causes of long QT interval and torsades de pointes

Bradycardia

- Bradycardia compounds other factors that cause torsades de pointes

Electrolyte disturbance

- Hypokalaemia
- Hypomagnesaemia
- Hypocalcaemia

Drugs

- Disopyramide, flecainide (and other class Ia, Ic anti-arrhythmic drugs, p. 574)
- Sotalol, amiodarone (and other class III anti-arrhythmic drugs)
- Amitriptyline (and other tricyclic antidepressants)
- Chlorpromazine (and other phenothiazines)
- Erythromycin (and other macrolides) … and many more

Congenital syndromes

- Long QT1: gene affected *KCNQ1*: K^+ channel, 30–35%
- Long QT2: gene affected *HERG*: K^+ channel, 25–30%
- Long QT3: gene affected *SCNSA*: Na^+ channel, 5–10%
- Long QT4–12: rare

Some of the common causes are listed in Box 18.34. The arrhythmia is more common in women and is often triggered by a combination of aetiological factors (e.g. QT-prolonging medications and hypokalaemia). The congenital long QT syndromes are a family of genetic disorders that are characterised by mutations in genes that code for cardiac sodium or potassium channels. Long QT syndrome subtypes have different triggers, which are important when counselling patients. Adrenergic stimulation (e.g. exercise) is a common trigger in long QT type 1, and a sudden noise (e.g. an alarm clock) may trigger arrhythmias in long QT type 2. Arrhythmias are more common during sleep in type 3.

Treatment should be directed at the underlying cause. Intravenous magnesium (8 mmol over 15 mins, then 72 mmol over 24 hrs) should be given in all cases. Atrial pacing will usually suppress the arrhythmia through rate-dependent shortening of the QT interval. Intravenous isoprenaline is a reasonable alternative to pacing but should be avoided in patients with the congenital long QT syndromes.

Long-term therapy may not be necessary if the underlying cause can be removed. Beta-blockers are effective at preventing syncope in patients with congenital long QT syndrome. Some patients, particularly those with extreme QT interval prolongation (> 500 ms) or certain high-risk genotypes should be considered for implantation of a defibrillator. Left stellate ganglion block may be of value in patients with resistant arrhythmias.

The Brugada syndrome is a related genetic disorder that may present with polymorphic VT or sudden death. It is characterised by a defect in sodium channel function and an abnormal ECG (right bundle branch block and ST elevation in V_1 and V_2 but not usually prolongation of the QT interval). The only known effective treatment is an implantable defibrillator.

Atrioventricular and bundle branch block

Atrioventricular block

Atrioventricular conduction is influenced by autonomic activity. AV block can therefore be intermittent and only evident when the conducting tissue is stressed by a rapid atrial rate. Accordingly, atrial tachyarrhythmias are often associated with AV block (see Fig. 18.44, p. 565).

First-degree atrioventricular block

In this condition, AV conduction is delayed and so the PR interval is prolonged (> 0.20 s; Fig. 18.51). It rarely causes symptoms.

Second-degree atrioventricular block

In this, dropped beats occur because some impulses from the atria fail to conduct to the ventricles.

In Mobitz type I second-degree AV block (Fig. 18.52), there is progressive lengthening of successive PR intervals, culminating in a dropped beat. The cycle then repeats itself. This is known as the Wenckebach phenomenon and is usually due to impaired conduction in the AV node itself. The phenomenon may be physiological and is sometimes observed at rest or during sleep in athletic young adults with high vagal tone.

In Mobitz type II second-degree AV block (Fig. 18.53), the PR interval of the conducted impulses remains constant but some P waves are not conducted. This is usually caused by disease of the His–Purkinje system and carries a risk of asystole.

In 2:1 AV block (Fig. 18.54), alternate P waves are conducted, so it is impossible to distinguish between Mobitz type I and type II block.

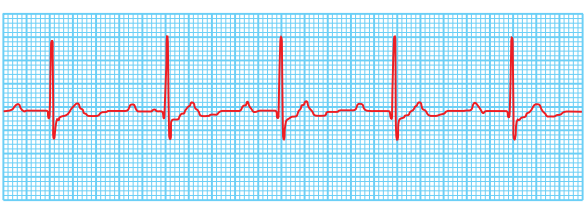

Fig. 18.51 First-degree AV block. The PR interval is prolonged and measures 0.26 s.

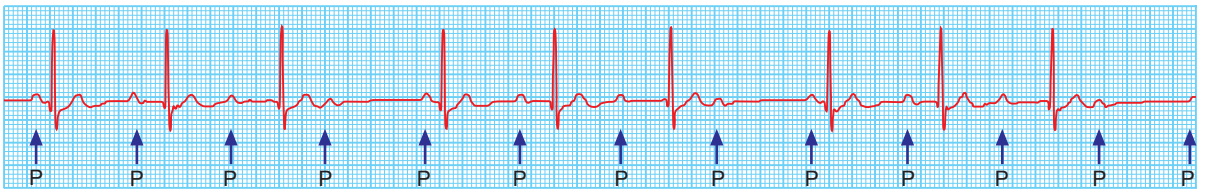

Fig. 18.52 Second-degree AV block (Mobitz type I – Wenckebach's phenomenon). The PR interval progressively increases until a P wave is not conducted. The cycle then repeats itself. In this example, conduction is at a ratio of 4:3, leading to groupings of three ventricular complexes in a row.

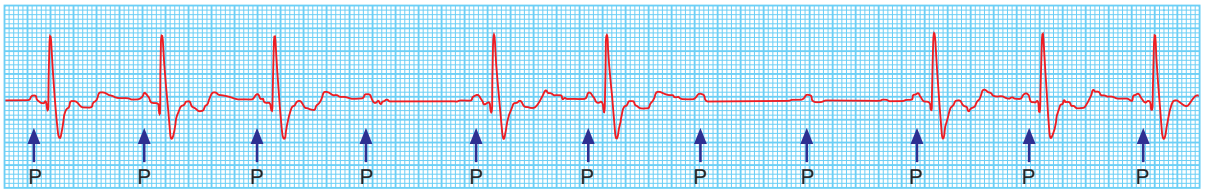

Fig. 18.53 Second-degree AV block (Mobitz type II). The PR interval of conducted beats is normal but some P waves are not conducted. The constant PR interval distinguishes this from Wenckebach's phenomenon.

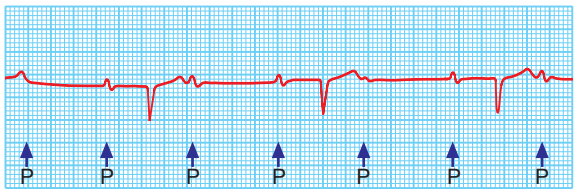

Fig. 18.54 Second-degree AV block with fixed 2:1 block. Alternate P waves are not conducted. This may be due to Mobitz type I or II block.

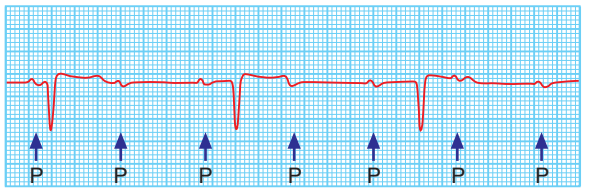

Fig. 18.55 Complete (third-degree) AV block. There is complete dissociation of atrial and ventricular complexes. The atrial rate is 80/min and the ventricular rate is 38/min.

18.35 Aetiology of complete AV block

Congenital

Acquired

- Idiopathic fibrosis
- MI/ischaemia
- Inflammation
  - Acute (e.g. aortic root abscess in infective endocarditis)
  - Chronic (e.g. sarcoidosis, p. 709; Chagas' disease, p. 360)
- Trauma (e.g. cardiac surgery)
- Drugs (e.g. digoxin, β-blocker)

Third-degree (complete) atrioventricular block

When AV conduction fails completely, the atria and ventricles beat independently (AV dissociation, Fig. 18.55). Ventricular activity is maintained by an escape rhythm arising in the AV node or bundle of His (narrow QRS complexes) or the distal Purkinje tissues (broad QRS complexes). Distal escape rhythms tend to be slower and less reliable.

Complete AV block (Box 18.35) produces a slow (25–50/min), regular pulse that, except in the case of congenital complete AV block, does not vary with exercise. There is usually a compensatory increase in stroke volume, producing a large-volume pulse. Cannon waves may be visible in the neck and the intensity of the first heart sound varies due to the loss of AV synchrony.

Stokes–Adams attacks

Episodes of ventricular asystole may complicate complete heart block or Mobitz type II second-degree AV block, or occur in patients with sinoatrial disease (see Fig. 18.39, p. 563). This may cause recurrent syncope or 'Stokes–Adams' attacks.

A typical episode is characterised by sudden loss of consciousness that occurs without warning and results in collapse. A brief anoxic seizure (due to cerebral ischaemia) may occur if there is prolonged asystole. There is pallor and a death-like appearance during the attack, but when the heart starts beating again, there is a characteristic flush. Unlike in epilepsy, recovery is rapid. Sinoatrial disease and neurocardiogenic syncope (p. 555) may cause similar symptoms.

Management

Atrioventricular block complicating acute myocardial infarction

Acute inferior MI is often complicated by transient AV block because the right coronary artery (RCA) supplies the AV node. There is usually a reliable escape rhythm and, if the patient remains well, no treatment is required. Symptomatic second- or third-degree AV block may respond to atropine (0.6 mg IV, repeated as necessary) or, if this fails, a temporary pacemaker. In most cases, the AV block will resolve within 7–10 days.

Second- or third-degree AV heart block complicating acute anterior MI indicates extensive ventricular damage involving both bundle branches and carries a

poor prognosis. Asystole may ensue and a temporary pacemaker should be inserted promptly. If the patient presents with asystole, IV atropine (3 mg) or IV isoprenaline (2 mg in 500 mL 5% dextrose, infused at 10–60 mL/hr) may help to maintain the circulation until a temporary pacing electrode can be inserted. External (transcutaneous) pacing can provide effective temporary rhythm support.

Chronic atrioventricular block

Patients with symptomatic bradyarrhythmias associated with AV block should receive a permanent pacemaker (see below). Asymptomatic first-degree or Mobitz type I second-degree AV block (Wenckebach phenomenon) does not require treatment but may be an indication of serious underlying heart disease. A permanent pacemaker is usually indicated in patients with asymptomatic Mobitz type II second- or third-degree AV heart block because of the risk of asystole and sudden death. Pacing improves prognosis.

Bundle branch block and hemiblock

Conduction block in the right or left bundle branch can occur as a result of many pathologies, including ischaemic or hypertensive heart disease or cardiomyopathies (Box 18.36). Depolarisation proceeds through a slow myocardial route in the affected ventricle rather than through the rapidly conducting Purkinje tissues that constitute the bundle branches. This causes delayed conduction into the LV or RV, broadens the QRS complex (≥ 0.12 s) and produces the characteristic alterations in QRS morphology (Figs 18.56 and 18.57). Right bundle branch block (RBBB) can occur in healthy people but left bundle branch block (LBBB) often signifies important underlying heart disease.

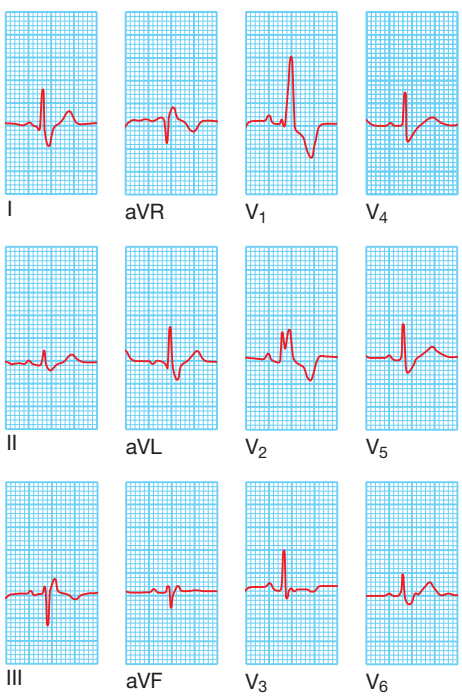

Fig. 18.56 Right bundle branch block. Note the wide QRS complexes with 'M'-shaped configuration in leads V, and V_2 and a wide S wave in lead I.

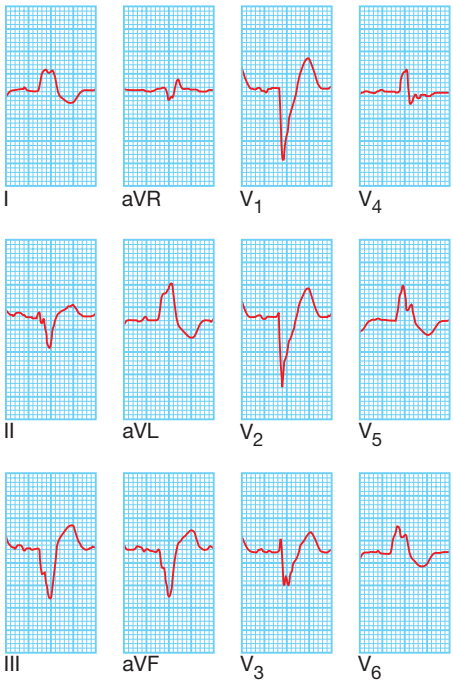

Fig. 18.57 Left bundle branch block. Note the wide QRS complexes with loss of the Q wave or septal vector in lead I and 'M'-shaped QRS complexes in V_5 and V_6.

18.36 Common causes of bundle branch block

Right bundle branch block	
• Normal variant • Right ventricular hypertrophy or strain, e.g. pulmonary embolism	• Congenital heart disease, e.g. atrial septal defect • Coronary artery disease
Left bundle branch block	
• Coronary artery disease • Hypertension	• Aortic valve disease • Cardiomyopathy

The left bundle branch divides into an anterior and a posterior fascicle. Damage to the conducting tissue at this point (hemiblock) does not broaden the QRS complex but alters the mean direction of ventricular depolarisation (mean QRS axis), causing left axis deviation in left anterior hemiblock and right axis deviation in left posterior hemiblock (see Fig. 18.7, p. 533). The combination of right bundle branch block and left anterior or posterior hemiblock is known as bifascicular block.

Anti-arrhythmic drug therapy

Classification

Anti-arrhythmic drugs may be classified according to their mode or site of action (Box 18.37 and Fig. 18.58).

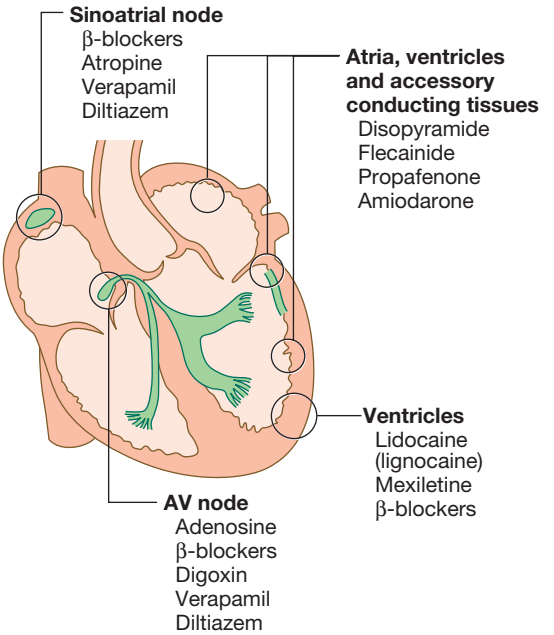

Fig. 18.58 Classification of anti-arrhythmic drugs by site of action.

18.37 Classification of anti-arrhythmic drugs by effect on the intracellular action potential

Class I: membrane-stabilising agents (sodium channel blockers)
(a) Block Na^+ channel and prolong action potential
• Quinidine, disopyramide
(b) Block Na^+ channel and shorten action potential
• Lidocaine, mexiletine
(c) Block Na^+ channel with no effect on action potential
• Flecainide, propafenone
Class II: β-adrenoceptor antagonists (β-blockers)
• Atenolol, bisoprolol, metoprolol
Class III: drugs whose main effect is to prolong the action potential
• Amiodarone, dronedarone, sotalol
Class IV: slow calcium channel blockers
• Verapamil, diltiazem
N.B. Some drugs (e.g. digoxin, ivabradine and adenosine) have no place in this classification, while others have properties in more than one class: e.g. amiodarone, which has actions in all four classes.

Identification of ion channel subtypes has led to refinement of drug classifications, according to the specific mechanisms targeted. The Vaughan-Williams classification is a simple system but is convenient for describing the main mode of action of anti-arrhythmic drugs (Box 18.38) that should be used following guiding principles (Box 18.39). Anti-arrhythmic drugs can also be more accurately categorised by referring to the cardiac ion channels and receptors on which they act.

Class I drugs

Class I drugs act principally by suppressing excitability and slowing conduction in atrial or ventricular muscle. They block sodium channels, of which there are several types in cardiac tissue. These drugs should generally be avoided in patients with heart failure because they depress myocardial function, and class Ia and Ic drugs are often pro-arrhythmic.

Class Ia drugs

These prolong cardiac action potential duration and increase the tissue refractory period. They are used to prevent both atrial and ventricular arrhythmias.

Disopyramide. An effective drug but causes anticholinergic side-effects, such as urinary retention, and can precipitate glaucoma. It can depress myocardial function and should be avoided in cardiac failure.

Quinidine. Now rarely used, as it increases mortality and causes gastrointestinal upset.

Class Ib drugs

These shorten the action potential and tissue refractory period. They act on channels found predominantly in ventricular myocardium and so are used to treat or prevent ventricular tachycardia and ventricular fibrillation.

Lidocaine. Must be given intravenously and has a very short plasma half-life.

Mexiletine. Can be given intravenously or orally, but has many side-effects (see Box 18.38).

Class Ic drugs

These affect the slope of the action potential without altering its duration or refractory period. They are used mainly for prophylaxis of atrial fibrillation but are effective in prophylaxis and treatment of supraventricular or ventricular arrhythmias. They are useful for WPW syndrome because they block conduction in accessory pathways. They should not be used as oral prophylaxis in patients with previous MI because of pro-arrhythmia.

Flecainide. Effective for prevention of atrial fibrillation, and an intravenous infusion may be used for pharmacological cardioversion of atrial fibrillation of less than 24 hours' duration. It should be prescribed along with an AV node-blocking drug, such as a β-blocker, to prevent pro-arrhythmia.

Propafenone. Also has some β-blocker (class II) properties. Important interactions with digoxin, warfarin and cimetidine have been described.

Class II drugs

This group comprises the β-adrenoceptor antagonists (β-blockers). These agents reduce the rate of SA node depolarisation and cause relative block in the AV node, making them useful for rate control in atrial flutter and atrial fibrillation. They can be used to prevent supraventricular and ventricular tachycardia. They reduce myocardial excitability and the risk of arrhythmic death in patients with coronary artery disease and heart failure.

'Non-selective' β-blockers. Act on both β_1 and β_2 receptors. $Beta_2$ blockade causes side-effects, such as bronchospasm and peripheral vasoconstriction. *Propranolol* is non-selective and is subject to extensive first-pass metabolism in the liver. The effective oral dose is therefore unpredictable and must be titrated after treatment is started with a small dose. Other non-selective drugs include *nadolol* and *carvedilol.*

18.38 The main uses, dosages and side-effects of the most widely used anti-arrhythmic drugs

Drug	Main uses	Route	Dose (adult)	Important side-effects
Class I				
Disopyramide	Prevention and treatment of atrial and ventricular tachyarrhythmias	IV	2 mg/kg at 30 mg/min, then 0.4 mg/kg/hr (max 800 mg/day)	Myocardial depression, hypotension, dry mouth, urinary retention
		Oral	300–800 mg daily in divided dosage	
Lidocaine	Treatment and short-term prevention of VT and VF	IV	Bolus 50–100 mg, 4 mg/min for 30 mins, then 2 mg/min for 2 hrs, then 1 mg/min for 24 hrs	Myocardial depression, confusion, convulsions
Mexiletine	Prevention and treatment of ventricular tachyarrhythmias	IV	Loading dose: 100–250 mg at 25 mg/min, then 250 mg in 1 hr, then 250 mg in 2 hrs	Myocardial depression, gastrointestinal irritation, confusion, dizziness, tremor, nystagmus, ataxia
		Oral	Maintenance therapy: 0.5 mg/min, 200–250 mg 3 times daily	
Flecainide	Prevention and treatment of atrial and ventricular tachyarrhythmias	IV	2 mg/kg over 10 mins, then 1.5 mg/kg/hr for 1 hr, then 0.1 mg/kg/hr	Myocardial depression, dizziness
		Oral	50–100 mg twice daily	
Propafenone	Prevention and treatment of atrial and ventricular tachyarrhythmias	Oral	150 mg 3 times daily for 1 wk, then 300 mg twice daily	Myocardial depression, dizziness
Class II				
Atenolol	Treatment and prevention of SVT and AF Prevention of VEs and exercise-induced VT	IV	2.5 mg at 1 mg/min, repeated at 5-min intervals (max 10 mg)	Myocardial depression, bradycardia, bronchospasm, fatigue, depression, nightmares, cold peripheries
Bisoprolol		Oral	25–100 mg daily	
Metoprolol		Oral IV	2.5–10 mg daily 5 mg over 2 mins to a maximum of 15 mg	
Class III				
Amiodarone	Serious or resistant atrial and ventricular tachyarrhythmias	IV	5 mg/kg over 20–120 mins, then up to 15 mg/kg/24 hrs	Photosensitivity, skin discoloration, corneal deposits, thyroid dysfunction, alveolitis, nausea and vomiting, hepatotoxicity, peripheral neuropathy, torsades de pointes; potentiates digoxin and warfarin
		Oral	Initially 600–1200 mg/day, then 100–400 mg daily	
Dronedarone	Paroxysmal atrial fibrillation	Oral	400 mg twice daily	Renal and hepatic dysfunction requiring regular blood monitoring
Sotalol	Atrial fibrillation, rarely ventricular tachyarrhythmias	IV	10–20 mg slowly	Can cause torsades de pointes
		Oral	40–160 mg twice daily	
Class IV				
Verapamil	Treatment of SVT, control of AF	IV	5–10 mg over 30 secs	Myocardial depression, hypotension, bradycardia, constipation
		Oral	40–120 mg 3 times daily or 240 mg SR daily	
Other				
Atropine	Treatment of bradycardia and/or hypotension due to vagal overactivity	IV	0.6–3 mg	Dry mouth, thirst, blurred vision, atrial and ventricular extrasystoles
Adenosine	Treatment of SVT, aid to diagnosis in unidentified tachycardia	IV	3 mg over 2 secs, followed if necessary by 6 mg, then 12 mg at intervals of 1–2 mins	Flushing, dyspnoea, chest pain Avoid in asthma
Digoxin	Treatment and prevention of SVT, rate control of AF	IV	Loading dose: 0.5–1 mg (total), 0.5 mg over 30 mins, then 0.25–0.5 mg 3–6 times daily, to maximum total of 1 mg, assessing response before each additional dose	Gastrointestinal disturbance, xanthopsia, arrhythmias (see Box 18.41)
		Oral	0.5 mg 4 times daily for 2 doses, then 0.125–0.25 mg daily	

(AF = atrial fibrillation; SR = sustained-release formulation; SVT = supraventricular tachycardia; VE = ventricular ectopic; VF = ventricular fibrillation; VT = ventricular tachycardia)

18.39 Anti-arrhythmic drugs: principles of use

Anti-arrhythmic drugs are potentially toxic and should be used carefully according to the following principles:

- Many arrhythmias are benign and do not require specific treatment
- Precipitating or causal factors should be corrected if possible, e.g. excess alcohol or caffeine consumption, myocardial ischaemia, hyperthyroidism, acidosis, hypokalaemia and hypomagnesaemia
- If drug therapy is required, it is best to use as few drugs as possible
- In difficult cases, programmed electrical stimulation (electrophysiological study) may help to identify the optimum therapy
- When managing life-threatening arrhythmias, it is essential to ensure that prophylactic treatment is effective. Ambulatory monitoring and exercise testing may be of value
- Patients on long-term anti-arrhythmic drugs should be reviewed regularly and attempts made to withdraw therapy if the factors which precipitated the arrhythmias are no longer operative
- For patients with recurrent SVT, radiofrequency ablation is often preferable to long-term drug therapy

'Cardioselective' β-blockers. Act mainly on myocardial β_1 receptors and are relatively well tolerated. *Bisoprolol* and *metoprolol* are examples of cardioselective β-blockers.

Sotalol. A racemic mixture of two isomers with non-selective β-blocker (mainly l-sotalol) and class III (mainly d-sotalol) activity. It may cause torsades de pointes.

Class III drugs

Class III drugs act by prolonging the plateau phase of the action potential, thus lengthening the refractory period. These drugs are very effective at preventing atrial and ventricular tachyarrhythmias. They cause QT interval prolongation and can predispose to torsades de pointes and ventricular tachycardia (p. 570), especially in patients with other predisposing risk factors (see Box 18.34, p. 571).

Amiodarone. The principal drug in this class, although both disopyramide and sotalol have class III activity. Amiodarone is a complex drug that also has class I, II and IV activity. It is probably the most effective drug currently available for controlling paroxysmal atrial fibrillation. It is also used to prevent episodes of recurrent ventricular tachycardia, particularly in patients with poor left ventricular function or those with implantable defibrillators (to prevent unnecessary DC shocks). Amiodarone has a very long tissue half-life (25–110 days). An intravenous or oral loading regime is often used to achieve therapeutic tissue concentrations rapidly. The drug's effects may last for weeks or months after treatment has been stopped. Side-effects are common (up to one-third of patients), numerous and potentially serious. Drug interactions are also common (see Box 18.38).

Dronedarone. A related drug that has a short tissue half-life and fewer side-effects. It has recently been shown to be effective at preventing episodes of atrial flutter and fibrillation. It is contraindicated in patients with permanent atrial fibrillation, or if there is heart failure or left ventricular impairment, because it increases mortality. Regular liver function test monitoring is required.

Class IV drugs

These block the 'slow calcium channel', which is important for impulse generation and conduction in atrial and nodal tissue, although it is also present in ventricular muscle. Their main indications are prevention of supraventricular tachycardia (by blocking the AV node) and rate control in patients with atrial fibrillation.

Verapamil. The most widely used drug in this class. Intravenous verapamil may cause profound bradycardia or hypotension, and should not be used in conjunction with β-blockers.

Diltiazem. Has similar properties.

Other anti-arrhythmic drugs

Atropine sulphate (0.6 mg IV, repeated if necessary to a maximum of 3 mg). Increases the sinus rate and SA and AV conduction, and is the treatment of choice for severe bradycardia or hypotension due to vagal overactivity. It is used for initial management of symptomatic bradyarrhythmias complicating inferior MI, and in cardiac arrest due to asystole. Repeat dosing may be necessary because the drug disappears rapidly from the circulation after parenteral administration. Side-effects are listed in Box 18.38.

Adenosine. Must be given intravenously. It produces transient AV block lasting a few seconds. It is used to terminate supraventricular tachycardias when the AV node is part of the re-entry circuit, or to help establish the diagnosis in difficult arrhythmias, such as atrial flutter with 2:1 AV block (see Fig. 18.41, p. 564) or broad-complex tachycardia (Boxes 18.38 and 18.40). Adenosine is given as an intravenous bolus, initially 3 mg over 2 seconds (see Box 18.38). If there is no response after 1–2 minutes, 6 mg should be given; if necessary, after another 1–2 minutes, the maximum dose of 12 mg may be given. Patients should be warned to expect short-lived and sometimes distressing flushing, breathlessness and chest pain. Adenosine can cause bronchospasm and should be avoided in asthmatics; its effects are greatly potentiated by dipyridamole and inhibited by theophylline and other xanthines.

18.40 Response to intravenous adenosine

Arrhythmia	Response
Supraventricular tachycardia	Termination
Atrial fibrillation, atrial flutter	Transient AV block
Ventricular tachycardia	No effect

Digoxin. A purified glycoside from the European foxglove, *Digitalis lanata*, which slows conduction and prolongs the refractory period in the AV node. This effect helps to control the ventricular rate in atrial fibrillation and may interrupt supraventricular tachycardias involving the AV node. Digoxin also shortens refractory periods and enhances excitability and conduction in other parts of the heart (including accessory conduction pathways). It may therefore increase atrial and ventricular ectopic activity and can lead to more complex atrial

18.41 Digoxin toxicity

Extracardiac manifestations	
• Anorexia, nausea, vomiting • Diarrhoea	• Altered colour vision (xanthopsia)
Cardiac manifestations	
• Bradycardia • Multiple ventricular ectopics • Ventricular bigeminy (alternate ventricular ectopics)	• Atrial tachycardia (with variable block) • Ventricular tachycardia • Ventricular fibrillation

and ventricular tachyarrhythmias. Digoxin is largely excreted by the kidneys, and the maintenance dose (see Box 18.38) should be reduced in children, older people and those with renal impairment. It is widely distributed and has a long tissue half-life (36 hours), so that effects may persist for several days. Measurement of plasma digoxin concentration helps identify digoxin toxicity or under-treatment (Box 18.41).

Therapeutic procedures

External defibrillation and cardioversion

The heart can be completely depolarised by passing a sufficiently large electrical current through it from an external source. This will interrupt any arrhythmia and produce a brief period of asystole that is usually followed by the resumption of sinus rhythm. Defibrillators deliver a DC, high-energy, short-duration shock via two large electrodes or paddles coated with conducting jelly or a gel pad, positioned over the upper right sternal edge and the apex. Modern units deliver a biphasic shock, during which the shock polarity is reversed mid-shock. This reduces the total shock energy required to depolarise the heart.

Electrical cardioversion

This is the termination of an organised rhythm, such as atrial fibrillation or ventricular tachycardia, with a synchronised shock, usually under general anaesthesia. The shock is delivered immediately after detection of the R wave because, if it is applied during ventricular repolarisation (on the T wave), it may provoke ventricular fibrillation. High-energy shocks may cause chest wall pain post-procedure, so, if there is no urgency, it is appropriate to begin with a lower-amplitude shock (e.g. 50 joules), going on to larger shocks if necessary. Patients with atrial fibrillation or flutter of more than 48 hours' duration are at risk of left atrial appendage thrombus, and thus systemic embolism after cardioversion. In such cases, cardioversion should be delayed until effective anticoagulation has been given for at least 4 weeks.

Defibrillation

This is the delivery of an unsynchronised shock during a cardiac arrest caused by ventricular fibrillation. The precise timing of the discharge is not important in this situation. In ventricular fibrillation and other emergencies, the energy of the first and second shocks should be 150 joules and thereafter up to 200 joules; there is no need for an anaesthetic, as the patient is unconscious.

Catheter ablation

Catheter ablation therapy is the treatment of choice for patients with supraventricular tachycardia or atrial flutter, and is a useful treatment for some patients with atrial fibrillation or ventricular arrhythmias (Fig. 18.59). A series of catheter electrodes are inserted into the heart via the venous system and are used to record the activation sequence of the heart in sinus rhythm, during tachycardia and after pacing manœuvres. Once the arrhythmia focus or circuit is identified (e.g. an accessory pathway in WPW syndrome), a catheter is used to ablate the culprit tissue using heat (via radiofrequency current) or sometimes by freezing (cryoablation). The procedure takes approximately 1–4 hours and does not require a general anaesthetic. The patient may experience some discomfort during the ablation itself. Serious complications are rare (< 1%) but include inadvertent complete heart block requiring pacemaker implantation, and cardiac tamponade. For many arrhythmias, radiofrequency ablation is very attractive because it offers the prospect of a lifetime cure, thereby eliminating the need for long-term drug therapy.

The technique has revolutionised the management of many arrhythmias and is now the treatment of choice for AVNRT and AV re-entrant (accessory pathway) tachycardias, when it is curative in over 90% of cases. Focal atrial tachycardias and atrial flutter can also be eliminated by radiofrequency ablation, although some patients subsequently experience episodes of atrial fibrillation. The applications of the technique are expanding and it can now be used to treat some forms of ventricular tachycardia. Catheter ablation techniques are also used to prevent atrial fibrillation. This involves ablation at two sites: the ostia of the pulmonary veins, from which ectopic beats may trigger paroxysms of arrhythmia, and in the LA itself, where re-entry circuits maintain atrial fibrillation, once established. This is effective at reducing episodes of atrial fibrillation in

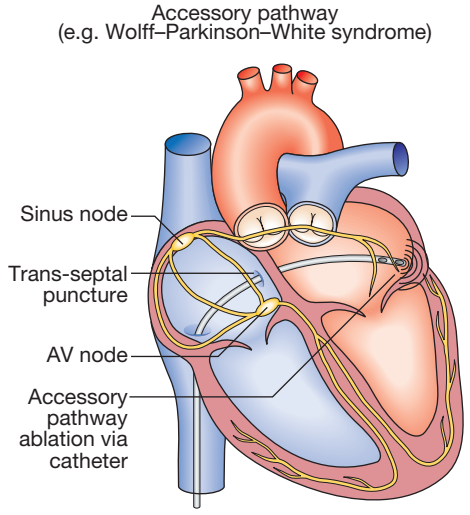

Fig. 18.59 Radiofrequency ablation.

around 70–80% of younger patients with structurally normal hearts, and tends to be reserved for patients with drug-resistant atrial fibrillation.

In patients with permanent atrial fibrillation and poor rate control, in whom drugs are ineffective or are not tolerated, rate control can be achieved by: (i) implantation of a permanent pacemaker, followed by (ii) ablation of the AV node to induce complete AV block and bradycardia, thus allowing the pacemaker to assume control of the heart rate.

Temporary pacemakers

Temporary pacing involves delivery of an electrical impulse into the heart to initiate tissue depolarisation and to trigger cardiac contraction. This is achieved by inserting a bipolar pacing electrode via the internal jugular, subclavian or femoral vein and positioning it at the apex of the RV, using fluoroscopic imaging. The electrode is connected to an external pacemaker with an adjustable energy output and pacing rate. The ECG of right ventricular pacing is characterised by regular broad QRS complexes with a left bundle branch block pattern. Each complex is immediately preceded by a 'pacing spike' (Fig. 18.60). Nearly all pulse generators are used in the 'demand' mode, so that the pacemaker will only operate if the heart rate falls below a preset level. Occasionally, temporary atrial or dual-chamber pacing (see below) is used.

Temporary pacing may be indicated in the management of transient AV block and other arrhythmias complicating acute MI or cardiac surgery, to maintain the rhythm in other situations of reversible bradycardia (i.e. due to metabolic disturbance or drug overdose), or as a bridge to permanent pacing. Complications include pneumothorax, brachial plexus or subclavian artery injury, local infection or septicaemia (usually *Staphylococcus aureus*), and pericarditis. Failure of the system may be due to lead displacement or a progressive increase in the threshold (exit block) caused by tissue oedema. Complication rates increase with time and so a temporary pacing system should ideally not be used for more than 7 days.

Transcutaneous pacing is administered by delivering an electrical stimulus through two large adhesive gel pad electrodes placed over the apex and upper right sternal edge, or over the anterior and posterior chest. It is easy and quick to set up, but causes discomfort because it induces forceful pectoral and intercostal muscle contraction. Modern external cardiac defibrillators often incorporate a transcutaneous pacing system that can be used during an emergency until transvenous pacing is established.

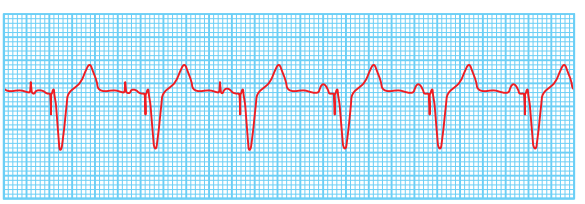

Fig. 18.60 Dual-chamber pacing. The first three beats show atrial and ventricular pacing with narrow pacing spikes in front of each P wave and QRS complex. The last four beats show spontaneous P waves with a different morphology and no pacing spike; the pacemaker senses or tracks these P waves and maintains AV synchrony by pacing the ventricle after an appropriate interval.

Permanent pacemakers

Permanent pacemakers are small, flat, metal devices that are implanted under the skin, usually in the pectoral area. They contain a battery, a pulse generator, and programmable electronics that allow adjustment of pacing and memory functions. Pacing electrodes (leads) can be placed via the subclavian or cephalic veins into the RV (usually at the apex), the right atrial appendage or, to maintain AV synchrony, both.

Permanent pacemakers are programmed using an external programmer via a wireless telemetry system. Pacing rate, output, timing and other parameters can be adjusted. This allows the device to be set to the optimum settings to suit the patient's needs. Pacemakers store useful diagnostic data about the patient's heart rate trends and the occurrence of tachyarrhythmias, such as ventricular tachycardia.

Single-chamber atrial pacing is used in patients with sinoatrial disease without AV block (the pacemaker acts as an external sinus node). Single-chamber ventricular pacing is used in patients with continuous atrial fibrillation and bradycardia. Dual-chamber pacing is most often used in patients with second- or third-degree AV block; here, the atrial electrode is used to detect spontaneous atrial activity and trigger ventricular pacing (see Fig. 18.60), thereby preserving AV synchrony and allowing the ventricular rate to increase, together with the sinus node rate, during exercise and other forms of stress. Dual-chamber pacing has many advantages over ventricular pacing; these include superior haemodynamics, leading to a better effort tolerance, a lower prevalence of atrial arrhythmias in patients with sinoatrial disease, and avoidance of 'pacemaker syndrome' (a fall in BP and dizziness precipitated by loss of AV synchrony).

A code is used to signify the pacing mode (Box 18.42). For example, a system that paces the atrium, senses the atrium and is inhibited if it senses spontaneous activity is designated AAI. Most dual-chamber pacemakers are programmed to a mode termed DDD; in this case, ventricular pacing is triggered by a sensed sinus P wave and inhibited by a sensed spontaneous QRS complex. A fourth letter, 'R', is added if the pacemaker has a rate response function (e.g. AAIR = atrial demand pacemaker with rate response function). Rate-responsive pacemakers are used in patients with chronotropic incompetence, who are unable to increase their heart rate during exercise. These devices have a sensor that triggers an increase in heart rate in response to movement or increased respiratory rate. The sensitivity of

18.42 International generic pacemaker code

Chamber paced	Chamber sensed	Response to sensing
O = none	O = none	O = none
A = atrium	A = atrium	T = triggered
V = ventricle	V = ventricle	I = inhibited
D = both	D = both	D = both

the sensor is programmable, as is the maximum paced heart rate.

Early complications of permanent pacing include pneumothorax, cardiac tamponade, infection and lead displacement. Late complications include infection (which usually necessitates removing the pacing system), erosion of the generator or lead, chronic pain related to the implant site, and lead fracture due to mechanical fatigue.

Implantable cardiac defibrillators

In addition to the functions of a permanent pacemaker, implantable cardiac defibrillators (ICDs) can also detect and terminate life-threatening ventricular tachyarrhythmias. ICDs are larger than pacemakers mainly because of the need for a large battery and capacitor to enable cardioversion or defibrillation. ICD leads are similar to pacing leads but have one or two shock coils along the length of the lead, used for delivering defibrillation. ICDs treat ventricular tachyarrhythmias using overdrive pacing, cardioversion or defibrillation. They are implanted in a similar manner to pacemakers and carry a similar risk of complications. In addition, patients can be prone to psychological problems and anxiety, particularly if they have experienced repeated shocks from their device.

The evidence-based indications for ICD implantation are shown in Box 18.43. These can be divided into 'secondary prevention' indications, when patients have already had a potentially life-threatening ventricular arrhythmia, and 'primary prevention' indications, when patients are considered to be at significant future risk of arrhythmic death. ICDs may be used prophylactically in selected patients with inherited conditions associated with a high risk of sudden cardiac death, such as long QT syndrome (p. 571), hypertrophic cardiomyopathy and arrhythmogenic right ventricular dysplasia (pp. 637 and 638). ICD treatment is expensive and so the indications for which the devices are routinely implanted depend on the health-care resources available.

18.43 Key indications for ICD therapy

Primary prevention

- After MI, if LV ejection fraction < 30%
- Mild to moderate symptomatic heart failure on optimal drug therapy, with LV ejection fraction < 35%

Secondary prevention

- Survivors of ventricular fibrillation or ventricular tachycardia cardiac arrest not due to transient or reversible cause
- Ventricular tachycardia with haemodynamic compromise or significant LV impairment (LV ejection fraction < 35%)

Cardiac resynchronisation therapy

Cardiac resynchronisation therapy (CRT) is a treatment for selected patients with heart failure, in whom cardiac function is further impaired by the presence of left bundle branch block. This conduction defect is associated with left ventricular dys-synchrony (poorly coordinated left ventricular contraction) and can aggravate heart failure in susceptible patients. CRT systems have an additional lead that is placed via the coronary sinus into one of the veins on the epicardial surface of the LV (see Fig. 18.28, p. 553). Simultaneous septal and left ventricular epicardial pacing resynchronises left ventricular contraction. These devices improve effort tolerance, reduce heart failure symptoms (Box 18.44), and are more effective in patients in sinus rhythm than in those with atrial fibrillation. Most devices are also defibrillators (CRT-D) because many patients with heart failure are predisposed to ventricular arrhythmias. CRT-pacemakers (CRT-P) are used in patients considered to be at relatively low risk of these arrhythmias.

EBM 18.44 Cardiac resynchronisation therapy (CRT) for heart failure

'CRT improves symptoms and quality of life, and reduces mortality in patients with moderate to severe (NYHA class III–IV) heart failure who are in sinus rhythm, with left bundle branch block and LV ejection fraction ≤ 35%. CRT also prevents heart failure progression in similar patients with mild (NYHA class I–II) heart failure symptoms.'

ATHEROSCLEROSIS

Atherosclerosis can affect any artery in the body. When it occurs in the heart, it may cause angina, MI and sudden death; in the brain, stroke and transient ischaemic attack (TIA); and in the limbs, claudication and critical limb ischaemia. Occult coronary artery disease is common in those who present with other forms of atherosclerotic vascular disease, such as intermittent claudication or stroke, and is an important cause of morbidity and mortality in these patients.

Pathophysiology

Atherosclerosis is a progressive inflammatory disorder of the arterial wall that is characterised by focal lipid-rich deposits of atheroma that remain clinically silent until they become large enough to impair tissue perfusion, or until ulceration and disruption of the lesion result in thrombotic occlusion or distal embolisation of the vessel. These mechanisms are common to the entire vascular tree, and the clinical manifestations of atherosclerosis depend upon the site of the lesion and the vulnerability of the organ supplied.

Atherosclerosis begins early in life. Abnormalities of arterial function have been detected among high-risk children and adolescents, such as cigarette smokers and those with familial hyperlipidaemia or hypertension. Early lesions have been found in the arteries of victims of accidental death in the second and third decades of life. Nevertheless, clinical manifestations often do not appear until the sixth, seventh or eighth decade.

Early atherosclerosis

Fatty streaks tend to occur at sites of altered arterial shear stress, such as bifurcations, and are associated with abnormal endothelial function. They develop when inflammatory cells, predominantly monocytes, bind to

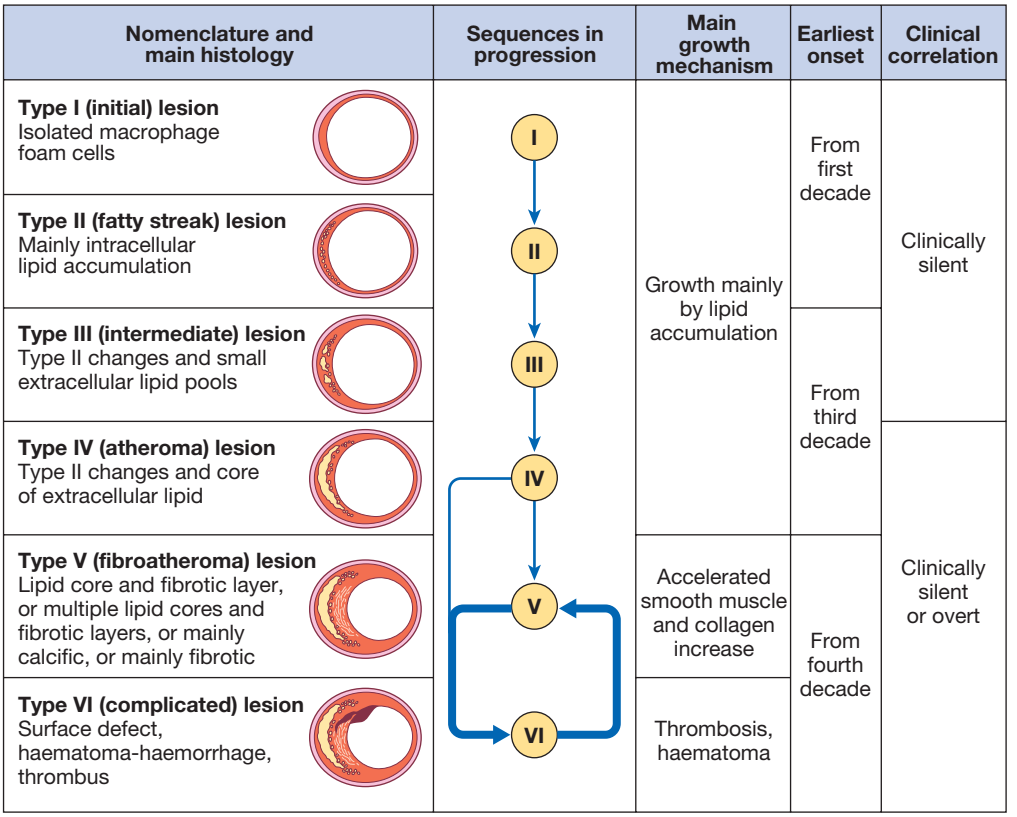

Fig. 18.61 The six stages of atherosclerosis. American Heart Association classification. From Stary, et al. 1995 – see p. 641.

receptors expressed by endothelial cells, migrate into the intima, take up oxidised low-density lipoprotein (LDL) particles and become lipid-laden macrophages or foam cells. Extracellular lipid pools appear in the intimal space when foam cells die and release their contents (Fig. 18.61). In response to cytokines and growth factors produced by activated macrophages, smooth muscle cells migrate from the media of the arterial wall into the intima, and change from a contractile to a repair phenotype in an attempt to stabilise the atherosclerotic lesion. If this is successful, the lipid core will be covered by smooth muscle cells and matrix, producing a stable atherosclerotic plaque that will remain asymptomatic until it becomes large enough to obstruct arterial flow.

Advanced atherosclerosis

In an established atherosclerotic plaque, macrophages mediate inflammation and smooth muscle cells promote repair. If inflammation predominates, the plaque becomes active or unstable and may be complicated by ulceration and thrombosis. Cytokines, such as interleukin-1, tumour necrosis factor-alpha, interferon-gamma, platelet-derived growth factors, and matrix metalloproteinases are released by activated macrophages; they cause the intimal smooth muscle cells overlying the plaque to become senescent and collagen cross-struts within the plaque to degrade. This results in thinning of the protective fibrous cap, making the lesion vulnerable to mechanical stress that ultimately causes erosion, fissuring or rupture of the plaque surface (see Fig. 18.61). Any breach in the integrity of the plaque will expose its contents to blood and will trigger platelet aggregation and thrombosis that extend into the atheromatous plaque and the arterial lumen. This type of plaque event may cause partial or complete obstruction at the site of the lesion or distal embolisation resulting in infarction or ischaemia of the affected organ. This common mechanism underlies many of the acute manifestations of atherosclerotic vascular disease, such as acute lower limb ischaemia, MI and stroke.

The number and complexity of arterial plaques increase with age and with risk factors (see below) but the rate of progression of individual plaques is variable. There is a complex and dynamic interaction between mechanical wall stress and atherosclerotic lesions. 'Vulnerable' plaques are characterised by a lipid-rich core, a thin fibrocellular cap, speckled calcification and an increase in inflammatory cells that release specific enzymes to degrade matrix proteins. In contrast, stable plaques are typified by a small lipid pool, a thick fibrous cap, heavy calcification and plentiful collagenous cross-struts. Fissuring or rupture tends to occur at sites of maximal mechanical stress, particularly the margins of an eccentric plaque, and may be triggered by a surge in BP, such as during exercise or emotional stress. Surprisingly, the majority of plaque events are subclinical and heal spontaneously, although this may allow thrombus to be incorporated into the lesion, producing plaque growth and further obstruction to flow.

Atherosclerosis may induce complex changes in the media that lead to arterial remodelling. Some arterial segments may slowly constrict (negative remodelling),

whilst others may gradually enlarge (positive remodelling). These changes are important because they may amplify or minimise the degree to which atheroma encroaches into the arterial lumen.

Risk factors

The role and relative importance of many risk factors for the development of coronary, peripheral and cerebrovascular disease have been defined in experimental animal studies, epidemiological studies and clinical interventional trials. Key factors have emerged but do not explain all the risk, and unknown factors may account for up to 40% of the variation in risk from one person to the next.

The impact of genetic risk is illustrated by twin studies; a monozygotic twin of an affected individual has an eightfold increased risk and a dizygotic twin a fourfold increased risk of dying from coronary artery disease, compared to the general population.

The effect of risk factors is multiplicative rather than additive. People with a combination of risk factors are at greatest risk and so assessment should take account of all identifiable risk factors. It is important to distinguish between relative risk (the proportional increase in risk) and absolute risk (the actual chance of an event). Thus, a man of 35 years with a plasma cholesterol of 7 mmol/L (approximately 170 mg/dL), who smokes 40 cigarettes a day, is relatively much more likely to die from coronary disease within the next decade than a non-smoking woman of the same age with a normal cholesterol, but the absolute likelihood of his dying during this time is still small (high relative risk, low absolute risk).

- *Age and sex*. Age is the most powerful independent risk factor for atherosclerosis. Pre-menopausal women have lower rates of disease than men, although this sex difference disappears after the menopause. However, hormone replacement therapy has no role in the primary or secondary prevention of coronary artery disease, and isolated oestrogen therapy may cause an increased cardiovascular event rate.
- *Family history*. Atherosclerotic vascular disease often runs in families, due to a combination of shared genetic, environmental and lifestyle factors. The most common inherited risk characteristics (hypertension, hyperlipidaemia, diabetes mellitus) are polygenic. A 'positive' family history is present when clinical problems in first-degree relatives occur at relatively young age, such as below 50 years for men and below 55 years for women.
- *Smoking*. This is probably the most important avoidable cause of atherosclerotic vascular disease. There is a strong, consistent and dose-linked relationship between cigarette smoking and coronary artery disease, especially in younger (< 70 years) individuals.
- *Hypertension* (see below). The incidence of atherosclerosis increases as BP rises, and this excess risk is related to both systolic and diastolic BP, as well as pulse pressure. Antihypertensive therapy reduces cardiovascular mortality, stroke and heart failure.
- *Hypercholesterolaemia* (p. 453). Risk rises with increasing serum cholesterol concentrations. Lowering serum total and LDL cholesterol concentrations reduces the risk of cardiovascular events, including death, MI, stroke and coronary revascularisation.
- *Diabetes mellitus*. This is a potent risk factor for all forms of atherosclerosis and is often associated with diffuse disease that is difficult to treat. Insulin resistance (normal glucose homeostasis with high levels of insulin) is associated with obesity and physical inactivity, and is a risk factor for coronary artery disease (p. 805). Glucose intolerance accounts for a major part of the high incidence of ischaemic heart disease in certain ethnic groups, e.g. South Asians.
- *Haemostatic factors*. Platelet activation and high plasma fibrinogen concentrations are associated with an increased risk of coronary thrombosis. Antiphospholipid antibodies are associated with recurrent arterial thromboses (p. 1055).
- *Physical activity*. Physical inactivity roughly doubles the risk of coronary artery disease and is a major risk factor for stroke. Regular exercise (brisk walking, cycling or swimming for 20 minutes two or three times a week) has a protective effect that may be related to increased serum high-density lipoprotein (HDL) cholesterol concentrations, lower BP, and collateral vessel development.
- *Obesity* (p. 115). Obesity, particularly if central or truncal, is an independent risk factor, although it is often associated with other adverse factors, such as hypertension, diabetes mellitus and physical inactivity.
- *Alcohol*. Alcohol consumption is associated with reduced rates of coronary artery disease. Excess alcohol consumption is associated with hypertension and cerebrovascular disease.
- *Other dietary factors*. Diets deficient in fresh fruit, vegetables and polyunsaturated fatty acids are associated with an increased risk of cardiovascular disease. The introduction of a Mediterranean-style diet reduces cardiovascular events. However, dietary supplements, such as vitamin C and E, beta-carotene, folate and fish oils, do not reduce cardiovascular events and, in some cases, have been associated with harm.
- *Personality*. Certain personality traits are associated with an increased risk of coronary disease. Nevertheless, there is little or no evidence to support the popular belief that stress is a major cause of coronary artery disease.
- *Social deprivation*. Health inequalities have a major influence on cardiovascular disease. The impact of established risk factors is amplified in patients who are socially deprived and current guidelines recommend that treatment thresholds should be lowered for them.

Primary prevention

Two complementary strategies can be used to prevent atherosclerosis in apparently healthy but at-risk individuals: population and targeted strategies.

The population strategy aims to modify the risk factors of the whole population through diet and lifestyle advice, on the basis that even a small reduction in

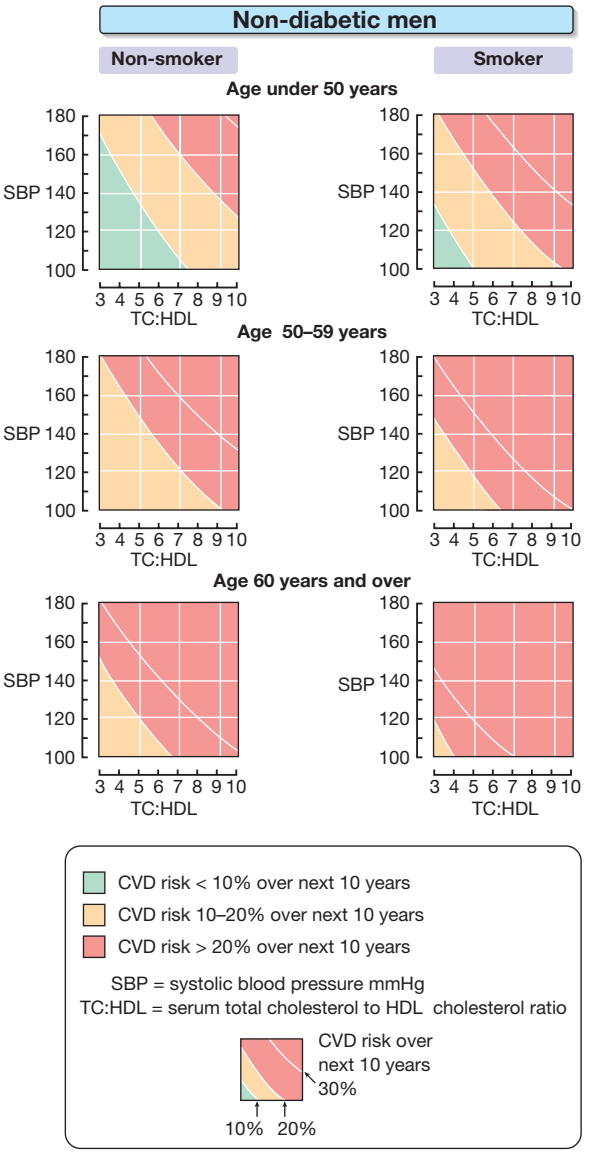

Fig. 18.62 Example of cardiovascular risk prediction chart for non-diabetic men. Cardiovascular risk is predicted from the patient's age, sex, smoking habit, BP and cholesterol ratio. The ratio of total to high-density lipoprotein (HDL) cholesterol can be determined in a non-fasting blood sample. Where HDL cholesterol concentration is unknown, it should be assumed to be 1 mmol/L; the lipid scale should be used as total serum cholesterol. Current guidelines suggest initiation of primary prevention in individuals with a 10-year cardiovascular risk ≥ 20%. Patients with diabetes mellitus should be assumed to have a 10-year cardiovascular risk of ≥ 20% and receive secondary prevention therapy. Modified charts exist for women. For further details, see www.who.int/cardiovascular_diseases/guidelines/Pocket_GL_information/en/index.html. From Joint British Societies Cardiovascular Risk Prediction Chart – see p. 641.

- To estimate an individual's absolute 10-year risk of developing cardiovascular disease (CVD), choose the panel for the appropriate gender, smoking status and age. Within this, define the level of risk from the point where the coordinates for systolic blood pressure (SBP) and ratio of the total to high-density lipoprotein (HDL)-cholesterol cross.
- Highest-risk individuals (red areas) are those whose 10-year CVD risk exceeds 20%, which is approximately equivalent to a 10-year coronary artery disease risk of > 15%. As a minimum, those with CVD risk > 30% (shown by the line within the red area) should be targeted and treated now. When resources allow, others with a CVD risk > 20% should be targeted progressively.
- The chart also assists in identification of individuals with a moderately high 10-year CVD risk, in the range of 10–20% (orange area) and those in whom it is < 10% (green area).
- Smoking status should reflect lifetime exposure to tobacco. For further information, see www.bhf.org.uk

18.45 Population advice to prevent coronary disease

- Do not smoke
- Take regular exercise (minimum of 20 mins, three times/wk)
- Maintain 'ideal' body weight
- Eat a mixed diet rich in fresh fruit and vegetables
- Aim to get no more than 10% of energy intake from saturated fat

smoking or average cholesterol, or modification of exercise and diet will produce worthwhile benefits (Box 18.45). Some risk factors for atheroma, such as obesity and smoking, are also associated with a higher risk of other diseases and should be actively discouraged through public health measures. Legislation restricting smoking in public places is associated with reductions in rates of MI.

The targeted strategy aims to identify and treat high-risk individuals, who usually have a combination of risk factors and can be identified by using composite scoring systems (Fig. 18.62). It is important to consider the absolute risk of atheromatous cardiovascular disease that an individual is facing before contemplating specific antihypertensive or lipid-lowering therapy because this will help to determine whether the possible benefits of intervention are likely to outweigh the expense, inconvenience and possible side-effects of treatment. For example, a 65-year-old man with an average BP of 150/90 mmHg, who smokes and has diabetes mellitus, a total:HDL cholesterol ratio of 8 and left ventricular hypertrophy on ECG, will have a 10-year risk of coronary artery disease of 68% and a 10-year risk of any cardiovascular event of 90%. Lowering his cholesterol will reduce these risks by 30% and lowering his BP will produce a further 20% reduction; both would obviously be worthwhile. Conversely, a 55-year-old woman who has an identical BP, is a non-smoker, does not have diabetes mellitus and has a normal ECG and a total:HDL cholesterol ratio of 6 has a much better outlook, with a predicted coronary artery disease risk of 14% and cardiovascular risk of 19% over the next 10 years. Although lowering her cholesterol and BP would also reduce risk by 30% and 20% respectively, the value of either or both treatments is questionable.

Secondary prevention

Patients who already have evidence of atheromatous vascular disease are at high risk of future cardiovascular events and should be offered treatments and measures to improve their outlook. The energetic correction of

modifiable risk factors, particularly smoking, hypertension and hypercholesterolaemia, is particularly important because the absolute risk of further vascular events is high. All patients with coronary artery disease should be given statin therapy, irrespective of their serum cholesterol concentration (Box 18.46). BP should be treated to a target of 140/85 mmHg or lower (p. 610). Aspirin and ACE inhibitors are of benefit in patients with evidence of vascular disease (Boxes 18.47 and 18.48). Beta-blockers benefit patients with a history of MI (see below) or heart failure.

Many clinical events offer an unrivalled opportunity to introduce effective secondary preventive measures; patients who have just survived an MI or undergone bypass surgery are usually keen to help themselves and may be particularly receptive to lifestyle advice, such as dietary modification and smoking cessation.

EBM 18.46 Use of statins in prevention of atherosclerotic disease

Primary prevention

'In patients *without evidence of coronary disease* but with high serum cholesterol concentrations, cholesterol-lowering with statins does not lower mortality but does prevent coronary events (angina and MI).'

Secondary prevention

'In patients *with established coronary disease* (MI or angina), statin therapy can safely reduce the 5-year incidence of all-cause death, as well as major coronary events, coronary revascularisation and stroke. Benefit depends on the overall risk of the study population but the NNT_B for 5 years to prevent 1 death ranges from 10 to 90.'

- Cholesterol Treatment Trialists' Collaborators. Lancet 2005; 366:1267–1277.

For further information: www.sign.ac.uk/guidelines/fulltext/93-97/index.html

EBM 18.47 ACE inhibitors and secondary prevention of atherosclerotic disease

'ACE inhibitor therapy reduces the risk of death, MI and stroke in patients with atherosclerotic vascular disease without apparent left ventricular systolic dysfunction or heart failure. NNT_B to avoid 1 event over 4 years ranges from 6 to 50, depending upon the level of cardiovascular risk.'

- HOPE trial. N Engl J Med 2000; 342:145–153.
- EUROPA trial. Lancet 2003; 362:782–788.

EBM 18.48 Aspirin and secondary prevention in atherosclerotic vascular disease

'In patients with established coronary artery disease, peripheral vascular disease or thrombotic stroke, aspirin is effective in reducing morbidity and mortality (non-fatal MI, stroke and cardiovascular death). In patients at high risk of future vascular events, the overall risk reduction is 22%.'

- Antithrombotic Trialist Collaboration. BMJ 2002; 324:71–86.

CORONARY ARTERY DISEASE

Coronary artery disease (CAD) is the most common form of heart disease and the single most important cause of premature death in Europe, the Baltic states, Russia, North and South America, Australia and New Zealand. By 2020, it is estimated that it will be the major cause of death in all regions of the world.

In the UK, 1 in 3 men and 1 in 4 women die from CAD, an estimated 330 000 people have a myocardial infarct each year, and approximately 1.3 million people have angina. The death rates from CAD in the UK are amongst the highest in Western Europe (more than 140 000 people) but are falling, particularly in younger age groups; in the last 10 years, CAD mortality has fallen by 42% among UK men and women aged 16–64. However, in Eastern Europe and much of Asia, the rates of CAD are rapidly rising.

Disease of the coronary arteries is almost always due to atheroma and its complications, particularly thrombosis (Box 18.49). Occasionally, the coronary arteries are involved in other disorders such as aortitis, polyarteritis and other connective tissue disorders.

18.49 Coronary artery disease: clinical manifestations and pathology

Clinical problem	Pathology
Stable angina	Ischaemia due to fixed atheromatous stenosis of one or more coronary arteries
Unstable angina	Ischaemia caused by dynamic obstruction of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Myocardial infarction	Myocardial necrosis caused by acute occlusion of a coronary artery due to plaque rupture or erosion with superimposed thrombosis
Heart failure	Myocardial dysfunction due to infarction or ischaemia
Arrhythmia	Altered conduction due to ischaemia or infarction
Sudden death	Ventricular arrhythmia, asystole or massive myocardial infarction

Stable angina

Angina pectoris is the symptom complex caused by transient myocardial ischaemia and constitutes a clinical syndrome rather than a disease. It may occur whenever there is an imbalance between myocardial oxygen supply and demand (Box 18.50). Coronary atheroma is by far the most common cause of angina, although the symptom may be a manifestation of other forms of heart disease, particularly aortic valve disease and hypertrophic cardiomyopathy

Clinical features

The history is the most important factor in making the diagnosis (p. 539). Stable angina is characterised by central chest pain, discomfort or breathlessness that is

18.50 Factors influencing myocardial oxygen supply and demand

Oxygen demand: cardiac work

- Heart rate
- BP
- Myocardial contractility
- Left ventricular hypertrophy
- Valve disease, e.g. aortic stenosis

Oxygen supply: coronary blood flow

- Duration of diastole
- Coronary perfusion pressure (aortic diastolic minus coronary sinus or right atrial diastolic pressure)
- Coronary vasomotor tone
- Oxygenation
  - Haemoglobin
  - Oxygen saturation

N.B. Coronary blood flow occurs mainly in diastole.

18.51 Activities precipitating angina

Common

- Physical exertion
- Cold exposure
- Heavy meals
- Intense emotion

Uncommon

- Lying flat (decubitus angina)
- Vivid dreams (nocturnal angina)

precipitated by exertion or other forms of stress (Box 18.51), and is promptly relieved by rest (see Figs 18.17 and 18.18, pp. 540 and 541). Some patients find the discomfort comes when they start walking, and that later it does not return despite greater effort ('warm-up angina').

Physical examination is frequently unremarkable but should include a careful search for evidence of valve disease (particularly aortic), important risk factors (e.g. hypertension, diabetes mellitus), left ventricular dysfunction (cardiomegaly, gallop rhythm), other manifestations of arterial disease (carotid bruits, peripheral vascular disease) and unrelated conditions that may exacerbate angina (anaemia, thyrotoxicosis).

Investigations

Resting ECG

The ECG may show evidence of previous MI but is often normal, even in patients with severe coronary artery disease. Occasionally, there is T-wave flattening or inversion in some leads, providing non-specific evidence of myocardial ischaemia or damage. The most convincing ECG evidence of myocardial ischaemia is the demonstration of reversible ST segment depression or elevation, with or without T-wave inversion, at the time the patient is experiencing symptoms (whether spontaneous or induced by exercise testing).

Exercise ECG

An exercise tolerance test (ETT) is usually performed using a standard treadmill or bicycle ergometer protocol (p. 534) while monitoring the patient's ECG, BP and general condition. Planar or down-sloping ST segment depression of 1 mm or more is indicative of ischaemia (Fig. 18.63). Up-sloping ST depression is less specific and often occurs in normal individuals.

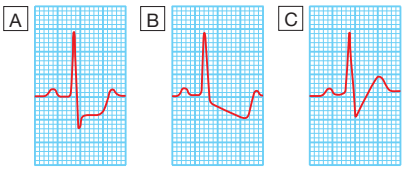

Fig. 18.63 Forms of exercise-induced ST depression. A Planar ST depression is usually indicative of myocardial ischaemia. B Down-sloping depression also usually indicates myocardial ischaemia. C Up-sloping depression may be a normal finding.

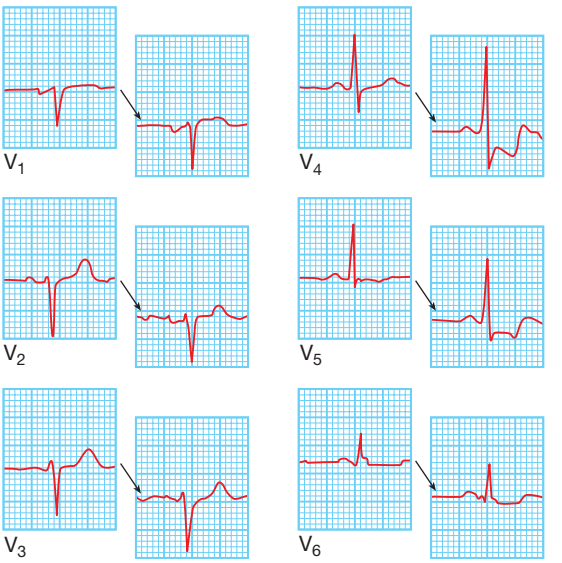

Fig. 18.64 A positive exercise test (chest leads only). The resting 12-lead ECG shows some minor T-wave changes in the inferolateral leads but is otherwise normal. After 3 minutes' exercise on a treadmill, there is marked planar ST depression in leads V_4 and V_5 (right offset). Subsequent coronary angiography revealed critical three-vessel coronary artery disease.

18.52 Risk stratification in stable angina

High risk	Low risk
Post-infarct angina	Predictable exertional angina
Poor effort tolerance	Good effort tolerance
Ischaemia at low workload	Ischaemia only at high workload
Left main or three-vessel disease	Single-vessel or two-vessel disease
Poor LV function	Good LV function

N.B. Patients may fall between these categories.

Exercise testing is also a useful means of assessing the severity of coronary disease and identifying high-risk individuals (Box 18.52). For example, the amount of exercise that can be tolerated and the extent and degree of any ST segment change (Fig. 18.64) provide a useful guide to the likely extent of coronary disease. Exercise testing is not infallible and may produce false-positive results in the presence of digoxin therapy, left ventricular hypertrophy, bundle branch block or WPW syndrome. The predictive accuracy of exercise testing is

lower in women than in men. The test should be classed as inconclusive (rather than negative) if the patient cannot achieve an adequate level of exercise because of locomotor or other non-cardiac problems.

Other forms of stress testing

- *Myocardial perfusion scanning.* This may be helpful in the evaluation of patients with an equivocal or uninterpretable exercise test and those who are unable to exercise (p. 539). It entails obtaining scintiscans of the myocardium at rest and during stress (either exercise testing or pharmacological stress, such as a controlled infusion of dobutamine), after the administration of an intravenous radioactive isotope, such as ^{99}technetium tetrofosmin. Thallium and tetrofosmin are taken up by viable perfused myocardium. A perfusion defect present during stress but not at rest provides evidence of reversible myocardial ischaemia (Fig. 18.65), whereas a persistent perfusion defect seen during both phases of the study is usually indicative of previous MI.
- *Stress echocardiography.* This is an alternative to myocardial perfusion scanning and can achieve similar predictive accuracy. It uses transthoracic echocardiography to identify ischaemic segments of myocardium and areas of infarction (p. 537). The former characteristically exhibit reversible defects in contractility during exercise or pharmacological stress, and the latter do not contract at rest or during stress.

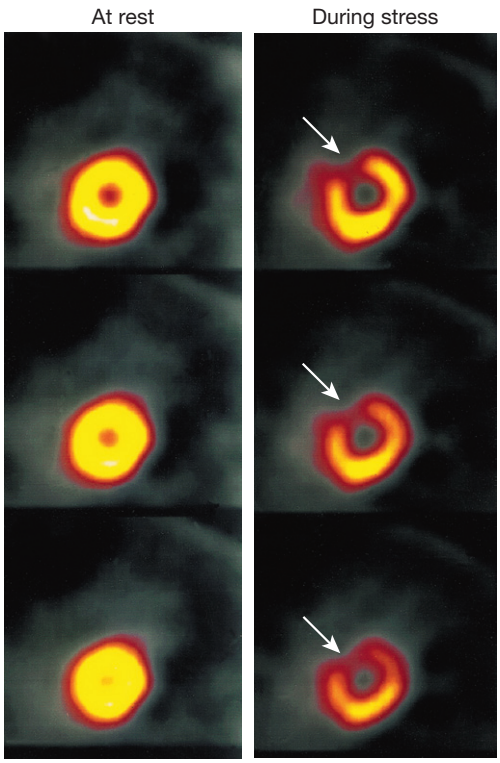

Fig. 18.65 A myocardial perfusion scan showing reversible anterior myocardial ischaemia. The images are cross-sectional tomograms of the LV. The resting scans (left) show even uptake of the ^{99}technetium-labelled tetrofosmin and look like doughnuts. During stress (e.g. a dobutamine infusion), there is reduced uptake of technetium, particularly along the anterior wall (arrows), and the scans look like crescents (right).

Coronary arteriography

This provides detailed anatomical information about the extent and nature of coronary artery disease (see Fig. 18.15, p. 538), and is usually performed with a view to coronary artery bypass graft (CABG) surgery or percutaneous coronary intervention (PCI) (pp. 587 and 588). In some patients, diagnostic coronary angiography may be indicated when non-invasive tests have failed to establish the cause of atypical chest pain. The procedure is performed under local anaesthesia and requires specialised radiological equipment, cardiac monitoring and an experienced operating team.

Management: general measures

The management of angina pectoris involves:

- a careful assessment of the likely extent and severity of arterial disease
- the identification and control of risk factors such as smoking, hypertension and hyperlipidaemia
- the use of measures to control symptoms
- the identification of high-risk patients for treatment to improve life expectancy.

Symptoms alone are a poor guide to the extent of coronary artery disease. Stress testing is therefore advisable in all patients who are potential candidates for revascularisation. An algorithm for the investigation and treatment of patients with stable angina is shown in Figure 18.66.

Management should start with a careful explanation of the problem and a discussion of the potential lifestyle and medical interventions that may relieve symptoms and improve prognosis (Box 18.53). Anxiety and misconceptions often contribute to disability; for example, some patients avoid all forms of exertion because they believe that each attack of angina is a 'mini heart attack' that results in permanent damage. Effective management of these psychological factors can make a huge difference to the patient's quality of life.

Antiplatelet therapy

Low-dose (75 mg) aspirin reduces the risk of adverse events such as MI and should be prescribed for all patients with coronary artery disease indefinitely (see Box 18.48). Clopidogrel (75 mg daily) is an equally effective antiplatelet agent that can be prescribed if aspirin causes troublesome dyspepsia or other side-effects.

18.53 Advice to patients with stable angina

- Do not smoke
- Aim for ideal body weight
- Take regular exercise (exercise up to, but not beyond, the point of chest discomfort is beneficial and may promote collateral vessels)
- Avoid severe unaccustomed exertion, and vigorous exercise after a heavy meal or in very cold weather
- Take sublingual nitrate before undertaking exertion that may induce angina

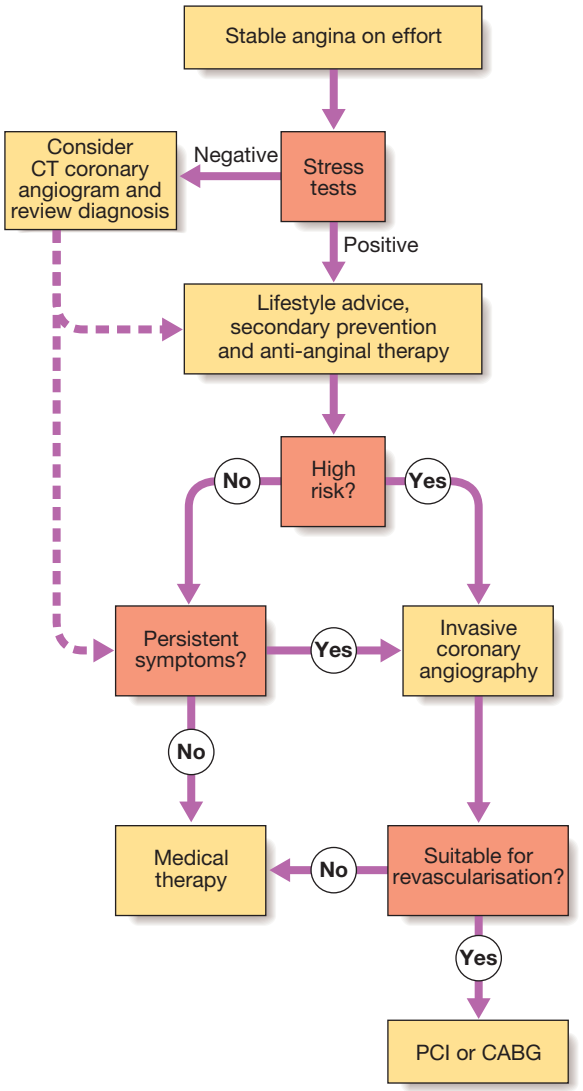

Fig. 18.66 A scheme for the investigation and treatment of stable angina on effort. The selection of percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) depends upon patient choice, coronary artery anatomy and extent of coronary artery disease. In general, left main stem and three-vessel coronary artery disease should be treated by CABG surgery.

Anti-anginal drug treatment

Five groups of drug are used to help relieve or prevent the symptoms of angina: nitrates, β-blockers, calcium antagonists, potassium channel activators and an I_f channel antagonist.

Nitrates

These drugs act directly on vascular smooth muscle to produce venous and arteriolar dilatation. Their beneficial effects are due to a reduction in myocardial oxygen demand (lower preload and afterload) and an increase in myocardial oxygen supply (coronary vasodilatation). Sublingual glyceryl trinitrate (GTN), administered from a metered-dose aerosol (400 µg per spray) or as a tablet (300 or 500 µg), will relieve an attack of angina in 2–3 minutes. Side-effects include headache, symptomatic hypotension and, rarely, syncope.

18.54 Duration of action of some nitrate preparations

Preparation	Peak action	Duration of action
Sublingual GTN	4–8 mins	10–30 mins
Buccal GTN	4–10 mins	30–300 mins
Transdermal GTN	1–3 hrs	Up to 24 hrs
Oral isosorbide dinitrate	45–120 mins	2–6 hrs
Oral isosorbide mononitrate	45–120 mins	6–10 hrs

(GTN = glyceryl trinitrate)

Patients should be encouraged to use the drug prophylactically before taking exercise that is liable to provoke symptoms. Sublingual GTN has a short duration of action (Box 18.54); however, a variety of alternative nitrate preparations can provide a more prolonged therapeutic effect. GTN can be given transcutaneously as a patch (5–10 mg daily), or as a slow-release buccal tablet (1–5 mg 4 times daily). GTN undergoes extensive first-pass metabolism in the liver and is ineffective when swallowed. Other nitrates, such as isosorbide dinitrate (10–20 mg 3 times daily) and isosorbide mononitrate (20–60 mg once or twice daily), can be given by mouth. Headache is common but tends to diminish if the patient perseveres with the treatment. Continuous nitrate therapy can cause pharmacological tolerance. This can be avoided by a 6–8-hour nitrate-free period, best achieved at night when the patient is inactive. If nocturnal angina is a predominant symptom, long-acting nitrates can be given at the end of the day.

Beta-blockers

These lower myocardial oxygen demand by reducing heart rate, BP and myocardial contractility, but they may provoke bronchospasm in patients with asthma. The properties and side-effects of β-blockers are discussed on page 599.

In theory, non-selective β-blockers may aggravate coronary vasospasm by blocking the coronary artery β_2-adrenoceptors and so a once-daily cardioselective preparation is used (e.g. slow-release metoprolol 50–200 mg daily, bisoprolol 5–15 mg daily). Beta-blockers should not be withdrawn abruptly as rebound effects may precipitate dangerous arrhythmias, worsening angina or MI: the β-blocker withdrawal syndrome.

Calcium channel antagonists

These drugs inhibit the slow inward current caused by the entry of extracellular calcium through the cell membrane of excitable cells, particularly cardiac and arteriolar smooth muscle, and lower myocardial oxygen demand by reducing BP and myocardial contractility.

Dihydropyridine calcium antagonists, such as nifedipine and nicardipine, often cause a reflex tachycardia. This may be counterproductive and it is best to use them in combination with a β-blocker. In contrast, verapamil and diltiazem are particularly suitable for patients who are not receiving a β-blocker (e.g. those with airways obstruction) because they slow SA node firing, inhibit conduction through the AV node and

18.55 Calcium channel antagonists used for the treatment of angina

Drug	Dose	Feature
Nifedipine	5–20 mg 3 times daily*	May cause marked tachycardia
Nicardipine	20–40 mg 3 times daily	May cause less myocardial depression than the other calcium antagonists
Amlodipine	2.5–10 mg daily	Ultra-long-acting
Verapamil	40–80 mg 3 times daily*	Commonly causes constipation; useful anti-arrhythmic properties (p. 576)
Diltiazem	60–120 mg 3 times daily*	Similar anti-arrhythmic properties to verapamil

*Once- or twice-daily slow-release preparations are available.

tend to cause a bradycardia. Calcium channel antagonists reduce myocardial contractility and can aggravate or precipitate heart failure. Other unwanted effects include peripheral oedema, flushing, headache and dizziness (Box 18.55).

Potassium channel activators

These have arterial and venous dilating properties but do not exhibit the tolerance seen with nitrates. Nicorandil (10–30 mg twice daily orally) is the only drug in this class currently available for clinical use.

I_f channel antagonist

Ivabradine is the first of this class of drug. It induces bradycardia by modulating ion channels in the sinus node. In contrast to β-blockers and rate-limiting calcium antagonists, it does not have other cardiovascular effects. It appears to be safe to use in patients with heart failure.

Although each of these anti-anginal drugs is superior to placebo in relieving the symptoms of angina, there is little evidence that one group is more effective than another. It is conventional to start therapy with low-dose aspirin, a statin, sublingual GTN and a β-blocker, and then add a calcium channel antagonist or a long-acting nitrate later, if needed. The goal is the control of angina with minimum side-effects and the simplest possible drug regimen. There is little evidence that prescribing multiple anti-anginal drugs is of benefit, and revascularisation should be considered if an appropriate combination of two or more drugs fails to achieve an acceptable symptomatic response.

Invasive treatment

Percutaneous coronary intervention

Percutaneous coronary intervention (PCI) is performed by passing a fine guidewire across a coronary stenosis under radiographic control and using it to position a balloon, which is then inflated to dilate the stenosis (Fig. 18.67). A coronary stent is a piece of coated metallic 'scaffolding' that can be deployed on a balloon and used to maximise and maintain dilatation of a stenosed vessel. The routine use of stents in appropriate vessels reduces

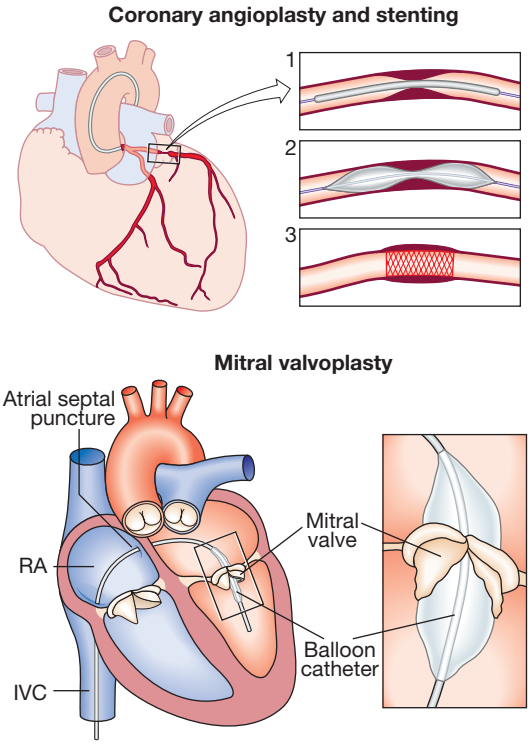

Fig. 18.67 Vascular and valvular balloon dilatations.

EBM 18.56 Angioplasty and intracoronary stents in angina

'In comparison with simple balloon angioplasty, intracoronary stents afford superior acute and long-term clinical and angiographic results, with lower rates of re-stenosis (e.g. 17% vs 40%) and recurrent angina (13% vs 30%). Re-stenosis rates are reduced even further (< 10%) with drug-eluting stents.'

- Stettler C, et al. BMJ 2008; 337:a1331.

For further information: http://guidance.nice.org.uk/TA152

both acute complications and the incidence of clinically important re-stenosis (Box 18.56 and Fig. 18.76, p. 595).

PCI provides an effective symptomatic treatment but definitive evidence that it improves survival in patients with chronic stable angina is lacking. It is mainly used in single- or two-vessel disease. Stenoses in bypass grafts can be dilated, as well as those in the native coronary arteries. The technique is often used to provide palliative therapy for patients with recurrent angina after CABG. Coronary surgery is usually the preferred option in patients with three-vessel or left main stem disease, although recent trials have demonstrated that PCI is also feasible in such patients.

The main acute complications of PCI are occlusion of the target vessel or a side branch by thrombus or a loose flap of intima (coronary artery dissection), and consequent myocardial damage. This occurs in about 2–5% of procedures and can often be corrected by deploying a stent; however, emergency CABG is sometimes required. Minor myocardial damage, as indicated by elevation of sensitive intracellular markers (troponins, p. 535), occurs

EBM 18.57 Percutaneous coronary intervention vs medical therapy in stable angina

'PCI is more effective than medical therapy in alleviating angina pectoris and improving exercise tolerance but does not reduce mortality. It carries risks of procedure-related MI, emergency CABG and repeat procedures for re-stenosis.'

- Weintraub WS, et al. N Engl J Med 2008; 359(7):677–687.

For further information: www.nice.org.uk/CG126

in up to 10% of cases. The main long-term complication of PCI is re-stenosis (Box 18.57), in up to one-third of cases. This is due to a combination of elastic recoil and smooth muscle proliferation (neo-intimal hyperplasia) and tends to occur within 3 months. Stenting substantially reduces the risk of re-stenosis, probably because it allows the operator to achieve more complete dilatation in the first place. Drug-eluting stents reduce this risk even further by allowing an antiproliferative drug, e.g. sirolimus or paclitaxel, to elute slowly from the coating and prevent neo-intimal hyperplasia and in-stent re-stenosis. There is an increased risk of late stent thrombosis with drug-eluting stents, although the absolute risk is small (< 0.5%). Recurrent angina (affecting up to 15–20% of patients receiving an intracoronary stent at 6 months) may require further PCI or bypass grafting.

The risk of complications and the likely success of the procedure are closely related to the morphology of the stenoses, the experience of the operator and the presence of important comorbidity, e.g. diabetes, peripheral arterial disease. A good outcome is less likely if the target lesion is complex, long, eccentric or calcified, lies on a bend or within a tortuous vessel, involves a branch or contains acute thrombus.

In combination with aspirin and heparin, adjunctive therapy with potent platelet inhibitors, such as clopidogrel or glycoprotein IIb/IIIa receptor antagonists, improves the outcome of PCI, with lower short- and long-term rates of death and MI.

Coronary artery bypass grafting

The internal mammary arteries, radial arteries or reversed segments of the patient's own saphenous vein can be used to bypass coronary artery stenoses (Fig. 18.68). This usually involves major surgery under cardiopulmonary bypass but, in some cases, grafts can be applied to the beating heart: 'off-pump' surgery. The operative mortality is approximately 1.5% but risks are higher in elderly patients, those with poor left ventricular function and those with significant comorbidity, such as renal failure.

Approximately 90% of patients are free of angina 1 year after CABG surgery, but fewer than 60% of patients are asymptomatic after 5 or more years. Early postoperative angina is usually due to graft failure arising from technical problems during the operation, or poor 'run-off' due to disease in the distal native coronary vessels. Late recurrence of angina may be due to progressive disease in the native coronary arteries or graft degeneration. Fewer than 50% of vein grafts are patent 10 years after surgery. However, arterial grafts have a much better long-term patency rate, with more than 80% of internal mammary artery grafts patent at

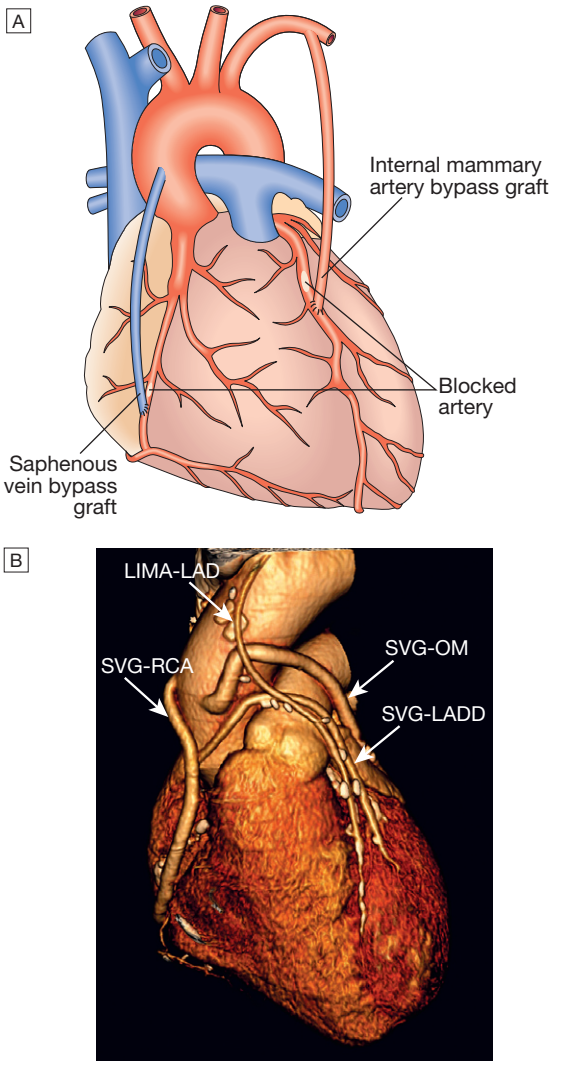

Fig. 18.68 Coronary artery bypass graft surgery. A Narrowed or stenosed arteries are bypassed using saphenous vein grafts connected to the aorta, or by utilising the internal mammary artery. B Three-dimensional reconstruction of multidetector CT of the heart. The image shows the patent saphenous vein grafts (SVG) to the right coronary artery (RCA), obtuse marginal branch (OM) and diagonal branch (LADD), and left internal mammary artery graft (LIMA) to the left anterior descending (LAD) coronary artery.

10 years. This has led many surgeons to consider total arterial revascularisation during CABG surgery. Aspirin (75–150 mg daily) and clopidogrel (75 mg daily) both improve graft patency, and one or other should be prescribed indefinitely, if well tolerated. Intensive lipid-lowering therapy slows the progression of disease in the native coronary arteries and bypass grafts, and reduces clinical cardiovascular events. There is substantial excess cardiovascular morbidity and mortality in patients who continue to smoke after bypass grafting. Persistent smokers are twice as likely to die in the 10 years following surgery than those who give up at surgery.

CABG improves survival in symptomatic patients with left main stem stenosis or three-vessel coronary disease (i.e. involving LAD, CX and right coronary arteries, Box 18.58) or two-vessel disease involving the

EBM 18.58 Coronary artery bypass grafting for stable angina

'CABG is superior to medical treatment for at least 10 years after surgery in terms of survival. Greatest benefit occurs in those with a significant stenosis in the left main coronary artery or those with three-vessel disease and impaired ventricular function.'

18.59 Comparison of PCI and CABG

	PCI	CABG
Death	< 0.5%	< 1.5%
Myocardial infarction*	2%	10%
Hospital stay	12–36 hrs	5–8 days
Return to work	2–5 days	6–12 wks
Recurrent angina	15–20% at 6 mths	10% at 1 yr
Repeat revascularisation	10–20% at 2 yrs	2% at 2 yrs
Neurological complications	Rare	Common (see text)
Other complications	Emergency CABG Vascular damage related to access site	Diffuse myocardial damage Infection (chest, wound) Wound pain

*Defined as CK-MB > 2 × normal, p. 589.

EBM 18.60 Comparison of PCI and CABG surgery in stable angina

'Systematic reviews and meta-analyses have found similar rates of death and MI, and similar quality of life. PCI is associated with a greater need for repeat procedures, although this has been halved by the introduction of intracoronary stent implantation. For patients with multi-vessel disease or diabetes, CABG appears to confer better survival rates at 4–5 years.'

- Serruys PW, et al. N Engl J Med 2009; 360:961–972.

For further information: www.nice.org.uk/CG126

proximal LAD coronary artery. Improvement in survival is most marked in those with impaired left ventricular function or positive stress testing prior to surgery and in those who have undergone left internal mammary artery grafting.

Neurological complications are common, with a 1–5% risk of peri-operative stroke. Between 30% and 80% of patients develop short-term cognitive impairment that typically resolves within 6 months. There are also reports of long-term cognitive decline that may be evident in more than 30% of patients at 5 years. PCI and CABG are compared in Boxes 18.59 and 18.60.

Prognosis

Symptoms are a poor guide to prognosis; nevertheless, the 5-year mortality of patients with severe angina (NYHA class III or IV, p. 539) is nearly double that of patients with mild symptoms. Exercise testing and other forms of stress testing are much more powerful predictors of mortality; for example, in one study, the 4-year mortality of patients with stable angina and a negative exercise test was 1%, compared to more than 20% in those with a strongly positive test.

In general, the prognosis of coronary artery disease is related to the number of diseased vessels and the degree of left ventricular dysfunction. A patient with single-vessel disease and good left ventricular function has an excellent outlook (5-year survival > 90%), whereas a patient with severe left ventricular dysfunction and extensive three-vessel disease has a poor prognosis (5-year survival < 30%) without revascularisation. Spontaneous symptomatic improvement due to the development of collateral vessels is common.

Angina with normal coronary arteries

Approximately 10% of patients who report stable angina on effort will have angiographically normal coronary arteries. Many of these patients are women and the mechanism of their symptoms is often difficult to establish. It is important to review the original diagnosis and explore other potential causes.

Coronary artery spasm

Vasospasm in coronary arteries may coexist with atheroma, especially in unstable angina (see below); in less than 1% of cases, vasospasm may occur without angiographically detectable atheroma. This is sometimes known as variant angina, and may be accompanied by spontaneous and transient ST elevation on the ECG (Prinzmetal's angina). Calcium channel antagonists, nitrates and other coronary vasodilators are the most useful therapeutic agents but may be ineffective.

Syndrome X

The constellation of typical angina on effort, objective evidence of myocardial ischaemia on stress testing, and angiographically normal coronary arteries is sometimes known as syndrome X. This disorder is poorly understood but carries a good prognosis and may respond to treatment with anti-anginal therapy.

Acute coronary syndrome

Acute coronary syndrome is a term that encompasses both unstable angina and myocardial infarction (MI). It is characterised by new-onset or rapidly worsening angina (crescendo angina), angina on minimal exertion or angina at rest in the absence of myocardial damage. In contrast, MI occurs when symptoms occur at rest and there is evidence of myocardial necrosis, as demonstrated by an elevation in cardiac troponin or creatine kinase-MB isoenzyme (Box 18.61).

An acute coronary syndrome may present as a new phenomenon or against a background of chronic stable angina. The culprit lesion is usually a complex

18.61 Universal definition of myocardial infarction

Criteria for acute myocardial infarction

The term acute myocardial infarction (MI) should be used when there is evidence of myocardial necrosis in a clinical setting consistent with acute myocardial ischaemia. Under these conditions, any one of the following criteria meets the diagnosis for MI:

- Detection of a rise and/or fall of cardiac biomarker values (preferably cardiac troponin (cTn)), with at least one value above the 99th centile upper reference limit (URL) and with at least one of the following:
  1. Symptoms of ischaemia
  2. New or presumed new significant ST segment–T wave (ST–T) changes or new left bundle branch block (LBBB)
  3. Development of pathological Q waves in the ECG
  4. Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
  5. Identification of an intracoronary thrombus by angiography or post-mortem
- Cardiac death with symptoms suggestive of myocardial ischaemia and presumed new ischaemic ECG changes or new LBBB, but death occurred before cardiac biomarkers were obtained, or before cardiac biomarker values would be increased
- Percutaneous coronary intervention (PCI)-related MI is arbitrarily defined by elevation of cTn values ($> 5 \times$ 99th centile URL) in patients with normal baseline values ($\leq$ 99th centile URL) or a rise of cTn values > 20% if the baseline values are elevated and are stable or falling. In addition, either (i) symptoms suggestive of myocardial ischaemia, or (ii) new ischaemic ECG changes, or (iii) angiographic findings consistent with a procedural complication, or (iv) imaging demonstration of new loss of viable myocardium or new regional wall motion abnormality are required
- Stent thrombosis associated with MI when detected by coronary angiography or post-mortem in the setting of myocardial ischaemia and with a rise and/or fall of cardiac biomarker values with at least one value above the 99th centile URL
- Coronary artery bypass grafting (CABG)-related MI is arbitrarily defined by elevation of cardiac biomarker values ($> 10 \times$ 99th centile URL) in patients with normal baseline cTn values ($\leq$ 99th centile URL). In addition, either (i) new pathological Q waves or new LBBB, or (ii) angiographic documented new graft or new native coronary artery occlusion, or (iii) imaging evidence of new loss of viable myocardium or new regional wall motion abnormality

Criteria for prior myocardial infarction

Any one of the following criteria meets the diagnosis for prior MI:

- Pathological Q waves with or without symptoms in the absence of non-ischaemic causes
- Imaging evidence of a region of loss of viable myocardium that is thinned and fails to contract, in the absence of a non-ischaemic cause

Pathological findings of a prior MI

Adapted from Thygesen K, et al. Eur Heart J 2012;33:2251–2267.

ulcerated or fissured atheromatous plaque with adherent platelet-rich thrombus and local coronary artery spasm (see Fig. 18.61, p. 580). This is a dynamic process whereby the degree of obstruction may either increase, leading to complete vessel occlusion, or regress due to the effects of platelet disaggregation and endogenous fibrinolysis. In acute MI, occlusive thrombus is almost always present at the site of rupture or erosion of an atheromatous plaque. The thrombus may undergo spontaneous lysis over the course of the next few days, although, by this time, irreversible myocardial damage has occurred. Without treatment, the infarct-related artery remains permanently occluded in 20–30% of patients. The process of infarction progresses over several hours (Fig. 18.69) and most patients present when it is still possible to salvage myocardium and improve outcome.

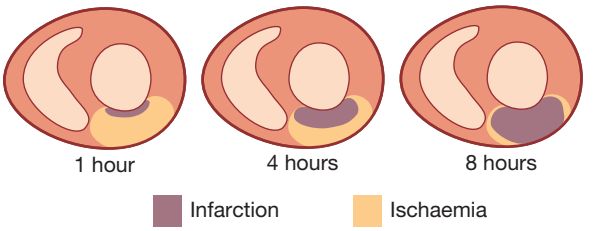

Fig. 18.69 The time course of MI. The relative proportion of ischaemic, infarcting and infarcted tissue slowly changes over a period of 12 hours. In the early stages of MI, a significant proportion of the myocardium in jeopardy is potentially salvageable.

Clinical features

Pain is the cardinal symptom of an acute coronary syndrome but breathlessness, vomiting and collapse are common features (Box 18.62). The pain occurs in the same sites as angina but is usually more severe and lasts longer; it is often described as a tightness, heaviness or constriction in the chest. In acute MI, the pain can be excruciating, and the patient's expression and pallor may vividly convey the seriousness of the situation.

Most patients are breathless and, in some, this is the only symptom. Indeed, MI may pass unrecognised. Painless or 'silent' MI is particularly common in older patients or those with diabetes mellitus. If syncope

18.62 Clinical features of acute coronary syndromes

Symptoms

- Prolonged cardiac pain: chest, throat, arms, epigastrium or back
- Anxiety and fear of impending death
- Nausea and vomiting
- Breathlessness
- Collapse/syncope

Physical signs

- Signs of sympathetic activation: pallor, sweating, tachycardia
- Signs of vagal activation: vomiting, bradycardia
- Signs of impaired myocardial function
  - Hypotension, oliguria, cold peripheries
  - Narrow pulse pressure
  - Raised JVP
  - Third heart sound
  - Quiet first heart sound
  - Diffuse apical impulse
  - Lung crepitations
- Signs of tissue damage: fever
- Signs of complications: e.g. mitral regurgitation, pericarditis

occurs, it is usually due to an arrhythmia or profound hypotension. Vomiting and sinus bradycardia are often due to vagal stimulation and are particularly common in patients with inferior MI. Nausea and vomiting may also be caused or aggravated by opiates given for pain relief. Sometimes infarction occurs in the absence of physical signs.

Sudden death, from ventricular fibrillation or asystole, may occur immediately and often within the first hour. If the patient survives this most critical stage, the liability to dangerous arrhythmias remains, but diminishes as each hour goes by. It is vital that patients know not to delay calling for help if symptoms occur. The development of cardiac failure reflects the extent of myocardial ischaemia and is the major cause of death in those who survive the first few hours.

Diagnosis and risk stratification

The differential diagnosis is wide and includes most causes of central chest pain or collapse (pp. 540 and 554). The assessment of acute chest pain depends heavily on an analysis of the character of the pain and its associated features, evaluation of the ECG, and serial measurements of biochemical markers of cardiac damage, such as troponin I and T. A 12-lead ECG is mandatory and defines the initial triage, management and treatment (see Fig. 18.19, p. 542). Patients with ST-segment elevation or new bundle branch block require emergency reperfusion therapy (see below). In patients with acute coronary syndrome without ST-segment elevation, the ECG may show transient or persistent ST–T wave changes, including ST depression and T-wave inversion.

Approximately 12% of patients will die within 1 month and a fifth within 6 months of the index event. The risk markers that are indicative of an adverse prognosis include recurrent ischaemia, extensive ECG changes at rest or during pain, the release of biochemical markers (creatine kinase or troponin), arrhythmias, recurrent ischaemia and haemodynamic complications (e.g. hypotension, mitral regurgitation) during episodes of ischaemia. Risk stratification is important because it guides the use of more complex pharmacological and interventional treatment (Figs 18.70 and 18.19 (p. 542)).

1. Find points for each predictive factor

Killip class	Points	SBP (mmHg)	Points	Heart rate (beats/min)	Points	Age (years)	Points	Serum creatinine level (μmol/L)	Points
I	0	≤ 80	58	≤ 50	0	≤ 30	0	0–34	1
II	20	80–99	53	50–69	3	30–39	8	35–70	4
III	39	100–119	43	70–89	9	40–49	25	71–105	7
IV	59	120–139	34	90–109	15	50–59	41	106–140	10
		140–159	24	110–149	24	60–69	58	141–176	13
		160–199	10	150–199	38	70–79	75	177–353	21
		≥ 200	0	≥ 200	46	80–89	91	≥ 353	28
						≥ 90	100		

Other risk factors	Points
Cardiac arrest at admission	39
ST-segment deviation	28
Elevated cardiac enzyme levels	14

2. Sum points for all predictive factors

Killip class	+	SBP	+	Heart rate	+	Age	+	Creatinine level	+	Cardiac arrest at admission	+	ST-segment deviation	+	Elevated cardiac enzyme levels	=	Total points

3. Look up risk corresponding to total points

Total points	≤ 60	70	80	90	100	110	120	130	140	150	160	170	180	190	200	210	220	230	240	≤ 250
Probability of in-hospital death (%)	≤ 0.2	0.3	0.4	0.6	0.8	1.1	1.6	2.1	2.9	3.9	5.4	7.3	9.8	13	18	23	29	36	44	≤ 52

Examples

A patient has Killip class II, SBP of 99 mmHg, heart rate of 100 beats/min, is 65 years of age, has a serum creatinine level of 76 μmol/L, did not have a cardiac arrest at admission but did have ST-segment deviation and elevated enzyme levels. His score would be: 20 + 53 + 15 + 58 + 7 + 0 + 28 + 14 = 195. This gives about a 16% risk of having an in-hospital death.

Similarly, a patient with Killip class I, SBP of 80 mmHg, heart rate of 60 beats/min, who is 55 years of age, has a serum creatinine level of 30 μmol/L, and no risk factors would have the following score: 0 + 58 + 3 + 41 + 1 = 103. This gives about a 0.9% risk of having an in-hospital death.

Fig. 18.70 Risk stratification in the acute coronary syndrome: the GRACE score. Killip class refers to a categorisation of the severity of heart failure based on easily obtained clinical signs. The main clinical features are as follows: class I = no heart failure; class II = crackles audible halfway up the chest; class III = crackles heard in all the lung fields; class IV = cardiogenic shock (SBP = systolic blood pressure). From SIGN 93 – see p. 641.

Investigations

Electrocardiography

The ECG is central to confirming the diagnosis but may be difficult to interpret if there is bundle branch block or previous MI. The initial ECG may be normal or non-diagnostic in one-third of cases. Repeated ECGs are important, especially where the diagnosis is uncertain or the patient has recurrent or persistent symptoms.

The earliest ECG change is usually ST-segment deviation. With proximal occlusion of a major coronary artery, ST-segment elevation (or new bundle branch block) is seen initially, with later diminution in the size of the R wave and, in transmural (full-thickness) infarction, development of a Q wave. Subsequently, the T wave becomes inverted because of a change in ventricular repolarisation; this change persists after the ST segment has returned to normal. These sequential features (Fig. 18.71) are sufficiently reliable for the approximate age of the infarct to be deduced.

In non-ST segment elevation acute coronary syndrome, there is partial occlusion of a major vessel or complete occlusion of a minor vessel, causing unstable angina or partial-thickness (subendocardial) MI. This is usually associated with ST-segment depression and T-wave changes. In the presence of infarction, this may be accompanied by some loss of R waves in the absence of Q waves (Fig. 18.72).

The ECG changes are best seen in the leads that 'face' the ischaemic or infarcted area. When there has been anteroseptal infarction, abnormalities are found in one or more leads from V_1 to V_4, while anterolateral infarction produces changes from V_4 to V_6, in aVL and in lead I. Inferior infarction is best shown in leads II, III and aVF, while, at the same time, leads I, aVL and the anterior chest leads may show 'reciprocal' changes of ST depression (Figs 18.73–18.74). Infarction of the posterior

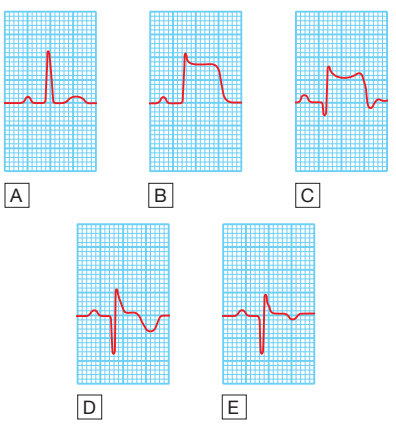

Fig. 18.71 The serial evolution of ECG changes in transmural MI. A Normal ECG complex. B Acute ST elevation ('the current of injury'). C Progressive loss of the R wave, developing Q wave, resolution of the ST elevation and terminal T-wave inversion. D Deep Q wave and T-wave inversion. E Old or established infarct pattern; the Q wave tends to persist but the T-wave changes become less marked. The rate of evolution is very variable but, in general, stage B appears within minutes, stage C within hours, stage D within days and stage E after several weeks or months. This should be compared with the 12-lead ECGs in Figures 18.72–18.74.

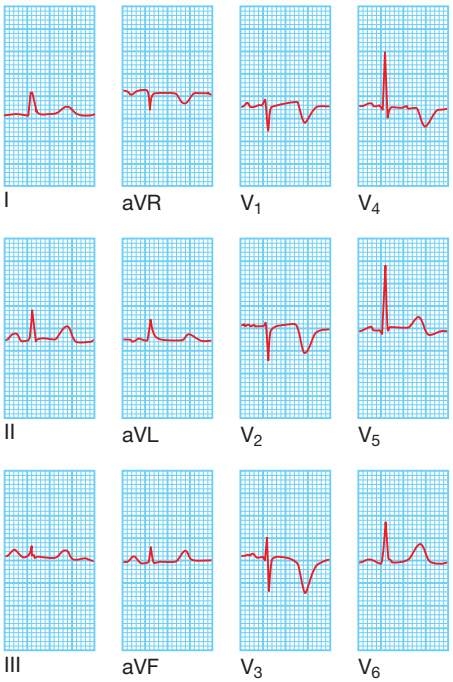

Fig. 18.72 Recent anterior non-ST elevation (subendocardial) MI. This ECG demonstrates deep symmetrical T-wave inversion, together with a reduction in the height of the R wave in leads V_1, V_2, V_3 and V_4.

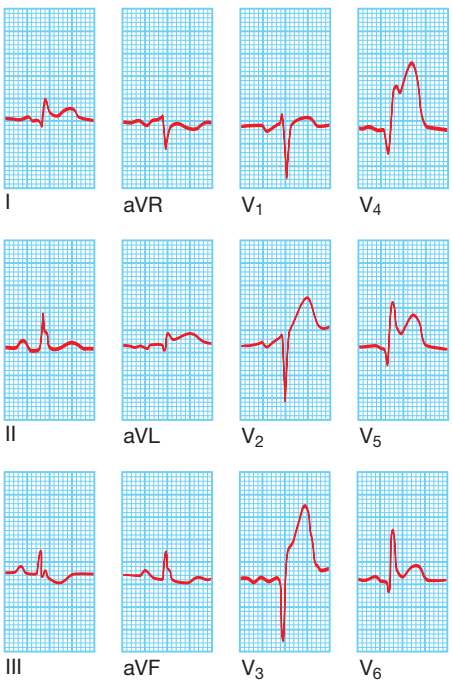

Fig. 18.73 Acute transmural anterior MI. This ECG was recorded from a patient who had developed severe chest pain 6 hours earlier. There is ST elevation in leads I, aVL, V_2, V_3, V_4, V_5 and V_6, and there are Q waves in leads V_3, V_4 and V_5. Anterior infarcts with prominent changes in leads V_2, V_3 and V_4 are sometimes called 'anteroseptal' infarcts, as opposed to anterolateral' infarcts, in which the ECG changes are predominantly found in V_4, V_5 and V_6.

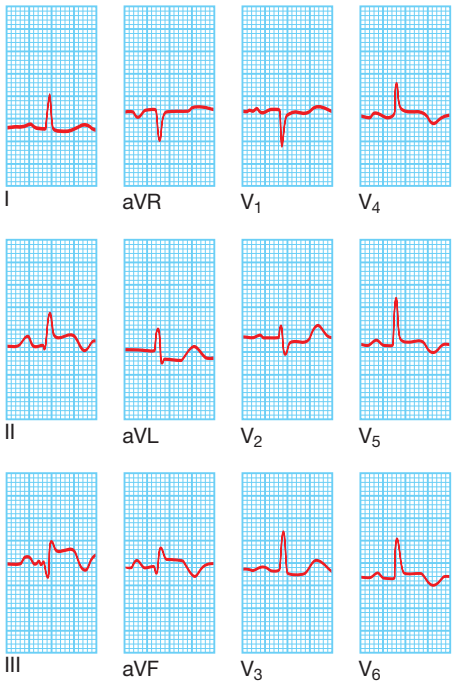

Fig. 18.74 Acute transmural inferolateral MI. This ECG was recorded from a patient who had developed severe chest pain 4 hours earlier. There is ST elevation in the inferior leads II, III and aVF and the lateral leads V_4, V_5 and V_6. There is also 'reciprocal' ST depression in leads aVL and V_2.

wall of the LV does not cause ST elevation or Q waves in the standard leads, but can be diagnosed by the presence of reciprocal changes (ST depression and a tall R wave in leads V_1–V_4). Some infarctions (especially inferior) also involve the RV. This may be identified by recording from additional leads placed over the right precordium.

Plasma cardiac biomarkers

In unstable angina, there is no detectable rise in cardiac biomarkers or enzymes, and the initial diagnosis is made from the clinical history and ECG only. In contrast, MI causes a rise in the plasma concentration of enzymes and proteins that are normally concentrated within cardiac cells. These biochemical markers are creatine kinase (CK), a more sensitive and cardio-specific isoform of this enzyme (CK-MB), and the cardio-specific proteins, troponins T and I (p. 535). Admission and serial (usually daily) estimations are helpful because it is the change in plasma concentrations of these markers that confirms the diagnosis of MI (Fig. 18.75 and Box 18.61).

CK starts to rise at 4–6 hours, peaks at about 12 hours and falls to normal within 48–72 hours. CK is also present in skeletal muscle, and a modest rise in CK (but not CK-MB) may sometimes be due to an intramuscular injection, vigorous physical exercise or, particularly in older people, a fall. Defibrillation causes significant release of CK but not CK-MB or troponins. The most sensitive markers of myocardial cell damage are the cardiac troponins T and I, which are released within 4–6 hours and remain elevated for up to 2 weeks.

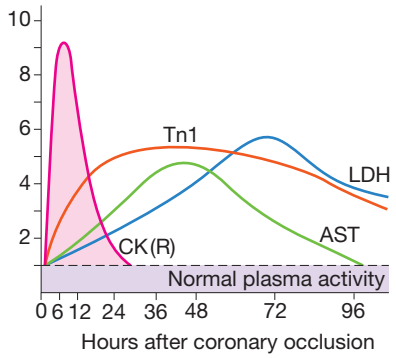

Fig. 18.75 Changes in plasma cardiac biomarker concentrations after MI. Creatine kinase (CK) and troponin I (Tn I) are the first to rise, followed by aspartate aminotransferase (AST) and then lactate (hydroxybutyrate) dehydrogenase (LDH). In patients treated with reperfusion therapy, a rapid rise in plasma creatine kinase (curve CK (R)) occurs, due to a washout effect.

Other blood tests

A leucocytosis is usual, reaching a peak on the first day. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are also elevated.

Chest X-ray

This may demonstrate pulmonary oedema that is not evident on clinical examination (see Fig. 18.25, p. 550). The heart size is often normal but there may be cardiomegaly due to pre-existing myocardial damage.

Echocardiography

This is useful for assessing ventricular function and for detecting important complications, such as mural thrombus, cardiac rupture, ventricular septal defect, mitral regurgitation and pericardial effusion.

Immediate management: the first 12 hours

Patients should be admitted urgently to hospital because there is a significant risk of death or recurrent myocardial ischaemia during the early unstable phase, and appropriate medical therapy can reduce the incidence of these by at least 60%. The essentials of the immediate in-hospital management of acute coronary syndrome are shown in Figure 18.19 (p. 542).

Patients are usually managed in a dedicated cardiac unit, where the necessary expertise, monitoring and resuscitation facilities can be concentrated. If there are no complications, the patient can be mobilised from the second day and discharged after 3–5 days.

Analgesia

Adequate analgesia is essential, not only to relieve distress but also to lower adrenergic drive and thereby reduce vascular resistance, BP, infarct size and susceptibility to ventricular arrhythmias. Intravenous opiates (initially, morphine sulphate 5–10 mg or diamorphine 2.5–5 mg) and antiemetics (initially, metoclopramide 10 mg) should be administered, and titrated by giving repeated small aliquots until the patient is comfortable. Intramuscular injections should be avoided because the clinical effect may be delayed by poor skeletal muscle

perfusion, and a painful haematoma may form following thrombolytic or antithrombotic therapy.

Antithrombotic therapy

Antiplatelet therapy

In patients with acute coronary syndrome, oral administration of 75–325 mg aspirin daily improves survival, with a 25% relative risk reduction in mortality. The first tablet (300 mg) should be given orally within the first 12 hours and therapy should be continued indefinitely if there are no side-effects. In combination with aspirin, the early (within 12 hours) use of clopidogrel (600 mg, followed by 150 mg daily for 1 week and 75 mg daily thereafter) confers a further reduction in ischaemic events (Box 18.63). In patients with an acute coronary syndrome, with or without ST-segment elevation, ticagrelor (180 mg, followed by 90 mg twice daily) is more effective than clopidogrel in reducing vascular death, MI or stroke, and all-cause death, without affecting overall major bleeding risk.

Glycoprotein IIb/IIIa receptor antagonists, such as tirofiban and abciximab, block the final common pathway of platelet aggregation and are potent inhibitors of platelet-rich thrombus formation. They are of particular benefit in patients with acute coronary syndromes who undergo PCI (Box 18.64), those with recurrent ischaemia and those at particularly high risk, such as patients with diabetes mellitus or an elevated troponin concentration.

Anticoagulants

Anticoagulation reduces the risk of thromboembolic complications, and prevents re-infarction in the absence of reperfusion therapy or after successful thrombolysis (Box 18.65). Anticoagulation can be achieved using unfractionated heparin, fractioned (low-molecular-weight) heparin or a pentasaccharide. Comparative clinical trials suggest that the pentasaccharides (subcutaneous fondaparinux 2.5 mg daily) have the best safety and efficacy profile, with low-molecular-weight heparin (subcutaneous enoxaparin 1 mg/kg twice daily) being a reasonable alternative. Anticoagulation should be continued for 8 days or until discharge from hospital or coronary revascularisation.

A period of treatment with warfarin should be considered if there is persistent atrial fibrillation or evidence of extensive anterior infarction, or if echocardiography shows mobile mural thrombus, because these patients are at increased risk of systemic thromboembolism.

EBM 18.63 Oral antiplatelet agents in acute coronary syndromes

'Aspirin alone (75–325 mg/day) reduces the risk of death, MI and stroke in acute coronary syndromes (NNT_B = 20–25). Although the addition of clopidogrel to aspirin reduces recurrent ischaemic events, ticagrelor (90 mg twice daily) is more effective than clopidogrel and causes a further reduction in these events (NNT_B = 60), including all-cause mortality (NNT_B = 85).'

EBM 18.64 Intravenous glycoprotein IIb/IIIa inhibitors in acute coronary syndromes

'In patients with acute coronary syndromes, antiplatelet treatment with IV glycoprotein IIb/IIIa inhibitors reduces the combined endpoint of death or MI. Most benefit is seen in the context of percutaneous coronary intervention, but there is no convincing evidence of benefit in patients who are treated without revascularisation (NNT_B (death or MI at 30 days) = 100; NNT_B (death, MI or revascularisation at 30 days) = 63).'

- Boersma E, et al. Lancet 2002; 359:189–198.

For further information: www.sign.ac.uk/guidelines/fulltext/93/index.html

EBM 18.65 Anticoagulation in acute coronary syndromes

'Aspirin plus low-molecular-weight heparin is more effective than aspirin alone in reducing the combined endpoint of death, MI, refractory angina and urgent need for revascularisation. In comparison to low-molecular-weight heparin, the pentasaccharide, fondaparinux (2.5 mg SC), is associated with lower bleeding rates and better overall survival.'

Anti-anginal therapy

Sublingual glyceryl trinitrate (300–500 µg) is a valuable first-aid measure in unstable angina or threatened infarction, and intravenous nitrates (glyceryl trinitrate 0.6–1.2 mg/hr or isosorbide dinitrate 1–2 mg/hr) are useful for the treatment of left ventricular failure and the relief of recurrent or persistent ischaemic pain.

Intravenous β-blockers (e.g. atenolol 5–10 mg or metoprolol 5–15 mg given over 5 mins) relieve pain, reduce arrhythmias and improve short-term mortality in patients who present within 12 hours of the onset of symptoms (see Fig. 18.19). However, they should be avoided if there is heart failure (pulmonary oedema), hypotension (systolic BP < 105 mmHg) or bradycardia (heart rate < 65/min).

A dihydropyridine calcium channel antagonist (e.g. nifedipine or amlodipine) can be added to the β-blocker if there is persistent chest discomfort but may cause tachycardia if used alone. Because of their rate-limiting action, verapamil and diltiazem are the calcium channel antagonists of choice if a β-blocker is contraindicated.

Reperfusion therapy

Non-ST segment elevation acute coronary syndrome

Immediate emergency reperfusion therapy has no demonstrable benefit in patients with non-ST segment elevation MI and thrombolytic therapy may be harmful. Selected medium- to high-risk patients do benefit from in-hospital coronary angiography and coronary revascularisation but this does not need to take place in the first 12 hours.

18.66 Angina in old age

- **Incidence**: coronary artery disease increases in and affects women almost as often as men.
- **Comorbid conditions**: anaemia and thyroid disease are common and may worsen angina.
- **Calcific aortic stenosis**: common and should be sought in all old people with angina.
- **Atypical presentations**: when myocardial ischaemia occurs, age-related changes in myocardial compliance and diastolic relaxation can cause the presentation to be with symptoms of heart failure, such as breathlessness, rather than with chest discomfort.
- **Angioplasty and coronary artery bypass surgery**: provide symptomatic relief, although with an increased procedure-related morbidity and mortality. Outcome is determined by the number of diseased vessels, severity of cardiac dysfunction and the number of concomitant diseases, as much as age itself.

ST segment elevation acute coronary syndrome

Immediate reperfusion therapy restores coronary artery patency, preserves left ventricular function and improves survival. Successful therapy is associated with pain relief, resolution of acute ST elevation and, sometimes, transient arrhythmias (e.g. idioventricular rhythm).

Primary percutaneous coronary intervention (PCI). This is the treatment of choice for ST segment elevation MI (Figs 18.19 and 18.76). Outcomes are best when it is used in combination with glycoprotein IIb/IIIa receptor antagonists and intracoronary stent implantation. In comparison to thrombolytic therapy, it is associated with a greater reduction in the risk of death, recurrent MI or stroke (Box 18.67). The universal use of primary PCI has been limited by availability of the necessary resources to provide this highly specialised emergency service. Thus, intravenous thrombolytic therapy remains the first-line reperfusion treatment in many hospitals, especially those in rural or remote areas. When primary PCI cannot be achieved within 2 hours of diagnosis, thrombolytic therapy should be administered.

Thrombolysis. The appropriate use of thrombolytic therapy can reduce hospital mortality by 25–50% and this survival advantage is maintained for at least 10 years (Box 18.68). The benefit is greatest in those patients who receive treatment within the first few hours: 'minutes mean muscle'.

Alteplase (human tissue plasminogen activator, or tPA) is a genetically engineered drug that is given over 90 minutes (bolus dose of 15 mg, followed by 0.75 mg/kg body weight but not exceeding 50 mg, over 30 mins, and then 0.5 mg/kg body weight but not exceeding 35 mg, over 60 mins). Its use is associated with better survival rates than other thrombolytic agents, such as streptokinase, but carries a slightly higher risk of intracerebral bleeding (10 per 1000 increased survival, but 1 per 1000 more non-fatal stroke).

Analogues of tPA, such as tenecteplase (TNK) and reteplase (rPA), have a longer plasma half-life than alteplase and can be given as an intravenous bolus. TNK is as effective as alteplase at reducing death and MI, whilst conferring similar intracerebral bleeding risks. However, other bleeding and transfusion risks are lower and the practical advantages of bolus administration provide opportunities for prompt treatment in the emergency department or in the pre-hospital setting. rPA is administered as a double bolus and also produces a similar outcome to that achieved with alteplase, although some of the bleeding risks appear slightly higher.

An overview of all large randomised trials confirms that thrombolytic therapy reduces short-term mortality in patients with MI if given within 12 hours of the onset

EBM 18.67 Primary PCI in acute ST segment elevation MI

'Primary PCI is more effective than thrombolysis for the treatment of acute MI. Death, non-fatal re-infarction and stroke are reduced from 14% with thrombolytic therapy to 8% with primary PCI ($NNT_B = 33$ for death and 9 for recurrent ischaemia).'

www.sign.ac.uk/guidelines/fulltext/93/index.html

EBM 18.68 Thrombolytic treatment in acute ST segment elevation MI

'Prompt thrombolytic treatment (within 12 hours, and particularly within 6 hours, of the onset of symptoms) reduces mortality in patients with acute MI and ECG changes of ST elevation or new bundle branch block ($NNT_B = 56$). Intracranial haemorrhage is more common in people given thrombolysis, with 1 additional stroke for every 250 people treated.'

- Fibrinolytic Therapy Trialists' (FTT) Collaborative Group. Lancet 1994; 343:311–322.
- Collins R. N Engl J Med 1997; 336:847–860.

For further information: www.escardio.org

18.69 Relative contraindications to thrombolytic therapy: potential candidates for primary PCI

- Active internal bleeding
- Previous subarachnoid or intracerebral haemorrhage
- Uncontrolled hypertension
- Recent surgery (within 1 mth)
- Recent trauma (including traumatic resuscitation)
- High probability of active peptic ulcer
- Pregnancy

of symptoms and the ECG shows bundle branch block or characteristic ST segment elevation of more than 1 mm in the limb leads or 2 mm in the chest leads (see Box 18.68). Thrombolysis appears to be of little net benefit and may be harmful in those who present more than 12 hours after the onset of symptoms and in those with a normal ECG or ST depression. In patients with ST elevation or bundle branch block, the absolute benefit of thrombolysis plus aspirin is approximately 50 lives saved per 1000 patients treated within 6 hours, and 40 lives saved per 1000 treated between 7 and 12 hours after the onset of symptoms. The benefit is greatest for patients treated within the first 2 hours.

The major hazard of thrombolytic therapy is bleeding. Cerebral haemorrhage causes 4 extra strokes per 1000 patients treated, and the incidence of other major bleeds is between 0.5% and 1%. Accordingly, the treatment should be withheld if there is a significant risk of serious bleeding (Box 18.69).

For some patients, thrombolytic therapy is contraindicated or fails to achieve coronary arterial reperfusion (see Fig. 18.19, p. 542). Early emergency PCI may then be considered, particularly where there is evidence of cardiogenic shock.

18.70 Common arrhythmias in acute coronary syndrome

- Ventricular fibrillation
- Ventricular tachycardia
- Accelerated idioventricular rhythm
- Ventricular ectopics
- Atrial fibrillation
- Atrial tachycardia
- Sinus bradycardia (particularly after inferior MI)
- Atrioventricular block

Complications of acute coronary syndrome

Complications are seen in all forms of acute coronary syndrome, although the frequency and extent vary with the severity of ischaemia and infarction. Major mechanical and structural complications are seen only with significant, often transmural, MI.

Arrhythmias

Many patients with acute coronary syndrome have some form of arrhythmia (Box 18.70). In the majority of cases this is transient and of no haemodynamic or prognostic importance. Pain relief, rest and the correction of hypokalaemia may help prevent arrhythmias. Diagnosis and management of arrhythmias are discussed in detail on pages 562–579.

Ventricular fibrillation

This occurs in 5–10% of patients who reach hospital and is thought to be the major cause of death in those who die before receiving medical attention. Prompt defibrillation restores sinus rhythm and is life-saving. The prognosis of patients with early ventricular fibrillation (within the first 48 hours) who are successfully and promptly resuscitated is identical to that of patients who do not suffer ventricular fibrillation.

Atrial fibrillation

This is common but frequently transient, and usually does not require emergency treatment. However, if it causes a rapid ventricular rate with hypotension or circulatory collapse, prompt cardioversion by immediate synchronised DC shock is essential. In other situations, digoxin or a β-blocker is usually the treatment of choice. Atrial fibrillation (due to acute atrial stretch) is often a feature of impending or overt left ventricular failure, and therapy may be ineffective if heart failure is not recognised and treated appropriately. Anticoagulation is required if atrial fibrillation persists.

Bradycardia

This does not usually require treatment, but if there is hypotension or haemodynamic deterioration, atropine (0.6–1.2 mg IV) may be given. AV block complicating inferior infarction is usually temporary and often resolves following reperfusion therapy. If there is clinical deterioration due to second-degree or complete AV block, a temporary pacemaker should be considered. AV block complicating anterior infarction is more serious because asystole may suddenly supervene; a prophylactic temporary pacemaker should be inserted (p. 578).

Ischaemia

Patients who develop recurrent angina at rest or on minimal exertion following an acute coronary syndrome

are at high risk and should be considered for prompt coronary angiography with a view to revascularisation. Patients with dynamic ECG changes and ongoing pain should be treated with intravenous glycoprotein IIb/IIIa receptor antagonists. Patients with resistant pain or marked haemodynamic changes should be considered for intra-aortic balloon counterpulsation and emergency coronary revascularisation.

Post-infarct angina occurs in up to 50% of patients treated with thrombolysis. Most patients have a residual stenosis in the infarct-related vessel, despite successful thrombolysis, and this may cause angina if there is still viable myocardium downstream. For this reason, all patients who have received successful thrombolysis should be considered for early (within the first 6–24 hours) coronary angiography with a view to coronary revascularisation.

Acute circulatory failure

Acute circulatory failure usually reflects extensive myocardial damage and indicates a bad prognosis. All the other complications of MI are more likely to occur when acute heart failure is present. The assessment and management of heart failure complicating acute MI are discussed in detail on page 545.

Pericarditis

This only occurs following infarction and is particularly common on the second and third days. The patient may recognise that a different pain has developed, even though it is at the same site, and that it is positional and tends to be worse or sometimes only present on inspiration. A pericardial rub may be audible. Opiate-based analgesia should be used. Non-steroidal (NSAIDs) and steroidal anti-inflammatory drugs may increase the risk of aneurysm formation and myocardial rupture in the early recovery period, and so should be avoided.

The post-MI syndrome (Dressler's syndrome) is characterised by persistent fever, pericarditis and pleurisy, and is probably due to autoimmunity. The symptoms tend to occur a few weeks or even months after the infarct and often subside after a few days; prolonged or severe symptoms may require treatment with high-dose aspirin, NSAIDs or even corticosteroids.

Mechanical complications

Part of the necrotic muscle in a fresh infarct may tear or rupture, with devastating consequences:

- *Rupture of the papillary muscle* can cause acute pulmonary oedema and shock due to the sudden onset of severe mitral regurgitation, which presents with a pansystolic murmur and third heart sound. In the presence of severe regurgitation, the murmur may be quiet or absent. The diagnosis is confirmed by echocardiography and emergency valve replacement may be necessary. Lesser degrees of mitral regurgitation due to papillary muscle dysfunction are common and may be transient.
- *Rupture of the interventricular septum* causes left-to-right shunting through a ventricular septal defect. This usually presents with sudden haemodynamic deterioration accompanied by a new loud pansystolic murmur radiating to the right sternal border, but may be difficult to distinguish from acute mitral regurgitation. However, patients with an acquired ventricular septal defect tend to develop right heart failure rather than pulmonary oedema. Doppler echocardiography and right heart catheterisation will confirm the diagnosis. Without prompt surgery, the condition is usually fatal.
- *Rupture of the ventricle* may lead to cardiac tamponade and is usually fatal (p. 545), although it may rarely be possible to support a patient with an incomplete rupture until emergency surgery is performed.

Embolism

Thrombus often forms on the endocardial surface of freshly infarcted myocardium. This can lead to systemic embolism and occasionally causes a stroke or ischaemic limb. Venous thrombosis and pulmonary embolism may occur but have become less common with the use of prophylactic anticoagulants and early mobilisation.

Impaired ventricular function, remodelling and ventricular aneurysm

Acute transmural MI is often followed by thinning and stretching of the infarcted segment (infarct expansion). This leads to an increase in wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling, Fig. 18.77). As the ventricle dilates, it becomes less efficient and heart failure may supervene. Infarct expansion occurs over a few days and weeks but ventricular remodelling can take years. ACE inhibitor therapy reduces late ventricular remodelling and can prevent the onset of heart failure (p. 551).

A left ventricular aneurysm develops in approximately 10% of patients with MI and is particularly common when there is persistent occlusion of the infarct-related vessel. Heart failure, ventricular arrhythmias, mural thrombus and systemic embolism are all recognised complications of aneurysm formation. Other features include a paradoxical impulse on the chest wall, persistent ST elevation on the ECG, and sometimes an unusual bulge from the cardiac silhouette on the chest X-ray. Echocardiography is diagnostic. Surgical removal

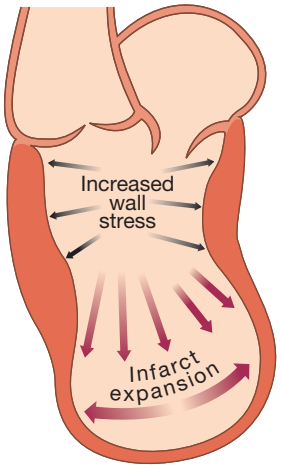

Fig. 18.77 Infarct expansion and ventricular remodelling.
Full-thickness MI causes thinning and stretching of the infarcted segment (infarct expansion), which leads to increased wall stress with progressive dilatation and hypertrophy of the remaining ventricle (ventricular remodelling).

of a left ventricular aneurysm carries a high morbidity and mortality but is sometimes necessary.

Later in-hospital management

Late management of MI is summarised in Box 18.71.

Risk stratification and further investigation

Simple clinical tools can be used to identify medium- to high-risk patients. The GRACE score (see Fig. 18.70, p. 591) is a simple method of calculating early mortality that can help guide which patients should be selected for intensive therapy, and specifically early inpatient coronary angiography.

The prognosis of patients who have survived an acute coronary syndrome is related to the extent of residual myocardial ischaemia, the degree of myocardial damage and the presence of ventricular arrhythmias.

Left ventricular function

The degree of left ventricular dysfunction can be crudely assessed from physical findings (tachycardia, third heart sound, crackles at the lung bases, elevated venous pressure and so on), ECG changes and chest X-ray (size of the heart and presence of pulmonary oedema). Formal assessment with echocardiography should, however, be undertaken in the early recovery phase.

Ischaemia

Patients with early ischaemia following an acute coronary syndrome should undergo coronary angiography with a view to revascularisation. Low-risk patients without spontaneous ischaemia should undergo an exercise tolerance test approximately 4 weeks after the acute coronary syndrome. This will help to identify those individuals with residual myocardial ischaemia who require further investigation, and may help to boost the confidence of the remainder.

If the exercise test is negative and the patient has a good effort tolerance, the outlook is good, with a 1–4% chance of an adverse event in the next 12 months. In contrast, patients with residual ischaemia in the form of chest pain or ECG changes at low exercise levels are at high risk, with a 15–25% chance of suffering a further ischaemic event in the next 12 months.

18.71 Late management of MI

Risk stratification and further investigation (see text)

Lifestyle modification

- Diet (weight control, lipid-lowering, 'Mediterranean diet')
- Cessation of smoking
- Regular exercise

Secondary prevention drug therapy

- Antiplatelet therapy (aspirin and/or clopidogrel)
- β-blocker
- ACE inhibitor/ARB
- Statin
- Additional therapy for control of diabetes and hypertension
- Mineralocorticoid receptor antagonist

Rehabilitation

Devices

- Implantable cardiac defibrillator (high-risk patients)

(ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocker)

Arrhythmias

The presence of ventricular arrhythmias during the convalescent phase of acute coronary syndrome may be a marker of poor ventricular function and may herald sudden death. Although empirical anti-arrhythmic treatment is of no value and is even hazardous, selected patients may benefit from electrophysiological testing and specific anti-arrhythmic therapy (including implantable cardiac defibrillators, p. 579).

Recurrent ventricular arrhythmias are sometimes manifestations of myocardial ischaemia or impaired left ventricular function and may respond to appropriate treatment directed at the underlying problem.

Lifestyle and risk factor modification

Smoking

The 5-year mortality of patients who continue to smoke cigarettes is double that of those who quit smoking at the time of their acute coronary syndrome. Giving up smoking is the single most effective contribution a patient can make to his or her future. The success of smoking cessation can be increased by supportive advice and pharmacological therapy (p. 100).

Hyperlipidaemia

The importance of lowering serum cholesterol following acute coronary syndrome has been demonstrated in large-scale randomised trials. Lipids should be measured within 24 hours of presentation because there is often a transient fall in cholesterol in the 3 months following infarction. HMG CoA reductase enzyme inhibitors ('statins', p. 456) can produce marked reductions in total (and LDL) cholesterol and reduce the subsequent risk of death, re-infarction, stroke and the need for revascularisation (see Box 18.46, p. 583). Irrespective of serum cholesterol concentrations, all patients should receive statin therapy after acute coronary syndrome, but those with serum LDL cholesterol concentrations above 3.2 mmol/L (~120 mg/dL) benefit from more intensive therapy, such as atorvastatin 80 mg daily.

Other risk factors

Maintaining an ideal body weight, eating a Mediterranean-style diet, taking regular exercise, and achieving good control of hypertension and diabetes mellitus may all improve the long-term outlook.

Mobilisation and rehabilitation

The necrotic muscle of an acute myocardial infarct takes 4–6 weeks to be replaced with fibrous tissue and it is conventional to restrict physical activities during this period. When there are no complications, the patient can mobilise on the second day, return home in 3–5 days and gradually increase activity, with the aim of returning to work in 4–6 weeks. The majority of patients may resume driving after 4–6 weeks, although, in most countries, vocational driving licence holders (e.g. heavy goods and public service vehicles) require special assessment.

Emotional problems, such as denial, anxiety and depression, are common and must be addressed. Many patients are severely and even permanently incapacitated as a result of the psychological effects of acute coronary syndrome rather than the physical ones, and all benefit from thoughtful explanation, counselling and

reassurance at every stage of the illness. Many patients mistakenly believe that 'stress' was the cause of their heart attack and may restrict their activity inappropriately. The patient's spouse or partner will also require emotional support, information and counselling. Formal rehabilitation programmes, based on graded exercise protocols with individual and group counselling, are often very successful and, in some cases, have been shown to improve the long-term outcome.

Secondary prevention drug therapy

Aspirin and clopidogrel

Low-dose aspirin therapy reduces the risk of further infarction and other vascular events by approximately 25% and should be continued indefinitely if there are no unwanted effects. Clopidogrel should be given in combination with aspirin for at least 3 months. If patients are intolerant of long-term aspirin, clopidogrel is a suitable alternative.

Beta-blockers

Continuous treatment with an oral β-blocker reduces long-term mortality by approximately 25% among the survivors of acute MI (Box 18.72). Unfortunately, a minority of patients do not tolerate β-blockers because of bradycardia, AV block, hypotension or asthma. Patients with heart failure, irreversible chronic obstructive pulmonary disease or peripheral vascular disease derive similar, if not greater secondary preventative benefits from β-blocker therapy if they can tolerate it, so it should be tried. The secondary preventative role of β-blockers in patients with unstable angina is unknown.

ACE inhibitors

Several clinical trials have shown that long-term treatment with an ACE inhibitor (e.g. enalapril 10 mg twice daily or ramipril 2.5–5 mg twice daily) can counteract ventricular remodelling, prevent the onset of heart failure, improve survival, reduce recurrent MI and avoid rehospitalisation. The benefits are greatest in those with overt heart failure (clinical or radiological) but extend to patients with asymptomatic left ventricular dysfunction and those with preserved left ventricular function. They should therefore be considered in all patients with acute coronary syndrome. Caution must be exercised in hypovolaemic or hypotensive patients because the introduction of an ACE inhibitor may exacerbate hypotension and impair coronary perfusion. In patients intolerant of ACE inhibitors, angiotensin receptor blockers (e.g. valsartan 40–160 mg twice daily or candesartan 4–16 mg daily) are alternatives and are better tolerated.

Patients with acute MI and left ventricular dysfunction (ejection fraction < 35%) and either pulmonary oedema or diabetes mellitus further benefit from additional mineralocorticoid receptor antagonism (e.g. eplerenone 25–50 mg daily).

Coronary revascularisation

Most low-risk patients stabilise with aspirin, clopidogrel, anticoagulation and anti-anginal therapy, and can be rapidly mobilised. In the absence of recurrent symptoms, low-risk patients do not benefit from routine coronary angiography. Coronary angiography should be considered with a view to revascularisation in all patients at moderate or high risk, including those who fail to settle on medical therapy, those with extensive ECG changes, those with an elevated plasma troponin and those with severe pre-existing stable angina. This often reveals disease that is amenable to PCI or urgent CABG. In these cases, coronary revascularisation is associated with short- and long-term benefits, including reductions in MI and death.

Device therapy

Implantable cardiac defibrillators are of benefit in preventing sudden cardiac death in patients who have severe left ventricular impairment (ejection fraction ≤ 30%) after MI (p. 579).

Prognosis

In almost one-quarter of all cases of MI, death occurs within a few minutes without medical care. Half the deaths occur within 24 hours of the onset of symptoms and about 40% of all affected patients die within the first month. The prognosis of those who survive to reach hospital is much better, with a 28-day survival of more than 85%. Patients with unstable angina have a mortality of approximately half that of those patients with MI.

Early death is usually due to an arrhythmia and is independent of the extent of MI. However, late outcomes are determined by the extent of myocardial damage, and unfavourable features include poor left ventricular function, AV block and persistent ventricular arrhythmias. The prognosis is worse for anterior than for inferior infarcts. Bundle branch block and high

EBM 18.72 Beta-blockers in secondary prevention after MI

'Beta-blockers reduce the risk of overall mortality ($NNT_B = 48$), sudden death ($NNT_B = 63$) and non-fatal re-infarction ($NNT_B = 56$) after MI. The greatest benefit is seen in those at highest risk, and about one-quarter of patients suffer adverse events.'

- Freemantle N, et al. BMJ 1999; 318:1730–1737.

For further information: www.sign.ac.uk/guidelines/fulltext/93/index.html

18.73 Myocardial infarction in old age

- **Atypical presentation**: often with anorexia, fatigue or weakness rather than chest pain.
- **Case fatality**: rises steeply. Hospital mortality exceeds 25% in those over 75 yrs old, which is five times greater than that seen in those aged less than 55 yrs.
- **Survival benefit of treatments**: not influenced by age. The absolute benefit of evidence-based treatments may therefore be greatest in older people.
- **Hazards of treatments**: rise with age (e.g. increased risk of intracerebral bleeding after thrombolysis) and are due partly to increased comorbidity.
- **Quality of evidence**: older patients, particularly those with significant comorbidity, were under-represented in many of the randomised controlled clinical trials that helped to establish the treatment of MI. The balance of risk and benefit for many treatments (e.g. thrombolysis, primary percutaneous transluminal coronary angiography) in frail older people is therefore uncertain.

cardiac marker levels both indicate extensive myocardial damage. Old age, depression and social isolation are also associated with a higher mortality.

Of those who survive an acute attack, more than 80% live for a further year, about 75% for 5 years, 50% for 10 years and 25% for 20 years.

Cardiac risk of non-cardiac surgery

Non-cardiac surgery, particularly major vascular, abdominal or thoracic surgery, can precipitate serious peri-operative cardiac complications, such as MI and death, in patients with coronary artery and other forms of heart disease. Careful pre-operative cardiac assessment may help to determine the balance of benefit versus risk on an individual basis, and identify measures that minimise the operative risk (Box 18.74).

A hypercoagulable state is part of the normal physiological response to surgery, and may promote coronary thrombosis leading to an acute coronary syndrome in the early post-operative period. Patients with a history of recent PCI or acute coronary syndrome are at greatest risk and, whenever possible, elective non-cardiac surgery should be avoided for 3 months after such an event. Antiplatelet agents, statins and β-blockers reduce the risk of peri-operative MI in patients with coronary artery disease and, where possible, should be prescribed throughout the peri-operative period.

Careful attention to fluid balance during and after surgery is particularly important in patients with impaired left ventricular function and valvular heart disease because antidiuretic hormone is released as part of the normal physiological response to surgery and, in these circumstances, the overzealous administration of intravenous fluids can easily precipitate heart failure. Patients with severe valvular heart disease, particularly aortic stenosis and mitral stenosis, are also at increased risk because they may not be able to increase their cardiac output in response to the stress of surgery.

Atrial fibrillation may be triggered by hypoxia, myocardial ischaemia or heart failure, and is a common post-operative complication in patients with pre-existing heart disease. It usually terminates spontaneously when the precipitating factors have been eliminated, but digoxin or β-blockers can be prescribed to control the heart rate.

18.74 Major risk factors for cardiac complications of non-cardiac surgery

- Recent (< 6 mths) MI or unstable angina
- Severe coronary artery disease: left main stem or three-vessel disease
- Severe stable angina on effort
- Severe left ventricular dysfunction
- Severe valvular heart disease (especially aortic stenosis)

VASCULAR DISEASE

Peripheral arterial disease

In developed countries, almost all peripheral arterial disease (PAD) is due to atherosclerosis (p. 579) and so shares common risk factors with coronary artery disease: namely, smoking, diabetes mellitus, hyperlipidaemia and hypertension. As with coronary artery disease, plaque rupture is responsible for the most serious manifestations of PAD, and not infrequently occurs in a plaque that hitherto has been asymptomatic.

Approximately 20% of middle-aged (55–75 years) people in the UK have PAD but only one-quarter of them will have symptoms. The clinical manifestations depend upon the anatomical site, the presence or absence of a collateral supply, the speed of onset and the mechanism of injury (Box 18.75).

18.75 Factors influencing the clinical manifestations of peripheral arterial disease

Anatomical site

Cerebral circulation
- TIA, amaurosis fugax, vertebrobasilar insufficiency

Renal arteries
- Hypertension and renal failure

Mesenteric arteries
- Mesenteric angina, acute intestinal ischaemia

Limbs (legs ≫ arms)
- Intermittent claudication, critical limb ischaemia, acute limb ischaemia

Collateral supply
- In a patient with a complete circle of Willis, occlusion of one carotid artery may be asymptomatic
- In a patient without cross-circulation, stroke is likely

Speed of onset
- Where PAD develops slowly, a collateral supply will develop
- Sudden occlusion of a previously normal artery is likely to cause severe distal ischaemia

Mechanism of injury

Haemodynamic
- Plaque must reduce arterial diameter by 70% ('critical stenosis') to reduce flow and pressure at rest. On exertion (e.g. walking), a much lesser stenosis may become 'critical'. This mechanism tends to have a relatively benign course due to collateralisation

Thrombotic
- Occlusion of a long-standing critical stenosis may be asymptomatic due to collateralisation. However, acute rupture and thrombosis of a non-haemodynamically significant plaque usually has severe consequences

Atheroembolic
- Symptoms depend upon embolic load and size
- Carotid (TIA, amaurosis fugax or stroke) and peripheral arterial (blue toe/finger syndrome) plaque are common examples

Thromboembolic
- Usually secondary to atrial fibrillation
- The consequences are usually dramatic, as the thrombus load is often large and occludes a major, previously healthy, non-collateralised artery suddenly and completely

(TIA = transient ischaemic attack)

Chronic lower limb arterial disease

PAD affects the leg eight times more often than the arm. The lower limb arterial tree comprises the aorto-iliac

('inflow'), femoro-popliteal and infra-popliteal ('outflow') segments. One or more segments may be affected in a variable and asymmetric manner. Lower limb ischaemia presents as two distinct clinical entities: intermittent claudication (IC) and critical limb ischaemia (CLI). The presence and severity of ischaemia can be determined by clinical examination (Box 18.76) and measurement of the ankle–brachial pressure index (ABPI), which is the ratio between the (highest systolic) ankle and brachial blood pressures. In health, the ABPI is over 1.0, in IC typically 0.5–0.9 and in CLI usually below 0.5.

Intermittent claudication

This term describes ischaemic pain affecting the muscles of the leg upon walking. The pain is usually felt in the calf because the disease most commonly affects the superficial femoral artery. However, the pain may be felt in the thigh or buttock if the iliac arteries are involved. Typically, the pain comes on after a reasonably constant 'claudication distance' and rapidly subsides on stopping walking. Resumption of walking leads to a return of the pain. Most patients describe a cyclical pattern of exacerbation and resolution due to the progression of disease and the subsequent development of collaterals.

Approximately 5% of middle-aged men report IC. Provided patients comply with 'best medical therapy' (BMT, Box 18.77), only 1–2% per year will deteriorate to a point where amputation and/or revascularisation are required. However, the annual mortality rate exceeds 5%, 2–3 times higher than in an equivalent non-claudicant population. This is because IC is nearly always found in association with widespread atherosclerosis, so that most claudicants succumb to MI or stroke. The mainstay of treatment is BMT, including (preferably supervised) exercise therapy. The peripheral vasodilator, cilostazol, has been shown to improve walking distance. Intervention with angioplasty, stenting, endarterectomy or bypass is usually only considered after BMT has been given at least 6 months to effect symptomatic improvement, and then only in patients who are severely disabled or whose livelihood is threatened by their disability.

18.76 Clinical features of chronic lower limb ischaemia

- Pulses: diminished or absent
- Bruits: denote turbulent flow but bear no relationship to the severity of the underlying disease
- Reduced skin temperature
- Pallor on elevation and rubor on dependency (Buerger's sign)
- Superficial veins that fill sluggishly and empty ('gutter') upon minimal elevation
- Muscle-wasting
- Skin and nails: dry, thin and brittle
- Loss of hair

18.77 Best medical therapy (BMT) for peripheral arterial disease*

- Smoking cessation
- Regular exercise (30 mins of walking, three times per week)
- Antiplatelet agent (aspirin 75 mg or clopidogrel 75 mg daily)
- Reduction of cholesterol (diet and statin therapy)
- Diagnosis and treatment of diabetes mellitus (all should have fasting glucose measured)
- Diagnosis and treatment of frequently associated conditions (e.g. hypertension, anaemia, heart failure)

*All patients with any manifestation of PAD should be considered for BMT.

Critical limb ischaemia

This is defined as rest (night) pain, requiring opiate analgesia, and/or tissue loss (ulceration or gangrene), present for more than 2 weeks, in the presence of an ankle BP of less than 50 mmHg (Fig. 18.78). Rest pain only, with ankle pressures above 50 mmHg, is known as subcritical limb ischaemia (SCLI). The term severe limb ischaemia (SLI) is used to describe both CLI and SCLI. Whereas IC is usually due to single-segment plaque, SLI is always due to multilevel disease.

Many patients with SLI have not previously sought medical advice for IC, principally because they have other comorbidity that prevents them from walking to a point where claudication pain might develop. In contrast to patients with IC, those with SLI are at high risk of losing their limb, and sometimes their life, in a matter of weeks or months without surgical bypass or endovascular revascularisation by angioplasty or stenting. Treatment is difficult, however, because patients

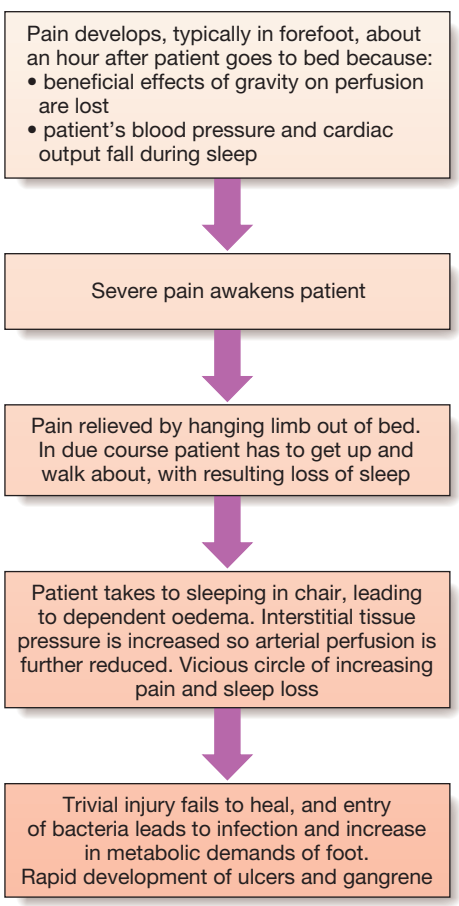

Fig. 18.78 Progressive night pain and the development of tissue loss.

have extensive and severe (often bilateral) end-stage disease, are usually elderly and nearly always have significant multisystem comorbidity. Imaging is performed using duplex ultrasonography, MRI or CT with intravenous injection of contrast agents. Intra-arterial digital subtraction angiography (IA-DSA) is usually reserved for those undergoing endovascular revascularisation.

Diabetic vascular disease

Approximately 5–10% of patients with PAD have diabetes but this proportion increases to 30–40% in those with SLI. Diabetes does not cause obstructive microangiopathy at the capillary level, as previously thought, and so is not a contraindication to lower limb revascularisation. Nevertheless, the 'diabetic foot' does pose a number of particular problems (Box 18.78 and p. 833). If the blood supply is adequate, then dead tissue can be excised in the expectation that healing will occur, provided infection is controlled and the foot is protected from pressure. However, if significant ischaemia is also present, the priority is to revascularise the foot if possible. Sadly, many diabetic patients present late with extensive tissue loss, which accounts for the high amputation rate.

18.78 Diabetic vascular disease: the 'diabetic foot'

Feature	Difficulty
Arterial calcification	Spuriously high ABPI due to incompressible ankle vessels. Inability to clamp arteries for the purposes of bypass surgery. Resistant to angioplasty
Immunocompromise	Prone to rapidly spreading cellulitis, gangrene and osteomyelitis
Multisystem arterial disease	Coronary and cerebral arterial disease increase the risks of intervention
Distal disease	Diabetic vascular disease has a predilection for the calf vessels. Although vessels in the foot are often spared, performing a satisfactory bypass or angioplasty to these small vessels is a technical challenge
Sensory neuropathy	Even severe ischaemia and/or tissue loss may be completely painless. Diabetic patients often present late with extensive destruction of the foot. Loss of proprioception leads to abnormal pressure loads and worsens joint destruction (Charcot joints)
Motor neuropathy	Weakness of the long and short flexors and extensors leads to abnormal foot architecture, abnormal pressure loads, callus formation and ulceration
Autonomic neuropathy	Leads to a dry foot deficient in sweat that normally lubricates the skin and is antibacterial. Scaling and fissuring create a portal of entry for bacteria. Abnormal blood flow in the bones of the ankle and foot may also contribute to osteopenia and bony collapse

(ABPI = ankle–brachial pressure index)

Buerger's disease (thromboangiitis obliterans)

This is an inflammatory obliterative arterial disease that is distinct from atherosclerosis and usually presents in young (20–30 years) male smokers. It is most common in those from the Mediterranean and North Africa. It characteristically affects distal arteries, giving rise to claudication in the feet or rest pain in the fingers or toes. Wrist and ankle pulses are absent but brachial and popliteal pulses are present. Disease also affects the veins, giving rise to superficial thrombophlebitis. It often remits if the patient stops smoking; sympathectomy and prostaglandin infusions may be helpful. Major limb amputation is the most frequent outcome if patients continue to smoke.

Chronic upper limb arterial disease

In the arm, the subclavian artery is the most common site of disease, which may manifest as:

- *Arm claudication* (rare).
- *Atheroembolism* (blue finger syndrome). Small emboli lodge in digital arteries and may be confused with Raynaud's phenomenon (see below) but, in this case, the symptoms are unilateral. Failure to make the diagnosis may eventually lead to amputation.
- *Subclavian steal*. When the arm is used, blood is 'stolen' from the brain via the vertebral artery. This leads to vertebro-basilar ischaemia, which is characterised by dizziness, cortical blindness and/or collapse. Where possible, subclavian artery disease is treated by means of angioplasty and stenting, as surgery (e.g. carotid–subclavian bypass) can be difficult.

Raynaud's phenomenon and Raynaud's disease

Cold (and emotional) stimuli may trigger vasospasm, leading to the characteristic sequence of digital pallor due to vasospasm, cyanosis due to deoxygenated blood, and rubor due to reactive hyperaemia.

Primary Raynaud's phenomenon (or disease)

This affects 5–10% of young women aged 15–30 years in temperate climates and may be familial. It does not

18.79 Atherosclerotic vascular disease in old age

- **Prevalence**: related almost exponentially to age in developed countries, although atherosclerosis is not considered part of the normal ageing process.
- **Statin therapy**: no role in the primary prevention of atherosclerotic disease in those over 75 yrs but reduces cardiovascular events in those with established vascular disease, albeit with no reduction in overall mortality.
- **Presentation in the frail**: frequently with advanced multisystem arterial disease, along with a host of other comorbidities.
- **Intervention in the frail**: in those with extensive disease and limited life expectancy, the risks of surgery may outweigh the benefits, and symptomatic care is all that should be offered.

progress to ulceration or infarction, and significant pain is unusual. The underlying cause is unclear. No investigation is necessary. The patient should be reassured and advised to avoid exposure to cold. Long-acting nifedipine may be helpful but sympathectomy is not indicated.

Secondary Raynaud's phenomenon (or syndrome)

This occurs in older people in association with connective tissue disease (most commonly systemic sclerosis or CREST syndrome, p. 1112), vibration-induced injury (from the use of power tools) and thoracic outlet obstruction (e.g. cervical rib). Unlike primary disease, it is often associated with fixed obstruction of the digital arteries, fingertip ulceration, and necrosis and pain. The fingers must be protected from cold and trauma, infection requires treatment with antibiotics, and surgery should be avoided if possible. Vasoactive drugs have no clear benefit. Sympathectomy helps for a year or two. Prostacyclin infusions are sometimes beneficial.

Acute limb ischaemia

This is most frequently caused by acute thrombotic occlusion of a pre-existing stenotic arterial segment, thromboembolism, and trauma that may be iatrogenic. Apart from paralysis (inability to wiggle toes/fingers) and paraesthesia (loss of light touch over the dorsum of the foot/hand), the so-called 'Ps of acute ischaemia' (Box 18.80) are non-specific for ischaemia and/or inconsistently related to its severity. Pain on squeezing the calf indicates muscle infarction and impending irreversible ischaemia.

All patients with suspected acutely ischaemic limbs must be discussed immediately with a vascular surgeon; a few hours can make the difference between death/amputation and complete recovery of limb function. If there are no contraindications (for example, acute aortic dissection or trauma, particularly head injury), an intravenous bolus of heparin (3000–5000 U) should be administered to limit propagation of thrombus and protect the collateral circulation. Distinguishing thrombosis from embolism is frequently difficult but is important because treatment and prognosis are different (Box 18.81). Acute limb ischaemia due to thrombosis in situ can usually be treated medically in the first instance with intravenous heparin (target activated partial thromboplastin time (APTT) 2.0–3.0), antiplatelet agents, high-dose statins, intravenous fluids to avoid dehydration, correction of anaemia, oxygen and sometimes prostaglandins, such as iloprost. Careful monitoring is required. Embolism will normally result in extensive tissue necrosis within 6 hours unless the limb is revascularised. The indications for thrombolysis, if any, remain controversial. Irreversible ischaemia mandates early amputation or palliative care.

18.80 Symptoms and signs of acute limb ischaemia

Symptoms/signs	Comment
Pain **P**allor **P**ulselessness	May be absent in complete acute ischaemia, and can be present in chronic ischaemia
Perishing cold	Unreliable, as the ischaemic limb takes on the ambient temperature
Paraesthesia **P**aralysis	Important features of impending irreversible ischaemia

18.81 Acute limb ischaemia: distinguishing features of embolism and thrombosis in situ

Clinical features	Embolism	Thrombosis in situ
Severity	Complete (no collaterals)	Incomplete (collaterals)
Onset	Seconds or minutes	Hours or days
Limb	Leg 3:1 arm	Leg 10:1 arm
Multiple sites	Up to 15%	Rare
Embolic source	Present (usually atrial fibrillation)	Absent
Previous claudication	Absent	Present
Palpation of artery	Soft, tender	Hard, calcified
Bruits	Absent	Present
Contralateral leg pulses	Present	Absent
Diagnosis	Clinical	Angiography
Treatment	Embolectomy, warfarin	Medical, bypass, thrombolysis
Prognosis	Loss of life > loss of limb	Loss of limb > loss of life

Cerebrovascular/renovascular disease and ischaemic gut injury

See Ch. 27 and pp. 494 and 909.

Diseases of the aorta

Aneurysm, dissection and aortitis are the main pathologies (Fig. 18.79).

Aortic aneurysm

This is an abnormal dilatation of the aortic lumen; a true aneurysm involves all the layers of the wall, whereas a false aneurysm does not.

Aetiology and types of aneurysm

Non-specific aneurysms

Why some patients develop occlusive vascular disease, some develop aneurysmal vascular disease and some develop both in response to atherosclerosis risk factors remains unclear. Unlike occlusive disease, aneurysmal disease tends to run in families and genetic factors are undoubtedly important. The most common site for 'non-specific' aneurysm formation is the infrarenal abdominal aorta. The suprarenal abdominal aorta and a variable length of the descending thoracic aorta may be affected in 10–20% of patients but the ascending aorta is usually spared.

Marfan's syndrome

This disorder of connective tissue is inherited as an autosomal dominant trait and is caused by mutations in the

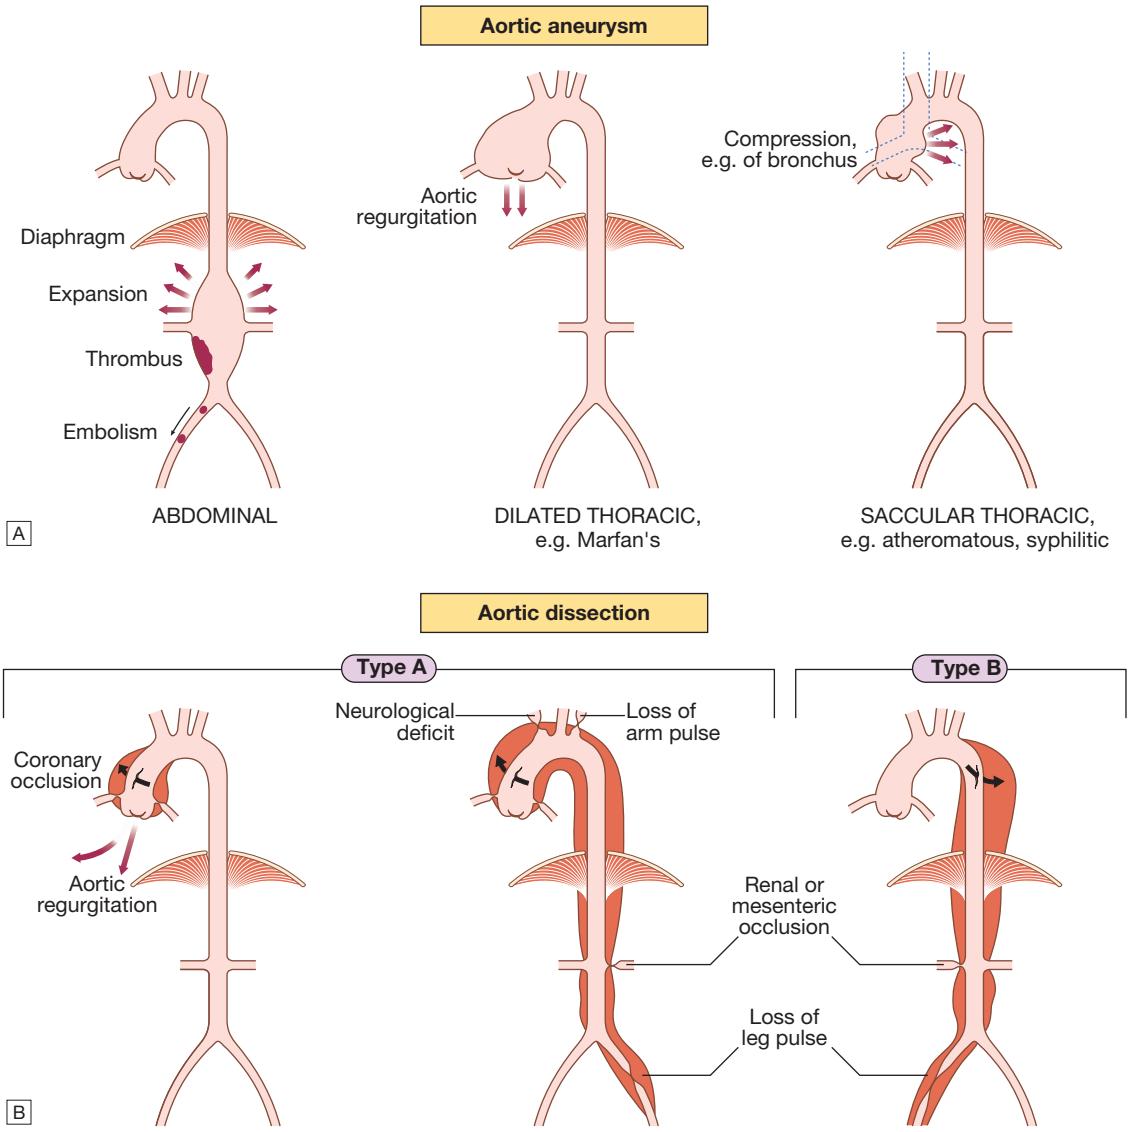

Fig. 18.79 **Types of aortic disease and their complications.** A Types of aortic aneurysm. B Types of aortic dissection.

fibrillin gene on chromosome 15. Affected systems include the skeleton (arachnodactyly, joint hypermobility, scoliosis, chest deformity and high arched palate), the eyes (dislocation of the lens) and the cardiovascular system (aortic disease and mitral regurgitation). Weakening of the aortic media leads to aortic root dilatation, regurgitation and dissection (see below). Pregnancy is particularly hazardous. Chest X-ray, echocardiography, MRI or CT may detect aortic dilatation at an early stage and can be used to monitor the disease.

Treatment with β-blockers reduces the rate of aortic dilatation and the risk of rupture. Elective replacement of the ascending aorta may be considered in patients with evidence of progressive aortic dilatation but carries a mortality of 5–10%.

Aortitis

Syphilis is a rare cause of aortitis that characteristically produces saccular aneurysms of the ascending aorta containing calcification. Other rare conditions associated with aortitis include Takayasu's disease (p. 1116), Reiter's syndrome (p. 1107), giant cell arteritis and ankylosing spondylitis (pp. 1105 and 1117).

Thoracic aortic aneurysms

These may produce chest pain, aortic regurgitation, compressive symptoms such as stridor (trachea, bronchus) and hoarseness (recurrent laryngeal nerve), and superior vena cava syndrome (see Fig. 18.79A). If they erode into adjacent structures, e.g. aorto-oesophageal fistula, massive bleeding occurs.

Abdominal aortic aneurysms

Abdominal aortic aneurysms (AAAs) are present in 5% of men aged over 60 years and 80% are confined to the infrarenal segment. Men are affected three times more commonly than women. AAAs can present in a number of ways (Box 18.82). The usual age at presentation is 65–75 years for elective presentations and 75–85 years for emergency presentations. Ultrasound is the best way of establishing the diagnosis and of following up patients with asymptomatic aneurysms that are not yet large

enough to warrant surgical repair. CT provides more accurate information about the size and extent of the aneurysm, the surrounding structures and whether there is any other intra-abdominal pathology. It is the standard pre-operative investigation but is not suitable for surveillance because of cost and radiation dose.

Management. Until an asymptomatic AAA has reached a maximum of 5.5 cm in diameter, the risks of surgery generally outweigh the risks of rupture (Box 18.83). All symptomatic AAAs should be considered for repair, not only to rid the patient of symptoms but also because pain often predates rupture. Distal embolisation is a strong indication for repair, regardless of size, because otherwise limb loss is common. Most patients with a ruptured AAA do not survive to reach hospital, but if they do and surgery is thought to be appropriate, there must be no delay in getting them to the operating theatre to clamp the aorta.

Open AAA repair has been the treatment of choice in both the elective and the emergency settings, and entails replacing the aneurysmal segment with a prosthetic (usually Dacron) graft. The 30-day mortality for this procedure is approximately 5–8% for elective asymptomatic AAA, 10–20% for emergency symptomatic AAA and 50% for ruptured AAA. However, patients who survive the operation to leave hospital have a long-term survival which approaches that of the normal population. Increasingly, endovascular aneurysm repair (EVAR), using a stent-graft introduced via the femoral arteries in the groin, is replacing open surgery. It is cost-effective and likely to become the treatment of choice for infrarenal AAA. It is possible to treat many suprarenal and thoraco-abdominal aneurysms by EVAR too.

In the UK, a national screening programme for men over 65 years of age has been introduced using ultrasound scanning. For every 10 000 men scanned, 65 ruptures are prevented and 52 lives saved.

18.82 Abdominal aortic aneurysm: common presentations

Incidental

- On physical examination, plain X-ray or, most commonly, abdominal ultrasound
- Even large AAAs can be difficult to feel, so many remain undetected until they rupture
- Studies are currently under way to determine whether screening will reduce the number of deaths from rupture (see Box 18.83)

Pain

- In the central abdomen, back, loin, iliac fossa or groin

Thromboembolic complications

- Thrombus within the aneurysm sac may be a source of emboli to the lower limbs
- Less commonly, the aorta may undergo thrombotic occlusion

Compression

- Surrounding structures such as the duodenum (obstruction and vomiting) and the inferior vena cava (oedema and deep vein thrombosis)

Rupture

- Into the retroperitoneum, the peritoneal cavity or surrounding structures (most commonly the inferior vena cava, leading to an aortocaval fistula)

EBM 18.83 Population screening and prevention of ruptured abdominal aortic aneurysm

'Ultrasound screening for AAA in men aged 65–75 years, with surgical repair of those AAAs that are bigger than 5.5 cm, are rapidly growing or become symptomatic, reduces the community incidence of rupture by approximately 50% and is cost-effective.'

Aortic dissection

A breach in the integrity of the aortic wall allows arterial blood to enter the media, which is then split into two layers, creating a 'false lumen' alongside the existing or 'true lumen' (see Fig. 18.79B). The aortic valve may be damaged and the branches of the aorta may be compromised. Typically, the false lumen eventually re-enters the true lumen, creating a double-barrelled aorta, but it may also rupture into the left pleural space or pericardium with fatal consequences.

The primary event is often a spontaneous or iatrogenic tear in the intima of the aorta; multiple tears or entry points are common. Other dissections are triggered by primary haemorrhage in the media of the aorta, which then ruptures through the intima into the true lumen. This form of spontaneous bleeding from the vasa vasorum is sometimes confined to the aortic wall, when it may present as a painful intramural haematoma.

Aortic disease and hypertension are the most important aetiological factors but other conditions may also be implicated (Box 18.84). Chronic dissections may lead to aneurysmal dilatation of the aorta, and thoracic aneurysms may be complicated by dissection. It can therefore be difficult to identify the primary pathology.

The peak incidence is in the sixth and seventh decades but dissection can occur in younger patients, usually in association with Marfan's syndrome, pregnancy or trauma; men are twice as frequently affected as women.

Aortic dissection is classified anatomically and for management purposes into type A and type B (see Fig. 18.79B), involving or sparing the ascending aorta, respectively. Type A dissections account for two-thirds of cases and frequently also extend into the descending aorta.

18.84 Factors that may predispose to aortic dissection

- Hypertension (in 80%)
- Aortic atherosclerosis
- Non-specific aortic aneurysm
- Aortic coarctation (p. 632)
- Collagen disorders (e.g. Marfan's syndrome, Ehlers–Danlos syndrome)
- Fibromuscular dysplasia
- Previous aortic surgery (e.g. CABG, aortic valve replacement)
- Pregnancy (usually third trimester)
- Trauma
- Iatrogenic (e.g. cardiac catheterisation, intra-aortic balloon pumping)

(CABG = coronary artery bypass grafting)

Clinical features

Involvement of the ascending aorta typically gives rise to anterior chest pain, and involvement of the descending aorta to intrascapular pain. The pain is typically described as 'tearing' and very abrupt in onset; collapse is common. Unless there is major haemorrhage, the patient is invariably hypertensive. There may be asymmetry of the brachial, carotid or femoral pulses and signs of aortic regurgitation. Occlusion of aortic branches may cause MI (coronary), stroke (carotid) paraplegia (spinal), mesenteric infarction with an acute abdomen (coeliac and superior mesenteric), renal failure (renal) and acute limb (usually leg) ischaemia.

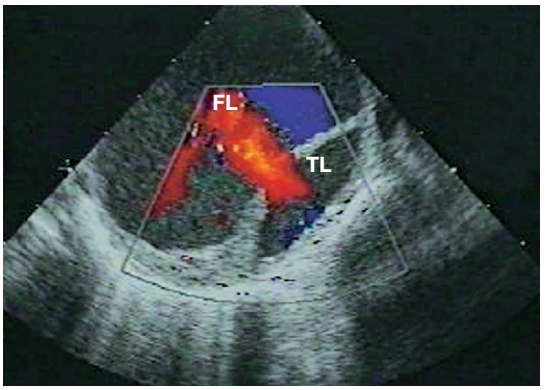

Fig. 18.80 Echocardiograms from a patient with a chronic aortic dissection. Colour flow Doppler shows flow from the larger false lumen (FL) into the true lumen (TL), characteristic of chronic disease.

Investigations

The chest X-ray characteristically shows broadening of the upper mediastinum and distortion of the aortic 'knuckle', but these findings are variable and are absent in 10% of cases. A left-sided pleural effusion is common. The ECG may show left ventricular hypertrophy in patients with hypertension, or rarely changes of acute MI (usually inferior). Doppler echocardiography may

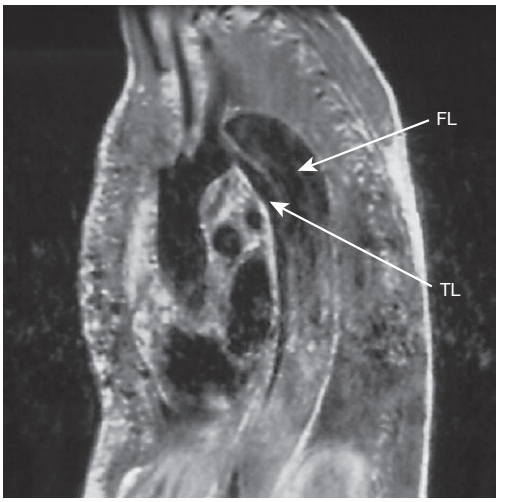

Fig. 18.81 Sagittal view of an MRI scan from a patient with longstanding aortic dissection, illustrating a biluminal aorta. There is sluggish flow in the false lumen (FL), accounting for its grey appearance. (TL = true lumen)

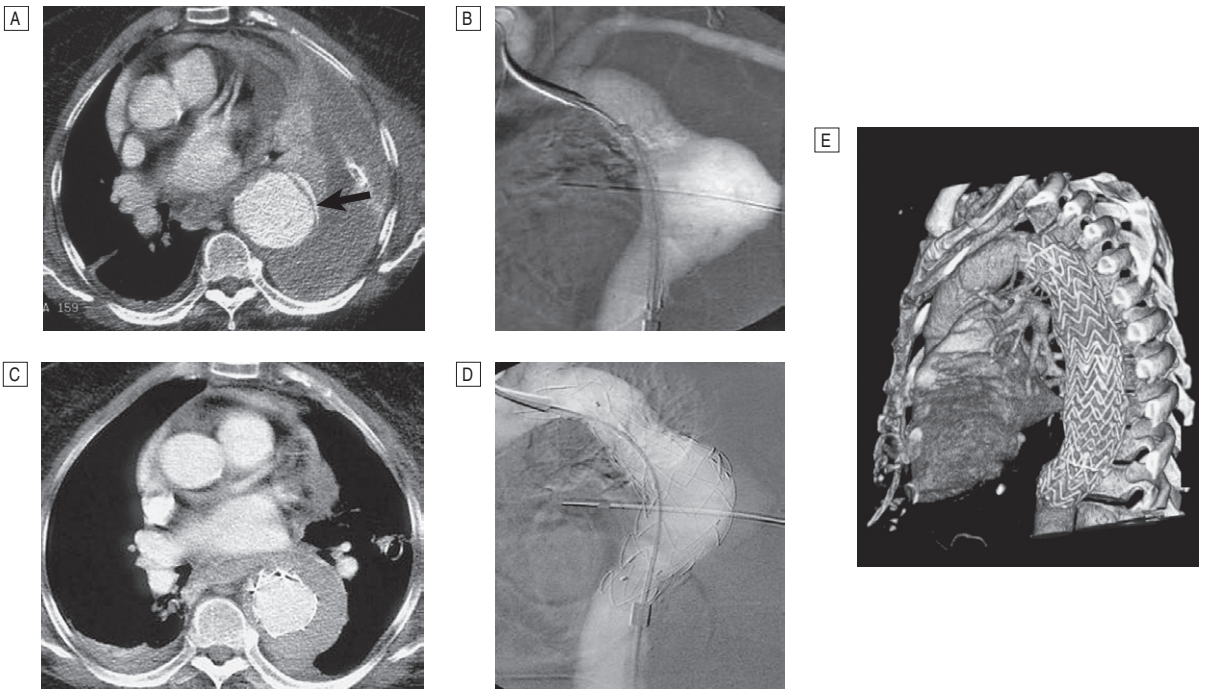

Fig. 18.82 Images from a patient with an acute type B aortic dissection that had ruptured into the left pleural space and was repaired by deploying an endoluminal stent graft. A CT scan illustrating an intimal flap (arrow) in the descending aorta and a large pleural effusion. B Aortogram illustrating aneurysmal dilatation; a stent graft has been introduced from the right femoral artery and is about to be deployed. C CT scan after endoluminal repair. The pleural effusion has been drained but there is a haematoma around the descending aorta. D Aortogram illustrating the stent graft. E Three-dimensional reconstruction of aortic stent graft.

show aortic regurgitation, a dilated aortic root and, occasionally, the flap of the dissection. Transoesophageal echocardiography is particularly helpful because transthoracic echocardiography can only provide images of the first 3–4 cm of the ascending aorta (Fig. 18.80). CT and MRI angiography (Figs 18.81 and 18.82) are both highly specific and sensitive.

Management

The early mortality of acute dissection is approximately 1–5% per hour and so treatment is urgently required. Initial management comprises pain control and antihypertensive treatment. Type A dissections require emergency surgery to replace the ascending aorta. Type B aneurysms are treated medically unless there is actual or impending external rupture, or vital organ (gut, kidneys) or limb ischaemia, as the morbidity and mortality associated with surgery are very high. The aim of medical management is to maintain a mean arterial pressure (MAP) of 60–75 mmHg to reduce the force of the ejection of blood from the LV. First-line therapy is with β-blockers; the additional α-blocking properties of labetalol make it especially useful. Rate-limiting calcium channel blockers, such as verapamil or diltiazem, are used if β-blockers are contraindicated. Sodium nitroprusside may be considered if these fail to control BP adequately.

Percutaneous or minimal access endoluminal repair is sometimes possible and involves either 'fenestrating' (perforating) the intimal flap so that blood can return from the false to the true lumen (so decompressing the former), or implanting a stent graft placed from the femoral artery (see Fig. 18.82).

Hypertension

Within any population, blood pressure values occur within a continuum, and are determined by mechanical, hormonal and environmental factors. Any definition of hypertension therefore utilises arbitrary threshold values within this continuum. Systemic BP rises with age, and the incidence of cardiovascular disease (particularly stroke and coronary artery disease) is closely related to average BP at all ages, even when BP readings are within the so-called 'normal range'.

The cardiovascular risks associated with BP depend upon the combination of risk factors in an individual, such as age, gender, weight, physical activity, smoking, family history, serum cholesterol, diabetes mellitus and pre-existing vascular disease. Thus a practical definition of hypertension is 'the level of BP at which the benefits of treatment outweigh the costs and hazards'. The British Hypertension Society classification is provided in Box 18.85 and is consistent with those defined by the European Society of Hypertension and the World Health Organization–International Society of Hypertension.

Aetiology

In more than 95% of cases, a specific underlying cause of hypertension cannot be found. Such patients are said to have essential hypertension. The pathogenesis is not clearly understood. Many factors may contribute to its development, including renal dysfunction, peripheral resistance vessel tone, endothelial dysfunction, autonomic tone, insulin resistance and neurohumoral factors.

18.85 Definition of hypertension

Category	Systolic BP (mmHg)	Diastolic BP (mmHg)
BP		
Optimal	< 120	< 80
Normal	< 130	85
High normal	130–139	85–89
Hypertension		
Grade 1 (mild)	140–159	90–99
Grade 2 (moderate)	160–179	100–109
Grade 3 (severe)	≥ 180	> 110
Isolated systolic hypertension		
Grade 1	140–159	< 90
Grade 2	≥ 160	< 90

18.86 Causes of secondary hypertension

Alcohol

Obesity

Pregnancy (pre-eclampsia)

Renal disease (Ch. 17)
- Parenchymal renal disease, particularly glomerulonephritis
- Renal vascular disease
- Polycystic kidney disease

Endocrine disease (Ch. 20)
- Phaeochromocytoma
- Cushing's syndrome
- Primary hyperaldosteronism (Conn's syndrome)
- Glucocorticoid-suppressible hyperaldosteronism
- Hyperparathyroidism
- Acromegaly
- Primary hypothyroidism
- Thyrotoxicosis
- Congenital adrenal hyperplasia due to 11-β-hydroxylase or 17-α-hydroxylase deficiency
- Liddle's syndrome (p. 441)
- 11-β-hydroxysteroid dehydrogenase deficiency

Drugs
- e.g. Oral contraceptives containing oestrogens, anabolic steroids, corticosteroids, NSAIDs, carbenoxolone, sympathomimetic agents

Coarctation of the aorta (p. 632)

Hypertension is more common in some ethnic groups, particularly African Americans and Japanese, and approximately 40–60% is explained by genetic factors. Important environmental factors include a high salt intake, heavy consumption of alcohol, obesity, lack of exercise and impaired intrauterine growth. There is little evidence that 'stress' causes hypertension.

In about 5% of cases, hypertension can be shown to be a consequence of a specific disease or abnormality leading to sodium retention and/or peripheral vasoconstriction (secondary hypertension, Box 18.86).

Approach to newly diagnosed hypertension

Hypertension is predominantly an asymptomatic condition and the diagnosis is usually made at routine examination or when a complication arises. A BP check is advisable every 5 years in adults.

The objectives of the initial evaluation of a patient with high BP readings are:

- to obtain accurate, representative BP measurements
- to identify contributory factors and any underlying cause (secondary hypertension)
- to assess other risk factors and quantify cardiovascular risk
- to detect any complications (target organ damage) that are already present
- to identify comorbidity that may influence the choice of antihypertensive therapy.

These goals are attained by a careful history, clinical examination and some simple investigations.

Measurement of blood pressure

A decision to embark upon antihypertensive therapy effectively commits the patient to life-long treatment, so BP readings must be as accurate as possible.

Measurements should be made to the nearest 2 mmHg, in the sitting position with the arm supported, and repeated after 5 minutes' rest if the first recording is high (Box 18.87). To avoid spuriously high readings in obese subjects, the cuff should contain a bladder that encompasses at least two-thirds of the arm circumference.

Home and ambulatory BP recordings

Exercise, anxiety, discomfort and unfamiliar surroundings can all lead to a transient rise in BP. Sphygmomanometry, particularly when performed by a doctor, can cause an unrepresentative surge in BP which has been termed 'white coat' hypertension, and as many as 20% of patients with apparent hypertension in the clinic may have a normal BP when it is recorded by automated devices used at home. The risk of cardiovascular disease in these patients is less than that in patients with sustained hypertension but greater than that in normotensive subjects.

A series of automated ambulatory BP measurements obtained over 24 hours or longer provides a better profile than a limited number of clinic readings and correlates more closely with evidence of target organ damage than casual BP measurements. Treatment thresholds and targets (see Box 18.93, p. 611) must be adjusted downwards, however, because ambulatory BP readings are systematically lower (approximately 12/7 mmHg) than clinic measurements. The average ambulatory daytime (not 24-hour or night-time) BP should be used to guide management decisions.

Patients can measure their own BP at home using a range of commercially available semi-automatic devices. The value of such measurements is less well established and is dependent on the environment and timing of the readings measured. Home or ambulatory BP measurements are particularly helpful in patients with unusually labile BP, those with refractory hypertension, those who may have symptomatic hypotension, and those in whom white coat hypertension is suspected.

18.87 How to measure blood pressure

- Use a machine that has been validated, well maintained and properly calibrated
- Measure sitting BP routinely, with additional standing BP in elderly and diabetic patients and those with possible postural hypotension
- Remove tight clothing from the arm
- Support the arm at the level of the heart
- Use a cuff of appropriate size (the bladder must encompass more than two-thirds of the arm)
- Lower the pressure slowly (2 mmHg per second)
- Read the BP to the nearest 2 mmHg
- Use phase V (disappearance of sounds) to measure diastolic BP
- Take two measurements at each visit

History

Family history, lifestyle (exercise, salt intake, smoking habit) and other risk factors should be recorded. A careful history will identify those patients with drug- or alcohol-induced hypertension and may elicit the symptoms of other causes of secondary hypertension, such as phaeochromocytoma (paroxysmal headache, palpitation and sweating, p. 781) or complications such as coronary artery disease (e.g. angina, breathlessness).

Examination

Radio-femoral delay (coarctation of the aorta; see Fig. 18.97, p. 632), enlarged kidneys (polycystic kidney disease), abdominal bruits (renal artery stenosis) and the characteristic facies and habitus of Cushing's syndrome are all examples of physical signs that may help to identify causes of secondary hypertension (see Box 18.86). Examination may also reveal features of important risk factors, such as central obesity and hyperlipidaemia (tendon xanthomas and so on). Most abnormal signs are due to the complications of hypertension.

Non-specific findings may include left ventricular hypertrophy (apical heave), accentuation of the aortic component of the second heart sound, and a fourth heart sound. The optic fundi are often abnormal (see Fig. 18.83 below) and there may be evidence of generalised atheroma or specific complications, such as aortic aneurysm or peripheral vascular disease.

Target organ damage

The adverse effects of hypertension on the organs can often be detected clinically.

Blood vessels

In larger arteries (> 1 mm in diameter), the internal elastic lamina is thickened, smooth muscle is hypertrophied and fibrous tissue is deposited. The vessels dilate and become tortuous, and their walls become less compliant. In smaller arteries (< 1 mm), hyaline arteriosclerosis occurs in the wall, the lumen narrows and aneurysms may develop. Widespread atheroma develops and may lead to coronary and cerebrovascular disease, particularly if other risk factors (e.g. smoking, hyperlipidaemia, diabetes) are present.

These structural changes in the vasculature often perpetuate and aggravate hypertension by increasing peripheral vascular resistance and reducing renal blood flow, thereby activating the renin–angiotensin–aldosterone axis (p. 547).

Hypertension is a major risk factor in the pathogenesis of aortic aneurysm and aortic dissection.

Central nervous system

Stroke is a common complication of hypertension and may be due to cerebral haemorrhage or infarction. Carotid atheroma and TIAs are more common in hypertensive patients. Subarachnoid haemorrhage is also associated with hypertension.

Hypertensive encephalopathy is a rare condition characterised by high BP and neurological symptoms, including transient disturbances of speech or vision, paraesthesiae, disorientation, fits and loss of consciousness. Papilloedema is common. A CT scan of the brain often shows haemorrhage in and around the basal ganglia; however, the neurological deficit is usually reversible if the hypertension is properly controlled.

Retina

The optic fundi reveal a gradation of changes linked to the severity of hypertension; fundoscopy can, therefore, provide an indication of the arteriolar damage occurring elsewhere (Box 18.88).

'Cotton wool' exudates are associated with retinal ischaemia or infarction, and fade in a few weeks (Fig. 18.83A). 'Hard' exudates (small, white, dense deposits of lipid) and microaneurysms ('dot' haemorrhages) are more characteristic of diabetic retinopathy (see Fig. 21.12, p. 829). Hypertension is also associated with central retinal vein thrombosis (Fig. 18.83B).

18.88 Hypertensive retinopathy

• **Grade 1**	Arteriolar thickening, tortuosity and increased reflectiveness ('silver wiring')
• **Grade 2**	Grade 1 plus constriction of veins at arterial crossings ('arteriovenous nipping')
• **Grade 3**	Grade 2 plus evidence of retinal ischaemia (flame-shaped or blot haemorrhages and 'cotton wool' exudates)
• **Grade 4**	Grade 3 plus papilloedema

Heart

The excess cardiac mortality and morbidity associated with hypertension are largely due to a higher incidence of coronary artery disease. High BP places a pressure load on the heart and may lead to left ventricular hypertrophy with a forceful apex beat and fourth heart sound. ECG or echocardiographic evidence of left ventricular hypertrophy is highly predictive of cardiovascular complications and therefore particularly useful in risk assessment.

Atrial fibrillation is common and may be due to diastolic dysfunction caused by left ventricular hypertrophy or the effects of coronary artery disease.

Severe hypertension can cause left ventricular failure in the absence of coronary artery disease, particularly when renal function, and therefore sodium excretion, are impaired.

Kidneys

Long-standing hypertension may cause proteinuria and progressive renal failure (p. 478) by damaging the renal vasculature.

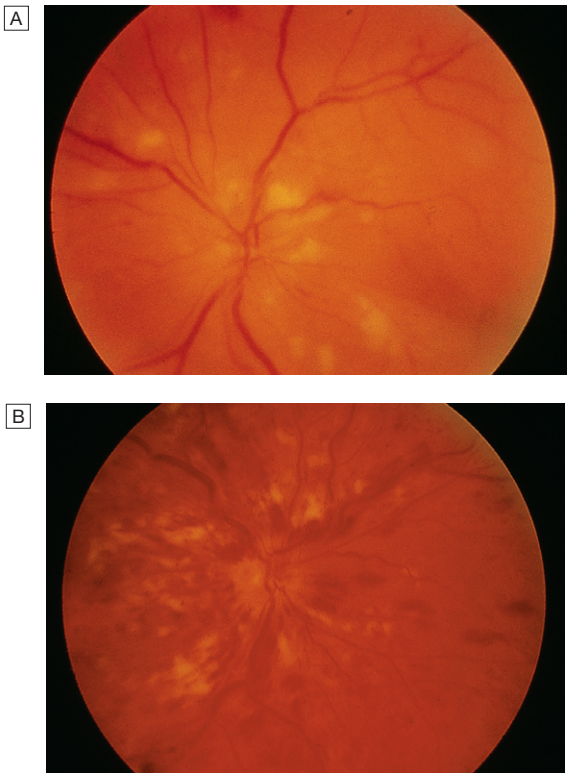

Fig. 18.83 Retinal changes in hypertension. **A** Grade 4 hypertensive retinopathy showing swollen optic disc, retinal haemorrhages and multiple cotton wool spots (infarcts). **B** Central retinal vein thrombosis showing swollen optic disc and widespread fundal haemorrhage, commonly associated with systemic hypertension.

'Malignant' or 'accelerated' phase hypertension

This rare condition may complicate hypertension of any aetiology and is characterised by accelerated microvascular damage with necrosis in the walls of small arteries and arterioles ('fibrinoid necrosis') and by intravascular thrombosis. The diagnosis is based on evidence of high BP and rapidly progressive end organ damage, such as retinopathy (grade 3 or 4), renal dysfunction (especially proteinuria) and/or hypertensive encephalopathy (see above). Left ventricular failure may occur and, if this is untreated, death occurs within months.

Investigations

All hypertensive patients should undergo a limited number of investigations (Box 18.89). Additional investigations are appropriate in selected patients (Box 18.90).

Management

Quantification of cardiovascular risk

The sole objective of antihypertensive therapy is to reduce the incidence of adverse cardiovascular events, particularly coronary artery disease, stroke and heart failure. Randomised controlled trials have demonstrated that antihypertensive therapy can reduce the incidence of stroke and, to a lesser extent, coronary artery disease (Box 18.91). The relative benefits (approximately 30% reduction in risk of stroke and 20% reduction in risk of coronary artery disease) are similar in all patient groups,

18.89 Hypertension: investigation of all patients

- Urinalysis for blood, protein and glucose
- Blood urea, electrolytes and creatinine
  N.B. Hypokalaemic alkalosis may indicate primary hyperaldosteronism but is usually due to diuretic therapy
- Blood glucose
- Serum total and HDL cholesterol
- Thyroid function tests
- 12-lead ECG (left ventricular hypertrophy, coronary artery disease)

(HDL = high-density lipoprotein)

18.90 Hypertension: investigation of selected patients

- Chest X-ray: to detect cardiomegaly, heart failure, coarctation of the aorta
- Ambulatory BP recording: to assess borderline or 'white coat' hypertension
- Echocardiogram: to detect or quantify left ventricular hypertrophy
- Renal ultrasound: to detect possible renal disease
- Renal angiography: to detect or confirm presence of renal artery stenosis
- Urinary catecholamines: to detect possible phaeochromocytoma (p. 781)
- Urinary cortisol and dexamethasone suppression test: to detect possible Cushing's syndrome (p. 773)
- Plasma renin activity and aldosterone: to detect possible primary aldosteronism (p. 780)

so the absolute benefit of treatment (total number of events prevented) is greatest in those at highest risk. For example, to extrapolate from the Medical Research Council (MRC) Mild Hypertension Trial (1985), 566 young patients would have to be treated with bendroflumethiazide for 1 year to prevent 1 stroke, while in the MRC trial of antihypertensive treatment in the elderly (1992), 1 stroke was prevented for every 286 patients treated for 1 year.

A formal estimate of absolute cardiovascular risk, which takes account of all the relevant risk factors, may help to determine whether the likely benefits of therapy will outweigh its costs and hazards. A variety of risk algorithms are available for this purpose (see Fig. 18.62, p. 582). Most of the excess morbidity and mortality associated with hypertension is attributable to coronary artery disease and many treatment guidelines are therefore based on estimates of the 10-year coronary artery disease risk. Total cardiovascular risk can be estimated by multiplying coronary artery disease risk by 4/3 (i.e. if coronary artery disease risk is 30%, cardiovascular risk is 40%). The value of this approach can be illustrated by comparing the two hypothetical cases on page 582.

Threshold for intervention

Systolic BP and diastolic BP are both powerful predictors of cardiovascular risk. The British Hypertension Society management guidelines therefore utilise both readings, and treatment should be initiated if they exceed the given threshold (Fig. 18.84).

EBM 18.91 Benefit of antihypertensive drug therapy

'Diuretics or β-blockers have been shown to reduce the risk of coronary artery disease by 16%, stroke by 38%, cardiovascular death by 21% and all causes of mortality by 13%. The effects of ACE inhibitors and calcium antagonists are similar. NNT_B varies greatly, according to the absolute baseline risk of cardiovascular disease.'

- Blood Pressure Lowering Treatment Trialists' Collaboration. Lancet 2003; 362:1527–1535.

Patients with diabetes or cardiovascular disease are at particularly high risk and the threshold for initiating antihypertensive therapy is therefore lower (≥ 140/90 mmHg) in these patient groups. The thresholds for treatment in the elderly are the same as for younger patients (Box 18.92).

Treatment targets

The optimum BP for reduction of major cardiovascular events has been found to be 139/83 mmHg, and even lower in patients with diabetes mellitus. Moreover, reducing BP below this level causes no harm. The targets suggested by the British Hypertension Society (Box 18.93) are ambitious. Primary care strategies have been devised to improve screening and detection of hypertension that, in the past, remained undetected in up to half of affected individuals. Application of new guidelines should help establish patients on appropriate treatment, and allow step-up if lifestyle modification and first-line drug therapy fail to control patients' BP.

Patients taking antihypertensive therapy require follow-up at 3-monthly intervals to monitor BP, minimise side-effects and reinforce lifestyle advice.

Non-drug therapy

Appropriate lifestyle measures may obviate the need for drug therapy in patients with borderline hypertension, reduce the dose and/or the number of drugs required in patients with established hypertension, and directly reduce cardiovascular risk.

Correcting obesity, reducing alcohol intake, restricting salt intake, taking regular physical exercise and increasing consumption of fruit and vegetables can all lower BP. Moreover, quitting smoking, eating oily fish and adopting a diet that is low in saturated fat may produce further reductions in cardiovascular risk.

18.92 Hypertension in old age

- **Prevalence**: affects more than half of all people over the age of 60 yrs (including isolated systolic hypertension).
- **Risks**: hypertension is the most important risk factor for MI, heart failure and stroke in older people.
- **Benefit of treatment**: absolute benefit from therapy is greatest in older people (at least up to age 80 yrs).
- **Target BP**: similar to that for younger patients.
- **Tolerance of treatment**: antihypertensives are tolerated as well as in younger patients.
- **Drug of choice**: low-dose thiazides but, in the presence of coexistent disease (e.g. gout, diabetes), other agents may be more appropriate.

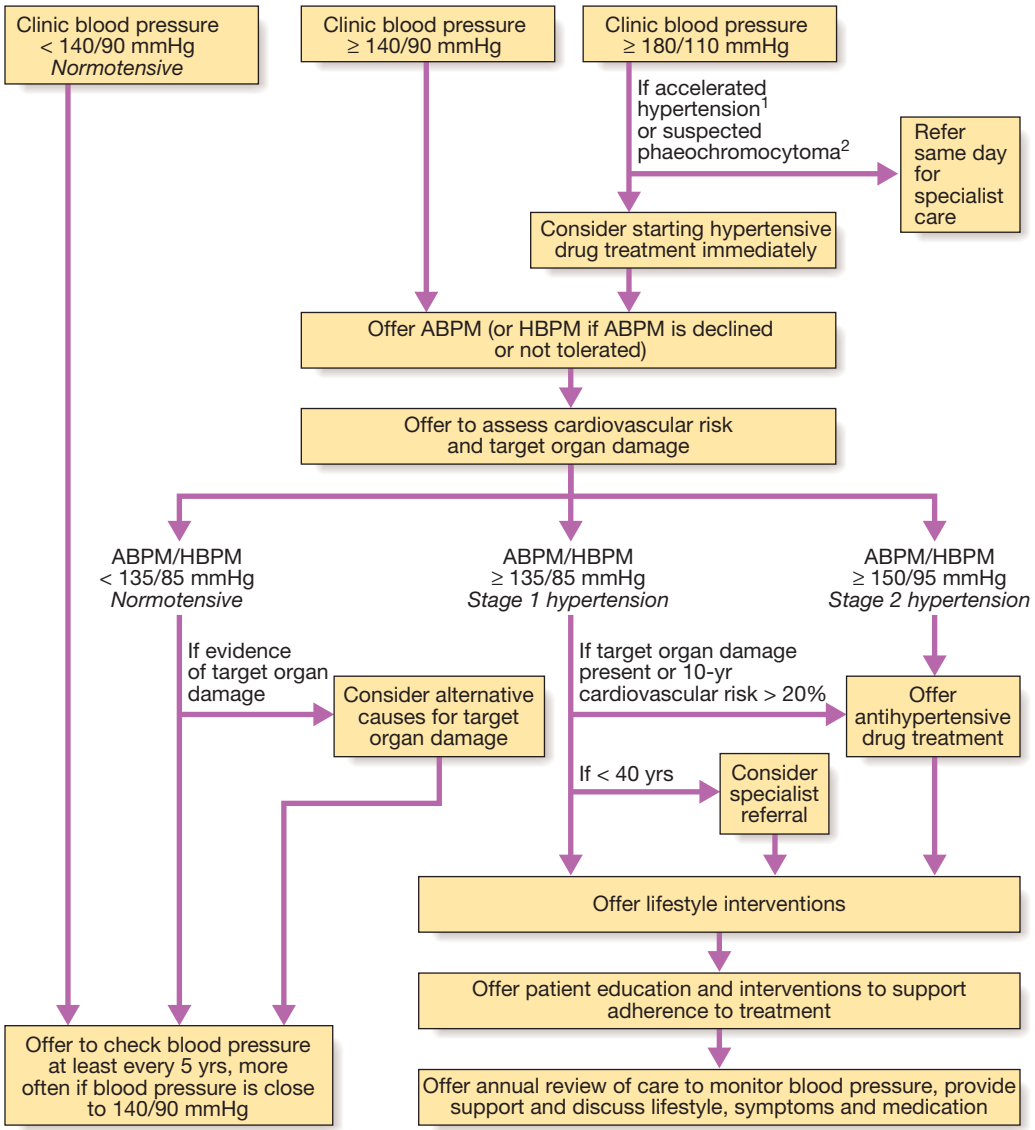

Fig. 18.84 Management of hypertension: British Hypertension Society guidelines. [1]Signs of papilloedema or retinal haemorrhage. [2]Labile or postural hypotension, headache, palpitations, pallor and diaphoresis (ABPM = ambulatory blood pressure monitoring; HBPM = home blood pressure monitoring). From NICE Clinical Guideline 127 – see p. 641.

18.93 Optimal target blood pressures[1]

Age	Clinic BP (mmHg)	Ambulatory or home BP (mmHg)[2]
< 80 yrs	< 140/90	< 135/85
≥ 80 yrs	< 150/90	< 140/85

[1]Both systolic and diastolic values should be attained.
[2]Average BP during waking hours.

Antihypertensive drugs

Thiazide and other diuretics. The mechanism of action of these drugs is incompletely understood and it may take up to a month for the maximum effect to be observed. An appropriate daily dose is 2.5 mg bendroflumethiazide or 0.5 mg cyclopenthiazide. More potent loop diuretics, such as furosemide (40 mg daily) or bumetanide (1 mg daily), have few advantages over thiazides in the treatment of hypertension, unless there is substantial renal impairment or they are used in conjunction with an ACE inhibitor.

ACE inhibitors. ACE inhibitors (e.g. enalapril 20 mg daily, ramipril 5–10 mg daily or lisinopril 10–40 mg daily) inhibit the conversion of angiotensin I to angiotensin II and are usually well tolerated. They should be used with particular care in patients with impaired renal function or renal artery stenosis because they can reduce the filtration pressure in the glomeruli and precipitate renal failure. Electrolytes and creatinine should be checked before and 1–2 weeks after commencing therapy. Side-effects include first-dose hypotension, cough, rash, hyperkalaemia and renal dysfunction.

Angiotensin receptor blockers. Angiotensin receptor blockers (e.g. irbesartan 150–300 mg daily, valsartan

40–160 mg daily) block the angiotensin II type I receptor and have similar effects to ACE inhibitors; however, they do not cause cough and are better tolerated.

Calcium channel antagonists. The dihydropyridines (e.g. amlodipine 5–10 mg daily, nifedipine 30–90 mg daily) are effective and usually well-tolerated antihypertensive drugs that are particularly useful in older people. Side-effects include flushing, palpitations and fluid retention. The rate-limiting calcium channel antagonists (e.g. diltiazem 200–300 mg daily, verapamil 240 mg daily) can be useful when hypertension coexists with angina but they may cause bradycardia. The main side-effect of verapamil is constipation.

Beta-blockers. These are no longer used as first-line antihypertensive therapy, except in patients with another indication for the drug (e.g. angina). Metoprolol (100–200 mg daily), atenolol (50–100 mg daily) and bisoprolol (5–10 mg daily) preferentially block cardiac β_1-adrenoceptors, as opposed to the β_2-adrenoceptors that mediate vasodilatation and bronchodilatation.

Labetalol and carvedilol. Labetalol (200 mg–2.4 g daily in divided doses) and carvedilol (6.25–25 mg twice daily) are combined β- and α-adrenoceptor antagonists which are sometimes more effective than pure β-blockers. Labetalol can be used as an infusion in malignant phase hypertension (see below).

Other drugs. A variety of vasodilators may be used. These include the α_1-adrenoceptor antagonists (α-blockers), such as prazosin (0.5–20 mg daily in divided doses), indoramin (25–100 mg twice daily) and doxazosin (1–16 mg daily), and drugs that act directly on vascular smooth muscle, such as hydralazine (25–100 mg twice daily) and minoxidil (10–50 mg daily). Side-effects include first-dose and postural hypotension, headache, tachycardia and fluid retention. Minoxidil also causes increased facial hair and is therefore unsuitable for female patients.

Choice of antihypertensive drug

Trials that have compared thiazides, calcium antagonists, ACE inhibitors and angiotensin receptor blockers have not shown consistent differences in outcome, efficacy, side-effects or quality of life. Beta-blockers, which previously featured as first-line therapy in guidelines, have a weaker evidence base (see Box 18.91). The choice of antihypertensive therapy is initially dictated by the patient's age and ethnic background, although cost and convenience will influence the exact drug and preparation used. Response to initial therapy and side-effects guides subsequent treatment. Comorbid conditions also have an influence on initial drug selection (Box 18.94); for example, a β-blocker might be the most appropriate treatment for a patient with angina. Thiazide diuretics and dihydropyridine calcium channel antagonists are the most suitable drugs for treatment in older people.

Although some patients can be treated with a single antihypertensive drug, a combination of drugs is often required to achieve optimal BP control (Fig. 18.85). Combination therapy may be desirable for other reasons; for example, low-dose therapy with two drugs may produce fewer unwanted effects than treatment with the maximum dose of a single drug. Some drug combinations have complementary or synergistic actions; for example, thiazides increase activity of the renin–angiotensin system, while ACE inhibitors block it.

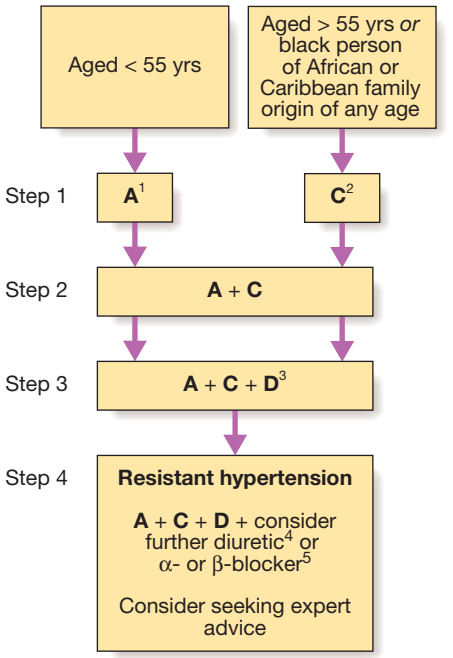

Fig. 18.85 Antihypertensive drug combinations. Black patients are those of African or Caribbean descent, and not mixed-race, Asian or Chinese patients. [1]A = ACE inhibitor or consider angiotensin II receptor blocker (ARB); choose a low-cost ARB. [2]C = calcium channel blocker (CCB); a CCB is preferred but consider a thiazide-like diuretic if a CCB is not tolerated or the person has oedema, evidence of heart failure or a high risk of heart failure. [3]D = thiazide-type diuretic. [4]Consider a low dose of spironolactone or higher doses of a thiazide-like diuretic. At the time of publication by NICE (August 2011), spironolactone did not have a UK marketing authorisation for this indication. Informed consent should be obtained and documented. [5]Consider an α- or β-blocker if further diuretic therapy is not tolerated, or is contraindicated or ineffective. From NICE Clinical Guideline 127 – see p. 641.

Emergency treatment of accelerated phase or malignant hypertension

In accelerated phase hypertension, lowering BP too quickly may compromise tissue perfusion (due to altered autoregulation) and can cause cerebral damage, including occipital blindness, and precipitate coronary or renal insufficiency. Even in the presence of cardiac failure or hypertensive encephalopathy, a controlled reduction to a level of about 150/90 mmHg over a period of 24–48 hours is ideal.

In most patients, it is possible to avoid parenteral therapy and bring BP under control with bed rest and oral drug therapy. Intravenous or intramuscular labetalol (2 mg/min to a maximum of 200 mg), intravenous glyceryl trinitrate (0.6–1.2 mg/hr), intramuscular hydralazine (5 or 10 mg aliquots repeated at half-hourly intervals) and intravenous sodium nitroprusside (0.3–1.0 μg/kg body weight/min) are all effective but require careful supervision, preferably in a high-dependency unit.

Refractory hypertension

The common causes of treatment failure in hypertension are non-adherence to drug therapy, inadequate therapy, and failure to recognise an underlying cause, such as

18.94 The influence of comorbidity on the choice of antihypertensive drug therapy

Class of drug	Compelling indications	Possible indications	Caution	Compelling contraindications
α-blockers	Benign prostatic hypertrophy	–	Postural hypotension, heart failure[1]	Urinary incontinence
ACE inhibitors	Heart failure Left ventricular dysfunction, post-MI or established coronary artery disease Type 1 diabetic nephropathy Secondary stroke prevention[4]	Chronic renal disease[2] Type 2 diabetic nephropathy	Renal impairment[2] Peripheral vascular disease[3]	Pregnancy Renovascular disease[2]
Angiotensin II receptor blockers	ACE inhibitor intolerance Type 2 diabetic nephropathy Hypertension with left ventricular hypertrophy Heart failure in ACE-intolerant patients, after MI	Left ventricular dysfunction after MI Intolerance of other antihypertensive drugs Proteinuric renal disease, chronic renal disease[2] Heart failure	Renal impairment[2] Peripheral vascular disease[3]	Pregnancy
β-blockers	MI, angina Heart failure[5]	–	Heart failure[5] Peripheral vascular disease Diabetes (except with coronary artery disease)	Asthma or chronic obstructive pulmonary disease Heart block
Calcium channel blockers (dihydropyridine)	Older patients, isolated systolic hypertension	Angina	–	–
Calcium channel blockers (rate-limiting)	Angina	Older patients	Combination with β-blockade	Atrioventricular block, heart failure
Thiazides or thiazide-like diuretics	Older patients, isolated systolic hypertension, heart failure, secondary stroke prevention	–	–	Gout[6]

[1]In heart failure when used as monotherapy. [2]ACE inhibitors or angiotensin II receptor blockers may be beneficial in chronic renal failure and renovascular disease but should be used with caution, close supervision and specialist advice when there is established and significant renal impairment. [3]Caution with ACE inhibitors and angiotensin II receptor blockers in peripheral vascular disease because of association with renovascular disease. [4]In combination with a thiazide or thiazide-like diuretic. [5]β-blockers are used increasingly to treat stable heart failure but may worsen acute heart failure. [6]Thiazides or thiazide-like diuretics may sometimes be necessary to control BP in people with a history of gout, ideally used in combination with allopurinol.

renal artery stenosis or phaeochromocytoma; of these, the first is by far the most prevalent. There is no easy solution to compliance problems but simple treatment regimens, attempts to improve rapport with the patient and careful supervision may all help.

Adjuvant drug therapy

- *Aspirin*. Antiplatelet therapy is a powerful means of reducing cardiovascular risk but may cause bleeding, particularly intracerebral haemorrhage, in a small number of patients. The benefits are thought to outweigh the risks in hypertensive patients aged 50 years or over who have well-controlled BP and either target organ damage, diabetes or a 10-year coronary artery disease risk of at least 15% (or 10-year cardiovascular disease risk of at least 20%).
- *Statins*. Treating hyperlipidaemia can produce a substantial reduction in cardiovascular risk. These drugs are strongly indicated in patients who have established vascular disease, or hypertension with a high (at least 20% in 10 years) risk of developing cardiovascular disease (p. 583).

DISEASES OF THE HEART VALVES

A diseased valve may be narrowed (stenosed) or may fail to close adequately, and thus permit regurgitation of blood. 'Incompetence' is a less precise term for regurgitation or reflux, and should be avoided. Box 18.95 gives the principal causes of valve disease.

Doppler echocardiography is the most useful technique for assessing valvular heart disease (p. 536) but may also detect minor and even 'physiological' abnormalities, e.g. trivial mitral regurgitation. Disease of the heart valves may progress with time and selected patients require regular review every 1 or 2 years, to ensure that deterioration is detected before complications, such as heart failure, ensue. Patients with valvular heart disease are susceptible to bacterial endocarditis, which can be prevented by good dental hygiene. The routine use of

18.95 Principal causes of valve disease

Valve regurgitation	
• Congenital	• Syphilitic aortitis
• Acute rheumatic carditis	• Traumatic valve rupture
• Chronic rheumatic carditis	• Senile degeneration
• Infective endocarditis	• Damage to chordae and papillary muscles (e.g. MI)
• Valve ring dilatation (e.g. dilated cardiomyopathy)	
Valve stenosis	
• Congenital	• Senile degeneration
• Rheumatic carditis	

antibiotic prophylaxis at times of bacteraemia, e.g. dental extraction, is no longer recommended.

Rheumatic heart disease

Acute rheumatic fever

Incidence and pathogenesis

Acute rheumatic fever usually affects children (most commonly between 5 and 15 years) or young adults, and has become very rare in Western Europe and North America. However, it remains endemic in parts of Asia, Africa and South America, with an annual incidence in some countries of more than 100 per 100 000, and is the most common cause of acquired heart disease in childhood and adolescence.

The condition is triggered by an immune-mediated delayed response to infection with specific strains of group A streptococci, which have antigens that may cross-react with cardiac myosin and sarcolemmal membrane protein. Antibodies produced against the streptococcal antigens cause inflammation in the endocardium, myocardium and pericardium, as well as the joints and skin. Histologically, fibrinoid degeneration is seen in the collagen of connective tissues. Aschoff nodules are pathognomonic and occur only in the heart. They are composed of multinucleated giant cells surrounded by macrophages and T lymphocytes, and are not seen until the subacute or chronic phases of rheumatic carditis.

Clinical features

Acute rheumatic fever is a multisystem disorder that usually presents with fever, anorexia, lethargy and joint pain, 2–3 weeks after an episode of streptococcal pharyngitis. There may, however, be no history of sore throat. Arthritis occurs in approximately 75% of patients. Other features include rashes, carditis and neurological changes (Fig. 18.86). The diagnosis, made using the revised Jones criteria (Box 18.96), is based upon two or more major manifestations, or one major and two or more minor manifestations, along with evidence of preceding streptococcal infection. Only about 25% of patients will have a positive culture for group A streptococcus at the time of diagnosis because there is a latent period between infection and presentation. Serological evidence of recent infection with a raised antistreptolysin O (ASO) antibody titre is helpful. A presumptive diagnosis of acute rheumatic fever can be made without evidence of preceding streptococcal infection in cases of isolated chorea or pancarditis, if other causes for these have been excluded. In cases of established rheumatic heart disease or prior rheumatic fever, a diagnosis of acute rheumatic fever can be made based only on the presence of multiple minor criteria and evidence of preceding group A streptococcal pharyngitis.

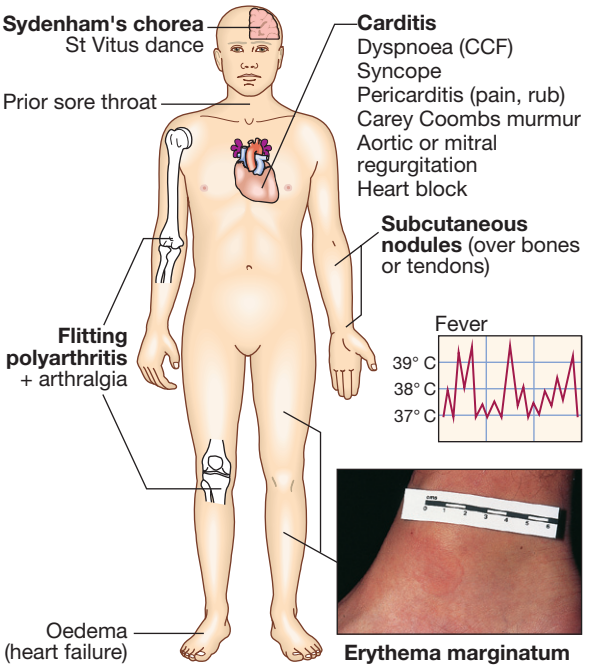

Fig. 18.86 Clinical features of rheumatic fever. Bold labels indicate Jones major criteria (CCF = congestive cardiac failure). *Inset (Erythema marginatum)* From Savin et al. 1997 – see p. 641.

18.96 Jones criteria for the diagnosis of rheumatic fever

Major manifestations	
• Carditis	• Erythema marginatum
• Polyarthritis	• Subcutaneous nodules
• Chorea	
Minor manifestations	
• Fever	• Raised ESR or CRP
• Arthralgia	• Leucocytosis
• Previous rheumatic fever	• First-degree AV block
Plus	
• Supporting evidence of preceding streptococcal infection: recent scarlet fever, raised antistreptolysin O or other streptococcal antibody titre, positive throat culture	

N.B. Evidence of recent streptococcal infection is particularly important if there is only one major manifestation.

Carditis

A 'pancarditis' involves the endocardium, myocardium and pericardium to varying degrees. Its incidence declines with increasing age, ranging from 90% at 3 years to around 30% in adolescence. It may manifest as breathlessness (due to heart failure or pericardial effusion), palpitations or chest pain (usually due to pericarditis or pancarditis). Other features include tachycardia,

cardiac enlargement and new or changed murmurs. A soft systolic murmur due to mitral regurgitation is very common. A soft mid-diastolic murmur (the Carey Coombs murmur) is typically due to valvulitis, with nodules forming on the mitral valve leaflets. Aortic regurgitation occurs in 50% of cases but the tricuspid and pulmonary valves are rarely involved. Pericarditis may cause chest pain, a pericardial friction rub and precordial tenderness. Cardiac failure may be due to myocardial dysfunction or valvular regurgitation. ECG changes commonly include ST and T wave changes. Conduction defects sometimes occur and may cause syncope.

Arthritis

This is the most common major manifestation and occurs early when streptococcal antibody titres are high. An acute painful asymmetric and migratory inflammation of the large joints typically affects the knees, ankles, elbows and wrists. The joints are involved in quick succession and are usually red, swollen and tender for between a day and 4 weeks. The pain characteristically responds to aspirin; if not, the diagnosis is in doubt.

Skin lesions

Erythema marginatum occurs in less than 5% of patients. The lesions start as red macules that fade in the centre but remain red at the edges, and occur mainly on the trunk and proximal extremities but not the face. The resulting red rings or 'margins' may coalesce or overlap (see Fig. 18.86). Subcutaneous nodules occur in 5–7% of patients. They are small (0.5–2.0 cm), firm and painless, and are best felt over extensor surfaces of bone or tendons. They typically appear more than 3 weeks after the onset of other manifestations and therefore help to confirm rather than make the diagnosis. Other systemic manifestations are rare but include pleurisy, pleural effusion and pneumonia.

Sydenham's chorea (St Vitus dance)

This is a late neurological manifestation that appears at least 3 months after the episode of acute rheumatic fever, when all the other signs may have disappeared. It occurs in up to one-third of cases and is more common in females. Emotional lability may be the first feature and is typically followed by purposeless, involuntary, choreiform movements of the hands, feet or face. Speech may be explosive and halting. Spontaneous recovery usually occurs within a few months. Approximately one-quarter of affected patients will go on to develop chronic rheumatic valve disease.

Investigations

The ESR and CRP are useful for monitoring progress of the disease (Box 18.97). Positive throat swab cultures are obtained in only 10–25% of cases. ASO titres are normal in one-fifth of adult cases of rheumatic fever and most cases of chorea. Echocardiography typically shows mitral regurgitation with dilatation of the mitral annulus and prolapse of the anterior mitral leaflet, and may also show aortic regurgitation and pericardial effusion.

18.97 Investigations in acute rheumatic fever

Evidence of a systemic illness (non-specific)

- Leucocytosis, raised ESR and CRP

Evidence of preceding streptococcal infection (specific)

- Throat swab culture: group A β-haemolytic streptococci (also from family members and contacts)
- Antistreptolysin O antibodies (ASO titres): rising titres, or levels of > 200 U (adults) or > 300 U (children)

Evidence of carditis

- Chest X-ray: cardiomegaly; pulmonary congestion
- ECG: first- and rarely second-degree AV block; features of pericarditis; T-wave inversion; reduction in QRS voltages
- Echocardiography: cardiac dilatation and valve abnormalities

Management of the acute attack

A single dose of benzyl penicillin (1.2 million U IM) or oral phenoxymethylpenicillin (250 mg 4 times daily for 10 days) should be given on diagnosis to eliminate any residual streptococcal infection. If the patient is penicillin-allergic, erythromycin or a cephalosporin can be used. Treatment is then directed towards limiting cardiac damage and relieving symptoms.

Bed rest and supportive therapy

Bed rest is important, as it lessens joint pain and reduces cardiac workload. The duration should be guided by symptoms, along with temperature, leucocyte count and ESR, and should be continued until these have settled. Patients can then return to normal physical activity but strenuous exercise should be avoided in those who have had carditis.

Cardiac failure should be treated as necessary. Some patients, particularly those in early adolescence, develop a fulminant form of the disease with severe mitral regurgitation and, sometimes, concomitant aortic regurgitation. If heart failure in these cases does not respond to medical treatment, valve replacement may be necessary and is often associated with a dramatic decline in rheumatic activity. AV block is seldom progressive and pacemaker insertion rarely needed.

Aspirin

This usually relieves the symptoms of arthritis rapidly and a response within 24 hours helps confirm the diagnosis. A reasonable starting dose is 60 mg/kg body weight/day, divided into six doses. In adults, 100 mg/kg per day may be needed up to the limits of tolerance or a maximum of 8 g per day. Mild toxicity includes nausea, tinnitus and deafness; vomiting, tachypnoea and acidosis are more serious. Aspirin should be continued until the ESR has fallen, and then gradually tailed off.

Corticosteroids

These produce more rapid symptomatic relief than aspirin and are indicated in cases with carditis or severe arthritis. There is no evidence that long-term steroids are beneficial. Prednisolone (1.0–2.0 mg/kg per day in divided doses) should be continued until the ESR is normal, and then tailed off.

Secondary prevention

Patients are susceptible to further attacks of rheumatic fever if another streptococcal infection occurs, and long-term prophylaxis with penicillin should be given as benzathine penicillin (1.2 million U IM monthly), if

compliance is in doubt, or oral phenoxymethylpenicillin (250 mg twice daily). Sulfadiazine or erythromycin may be used if the patient is allergic to penicillin; sulphonamides prevent infection but are not effective in the eradication of group A streptococci. Further attacks of rheumatic fever are unusual after the age of 21, when treatment may be stopped. However, it should be extended if an attack has occurred in the last 5 years, or if the patient lives in an area of high prevalence or has an occupation (e.g. teaching) with high exposure to streptococcal infection. In those with residual heart disease, prophylaxis should continue until 10 years after the last episode or 40 years of age, whichever is later. Long-term antibiotic prophylaxis prevents another attack of acute rheumatic fever but does not protect against infective endocarditis.

Chronic rheumatic heart disease

Chronic valvular heart disease develops in at least half of those affected by rheumatic fever with carditis. Two-thirds of cases occur in women. Some episodes of rheumatic fever pass unrecognised and it is only possible to elicit a history of rheumatic fever or chorea in about half of all patients with chronic rheumatic heart disease.

The mitral valve is affected in more than 90% of cases; the aortic valve is the next most frequently involved, followed by the tricuspid and then the pulmonary valve. Isolated mitral stenosis accounts for about 25% of all cases, and an additional 40% have mixed mitral stenosis and regurgitation. Valve disease may be symptomatic during fulminant forms of acute rheumatic fever but may remain asymptomatic for many years.

Pathology

The main pathological process in chronic rheumatic heart disease is progressive fibrosis. The heart valves are predominantly affected but involvement of the pericardium and myocardium may contribute to heart failure and conduction disorders. Fusion of the mitral valve commissures and shortening of the chordae tendineae may lead to mitral stenosis with or without regurgitation. Similar changes in the aortic and tricuspid valves produce distortion and rigidity of the cusps, leading to stenosis and regurgitation. Once a valve has been damaged, the altered haemodynamic stresses perpetuate and extend the damage, even in the absence of a continuing rheumatic process.

Mitral valve disease

Mitral stenosis

Aetiology and pathophysiology

Mitral stenosis is almost always rheumatic in origin, although in older people it can be caused by heavy calcification of the mitral valve apparatus. There is also a rare form of congenital mitral stenosis.

In rheumatic mitral stenosis, the mitral valve orifice is slowly diminished by progressive fibrosis, calcification of the valve leaflets, and fusion of the cusps and subvalvular apparatus. The flow of blood from LA to LV is restricted and left atrial pressure rises, leading to pulmonary venous congestion and breathlessness. There is dilatation and hypertrophy of the LA, and left ventricular filling becomes more dependent on left atrial contraction.

Any increase in heart rate shortens diastole when the mitral valve is open and produces a further rise in left atrial pressure. Situations that demand an increase in cardiac output also increase left atrial pressure, so exercise and pregnancy are poorly tolerated.

The mitral valve orifice is normally about 5 cm^2 in diastole and may be reduced to 1 cm^2 in severe mitral stenosis. Patients usually remain asymptomatic until the stenosis is less than 2 cm^2. Reduced lung compliance, due to chronic pulmonary venous congestion, contributes to breathlessness, and a low cardiac output may cause fatigue.

Atrial fibrillation due to progressive dilatation of the LA is very common. Its onset often precipitates pulmonary oedema because the accompanying tachycardia and loss of atrial contraction lead to marked haemodynamic deterioration with a rapid rise in left atrial pressure. In contrast, a more gradual rise in left atrial pressure tends to cause an increase in pulmonary vascular resistance, which leads to pulmonary hypertension that may protect the patient from pulmonary oedema. Pulmonary hypertension leads to right ventricular hypertrophy and dilatation, tricuspid regurgitation and right heart failure.

Fewer than 20% of patients remain in sinus rhythm; many of these have a small fibrotic LA and severe pulmonary hypertension.

Clinical features

Effort-related dyspnoea is usually the dominant symptom (Box 18.98). Exercise tolerance typically diminishes very slowly over many years and patients often do not appreciate the extent of their disability. Eventually, symptoms occur at rest. Acute pulmonary oedema or pulmonary hypertension can lead to haemoptysis. All patients with mitral stenosis, and particularly those with atrial fibrillation, are at risk from left atrial thrombosis and systemic thromboembolism. Prior to the advent of anticoagulant therapy, emboli caused one-quarter of all deaths.

18.98 Clinical features (and their causes) in mitral stenosis

Symptoms

- Breathlessness (pulmonary congestion)
- Fatigue (low cardiac output)
- Oedema, ascites (right heart failure)
- Palpitation (atrial fibrillation)
- Haemoptysis (pulmonary congestion, pulmonary embolism)
- Cough (pulmonary congestion)
- Chest pain (pulmonary hypertension)
- Thromboembolic complications (e.g. stroke, ischaemic limb)

Signs

- Atrial fibrillation
- Mitral facies
- Auscultation
  - Loud first heart sound, opening snap
  - Mid-diastolic murmur
- Crepitations, pulmonary oedema, effusions (raised pulmonary capillary pressure)
- RV heave, loud P_2 (pulmonary hypertension)

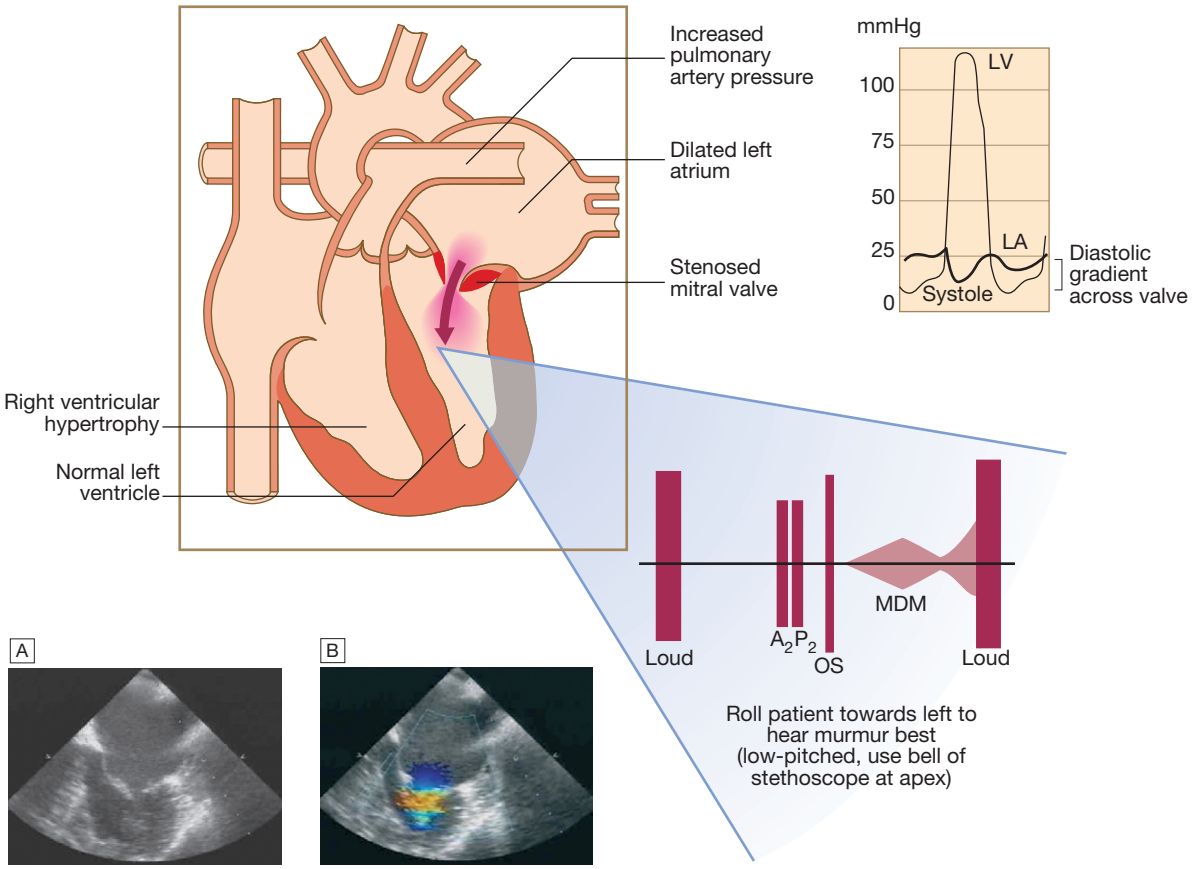

Fig. 18.87 Mitral stenosis: murmur and the diastolic pressure gradient between LA and LV. (Mean gradient is reflected by the area between LA and LV in diastole.) The first heart sound is loud, and there is an opening snap (OS) and mid-diastolic murmur (MDM) with pre-systolic accentuation. **A** Echocardiogram showing reduced opening of the mitral valve in diastole. **B** Colour Doppler showing turbulent flow.

The physical signs of mitral stenosis are often found before symptoms develop and their recognition is of particular importance in pregnancy. The forces that open and close the mitral valve increase as left atrial pressure rises. The first heart sound (S1) is therefore loud and can be palpable (tapping apex beat). An opening snap may be audible and moves closer to the second sound (S2) as the stenosis becomes more severe and left atrial pressure rises. However, the first heart sound and opening snap may be inaudible if the valve is heavily calcified.

Turbulent flow produces the characteristic low-pitched mid-diastolic murmur and sometimes a thrill (Fig. 18.87). The murmur is accentuated by exercise and during atrial systole (pre-systolic accentuation). Early in the disease, a pre-systolic murmur may be the only auscultatory abnormality but, in patients with symptoms, the murmur extends from the opening snap to the first heart sound. Coexisting mitral regurgitation causes a pansystolic murmur that radiates towards the axilla.

Pulmonary hypertension may ultimately lead to right ventricular hypertrophy and dilatation with secondary tricuspid regurgitation, which causes a systolic murmur and giant '*v* waves' in the venous pulse.

Investigations

The ECG may show either atrial fibrillation or bifid P waves (P mitrale) associated with left atrial hypertrophy (Box 18.99). A typical chest X-ray is shown in Figure 18.9 (p. 535). Doppler echocardiography provides the definitive evaluation of mitral stenosis (see Fig. 18.87). Cardiac catheterisation is used to assess coexisting conditions.

18.99 Investigations in mitral stenosis

ECG	
• Right ventricular hypertrophy: tall R waves in V_1–V_3	• P mitrale or atrial fibrillation
Chest X-ray	
• Enlarged LA and appendage	• Signs of pulmonary venous congestion
Echo	
• Thickened immobile cusps • Reduced valve area • Enlarged LA	• Reduced rate of diastolic filling of LV
Doppler	
• Pressure gradient across mitral valve	• Pulmonary artery pressure • Left ventricular function
Cardiac catheterisation	
• Coronary artery disease • Pulmonary artery pressure	• Mitral stenosis and regurgitation

Management

Patients with minor symptoms should be treated medically. Intervention by balloon valvuloplasty, mitral valvotomy or mitral valve replacement should be considered if the patient remains symptomatic despite medical treatment or if pulmonary hypertension develops.

Medical management

This consists of anticoagulation to reduce the risk of systemic embolism, ventricular rate control (digoxin, β-blockers or rate-limiting calcium antagonists) in atrial fibrillation, and diuretic therapy to control pulmonary congestion. Antibiotic prophylaxis against infective endocarditis is no longer routinely recommended.

Mitral balloon valvuloplasty and valve replacement

Valvuloplasty is the treatment of choice if specific criteria are fulfilled (Box 18.100 and Fig. 18.67, p. 587), although surgical closed or open mitral valvotomy is an acceptable alternative. Patients who have undergone mitral valvuloplasty or valvotomy should be followed up at 1–2-yearly intervals because re-stenosis may occur. Clinical symptoms and signs are a guide to the severity of mitral re-stenosis but Doppler echocardiography provides a more accurate assessment.

Valve replacement is indicated if there is substantial mitral reflux or if the valve is rigid and calcified (p. 629).

18.100 Criteria for mitral valvuloplasty*

- Significant symptoms
- Isolated mitral stenosis
- No (or trivial) mitral regurgitation
- Mobile, non-calcified valve/subvalve apparatus on echo
- LA free of thrombus

*For comprehensive guidelines on valvular heart disease, see www.acc.org

Mitral regurgitation

Aetiology and pathophysiology

Rheumatic disease is the principal cause in countries where rheumatic fever is common, but elsewhere, including in the UK, other causes are more important (Box 18.101). Mitral regurgitation may also follow mitral valvotomy or valvuloplasty.

Chronic mitral regurgitation causes gradual dilatation of the LA with little increase in pressure and therefore relatively few symptoms. Nevertheless, the LV dilates slowly and the left ventricular diastolic and left atrial pressures gradually increase as a result of chronic volume overload of the LV. In contrast, acute mitral regurgitation causes a rapid rise in left atrial pressure (because left atrial compliance is normal) and marked symptomatic deterioration.

18.101 Causes of mitral regurgitation

- Mitral valve prolapse
- Dilatation of the LV and mitral valve ring (e.g. coronary artery disease, cardiomyopathy)
- Damage to valve cusps and chordae (e.g. rheumatic heart disease, endocarditis)
- Ischaemia or infarction of the papillary muscle
- Myocardial infarction

Mitral valve prolapse

This is also known as 'floppy' mitral valve and is one of the more common causes of mild mitral regurgitation (Fig. 18.88). It is caused by congenital anomalies or degenerative myxomatous changes, and is sometimes a feature of connective tissue disorders such as Marfan's syndrome (p. 603).

In its mildest forms, the valve remains competent but bulges back into the atrium during systole, causing a mid-systolic click but no murmur. In the presence of a regurgitant valve, the click is followed by a late systolic murmur, which lengthens as the regurgitation becomes more severe. A click is not always audible and the physical signs may vary with both posture and respiration. Progressive elongation of the chordae tendineae leads to increasing mitral regurgitation, and if chordal rupture occurs, regurgitation suddenly becomes severe. This is rare before the fifth or sixth decade of life.

Mitral valve prolapse is associated with a variety of typically benign arrhythmias, atypical chest pain and a very small risk of embolic stroke or TIA. Nevertheless, the overall long-term prognosis is good.

Other causes of mitral regurgitation

Mitral valve function depends on the chordae tendineae and their papillary muscles; dilatation of the LV distorts the geometry of these and may cause mitral regurgitation (see Box 18.101). Dilated cardiomyopathy and heart failure from coronary artery disease are common causes of so-called 'functional' mitral regurgitation. Endocarditis is an important cause of acute mitral regurgitation.

Clinical features

Symptoms depend on how suddenly the regurgitation develops (Box 18.102). Chronic mitral regurgitation produces a symptom complex that is similar to that of mitral stenosis, but sudden-onset mitral regurgitation usually presents with acute pulmonary oedema.

The regurgitant jet causes an apical systolic murmur (see Fig. 18.88), which radiates into the axilla and may be accompanied by a thrill. Increased forward flow through the mitral valve causes a loud third heart sound

18.102 Clinical features (and their causes) in mitral regurgitation

Symptoms

- Dyspnoea (pulmonary venous congestion)
- Fatigue (low cardiac output)
- Palpitation (atrial fibrillation, increased stroke volume)
- Oedema, ascites (right heart failure)

Signs

- Atrial fibrillation/flutter
- Cardiomegaly: displaced hyperdynamic apex beat
- Apical pansystolic murmur ± thrill
- Soft S1, apical S3
- Signs of pulmonary venous congestion (crepitations, pulmonary oedema, effusions)
- Signs of pulmonary hypertension and right heart failure

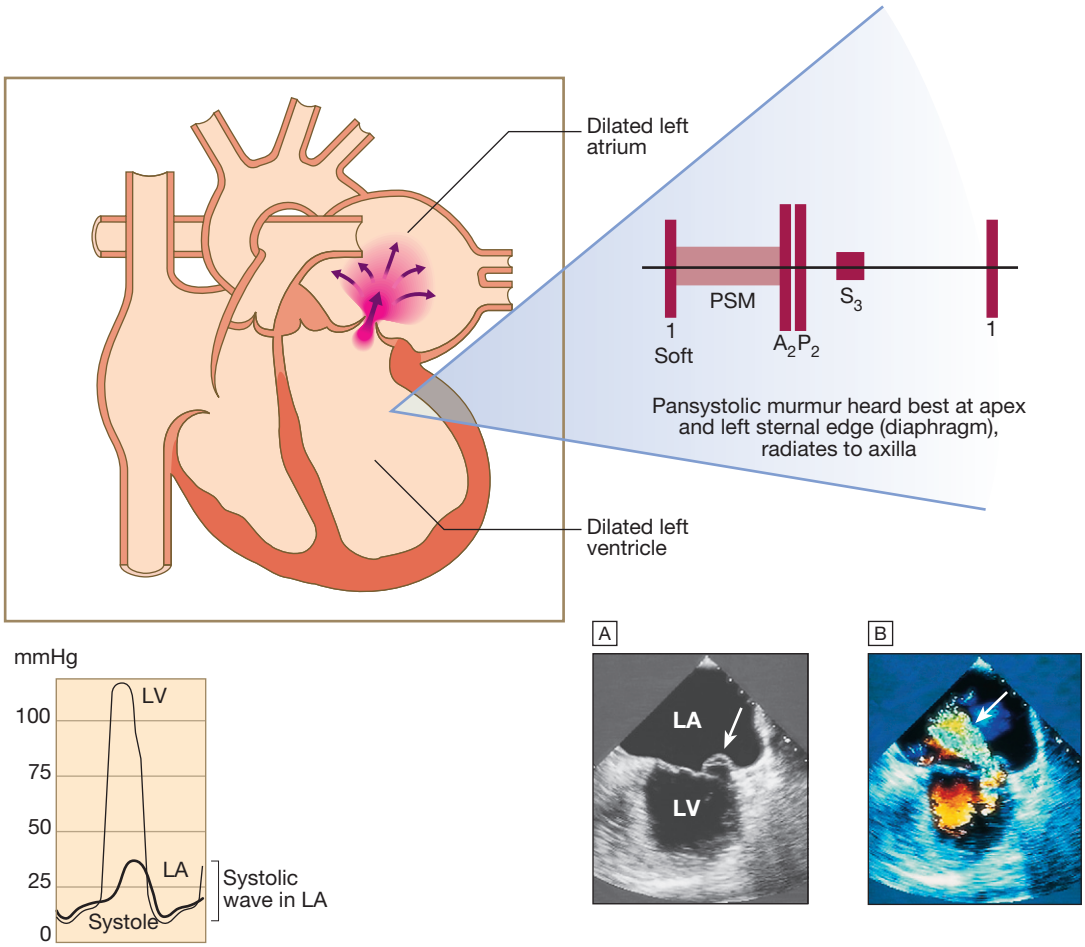

Fig. 18.88 Mitral regurgitation: murmur and systolic wave in left atrial pressure. The first sound is normal or soft and merges with a pansystolic murmur (PSM) extending to the second heart sound. A third heart sound occurs with severe regurgitation. A A transoesophageal echocardiogram shows mitral valve prolapse, with one leaflet bulging towards the LA (arrow). B This results in a jet of mitral regurgitation on colour Doppler (arrow).

and even a short mid-diastolic murmur. The apex beat feels active and rocking due to left ventricular volume overload and is usually displaced to the left as a result of left ventricular dilatation.

Investigations

Atrial fibrillation is common, as a consequence of atrial dilatation. At cardiac catheterisation (Box 18.103), the severity of mitral regurgitation can be assessed by left ventriculography and by the size of the *v* (systolic) waves in the left atrial or pulmonary artery wedge pressure trace.

Management

Mitral regurgitation of moderate severity can be treated medically (Box 18.104). In all patients with mitral regurgitation, high afterload may worsen the degree of regurgitation, and hypertension should be treated with vasodilators, such as ACE inhibitors. Patients should be reviewed at regular intervals because worsening symptoms, progressive cardiomegaly or echocardiographic evidence of deteriorating left ventricular function are indications for mitral valve replacement or repair. Mitral

18.103 Investigations in mitral regurgitation

ECG
• Left atrial hypertrophy (if not in atrial fibrillation) • Left ventricular hypertrophy
Chest X-ray
• Enlarged LA • Enlarged LV • Pulmonary venous congestion • Pulmonary oedema (if acute)
Echo
• Dilated LA, LV • Dynamic LV (unless myocardial dysfunction predominates) • Structural abnormalities of mitral valve (e.g. prolapse)
Doppler
• Detects and quantifies regurgitation
Cardiac catheterisation
• Dilated LA, dilated LV, mitral regurgitation • Pulmonary hypertension • Coexisting coronary artery disease

18.104 Medical management of mitral regurgitation

- Diuretics
- Vasodilators, e.g. ACE inhibitors
- Digoxin if atrial fibrillation is present
- Anticoagulants if atrial fibrillation is present

valve repair is used to treat mitral valve prolapse and offers many advantages when compared to mitral valve replacement, such that it is now advocated for severe regurgitation, even in asymptomatic patients, because results are excellent and early repair prevents irreversible left ventricular damage. Mitral regurgitation often accompanies the ventricular dilatation and dysfunction that are concomitants of coronary artery disease. If such patients are to undergo coronary bypass graft surgery, it is common practice to repair the valve and restore mitral valve function by inserting an annuloplasty ring to overcome annular dilatation and to bring the valve leaflets closer together. It can be difficult, however, to determine whether it is the ventricular dilatation or the mitral regurgitation that is the predominant problem. If ventricular dilatation is the underlying cause of mitral regurgitation, then mitral valve repair or replacement may actually worsen ventricular function, as the ventricle can no longer empty into the low-pressure LA.

Aortic valve disease

Aortic stenosis

Aetiology and pathophysiology

The likely aetiology depends on the age of the patient (Box 18.105). In congenital aortic stenosis, obstruction is present from birth or becomes apparent in infancy. With bicuspid aortic valves, obstruction may take years to develop as the valve becomes fibrotic and calcified. The aortic valve is the second most frequently affected by rheumatic fever and, commonly, both the aortic and mitral valves are involved. In older people, a structurally normal tricuspid aortic valve may be affected by fibrosis and calcification, in a process that is histologically similar to that of atherosclerosis affecting the arterial wall. Haemodynamically significant stenosis develops slowly, typically occurring at 30–60 years in those with rheumatic disease, 50–60 in those with bicuspid aortic valves and 70–90 in those with degenerative calcific disease.

Cardiac output is initially maintained at the cost of a steadily increasing pressure gradient across the aortic valve. The LV becomes increasingly hypertrophied and coronary blood flow may then be inadequate; patients may therefore develop angina, even in the absence of concomitant coronary disease. The fixed outflow obstruction limits the increase in cardiac output required on exercise. Eventually, the LV can no longer overcome the outflow tract obstruction and pulmonary oedema supervenes. In contrast to patients with mitral stenosis, which tends to progress very slowly, those with aortic stenosis typically remain asymptomatic for many years but deteriorate rapidly when symptoms develop, and death usually ensues within 3–5 years of these.

18.105 Causes of aortic stenosis

Infants, children, adolescents

- Congenital aortic stenosis
- Congenital subvalvular aortic stenosis
- Congenital supravalvular aortic stenosis

Young adults to middle-aged

- Calcification and fibrosis of congenitally bicuspid aortic valve
- Rheumatic aortic stenosis

Middle-aged to elderly

- Senile degenerative aortic stenosis
- Calcification of bicuspid valve
- Rheumatic aortic stenosis

18.106 Clinical features of aortic stenosis

Symptoms

- Mild or moderate stenosis: usually asymptomatic
- Exertional dyspnoea
- Angina
- Exertional syncope
- Sudden death
- Episodes of acute pulmonary oedema

Signs

- Ejection systolic murmur
- Slow-rising carotid pulse
- Thrusting apex beat (LV pressure overload)
- Narrow pulse pressure
- Signs of pulmonary venous congestion (e.g. crepitations)

Clinical features

Aortic stenosis is commonly picked up in asymptomatic patients at routine clinical examination but the three cardinal symptoms are angina, breathlessness and syncope (Box 18.106). Angina arises because of the increased demands of the hypertrophied LV working against the high-pressure outflow tract obstruction, leading to a mismatch between oxygen demand and supply, but may also be due to coexisting coronary artery disease, especially in old age, when it affects over 50% of patients. Exertional breathlessness suggests cardiac decompensation as a consequence of the excessive pressure overload placed on the LV. Syncope usually occurs on exertion when cardiac output fails to rise to meet demand, leading to a fall in BP.

The characteristic clinical signs of severe aortic stenosis are shown in Box 18.106. A harsh ejection systolic murmur radiates to the neck, with a soft second heart sound, particularly in those with calcific valves. The murmur is often likened to a saw cutting wood and may (especially in older patients) have a musical quality like the 'mew' of a seagull (Fig. 18.89). The severity of aortic stenosis may be difficult to gauge clinically, as older patients with a non-compliant 'stiff' arterial system may have an apparently normal carotid upstroke in the presence of severe aortic stenosis. Milder degrees of stenosis may be difficult to distinguish from aortic sclerosis, in which the valve is thickened or calcified but not obstructed. A careful examination should be made for other valve lesions, particularly in rheumatic heart disease, when there is frequently concomitant mitral valve disease.

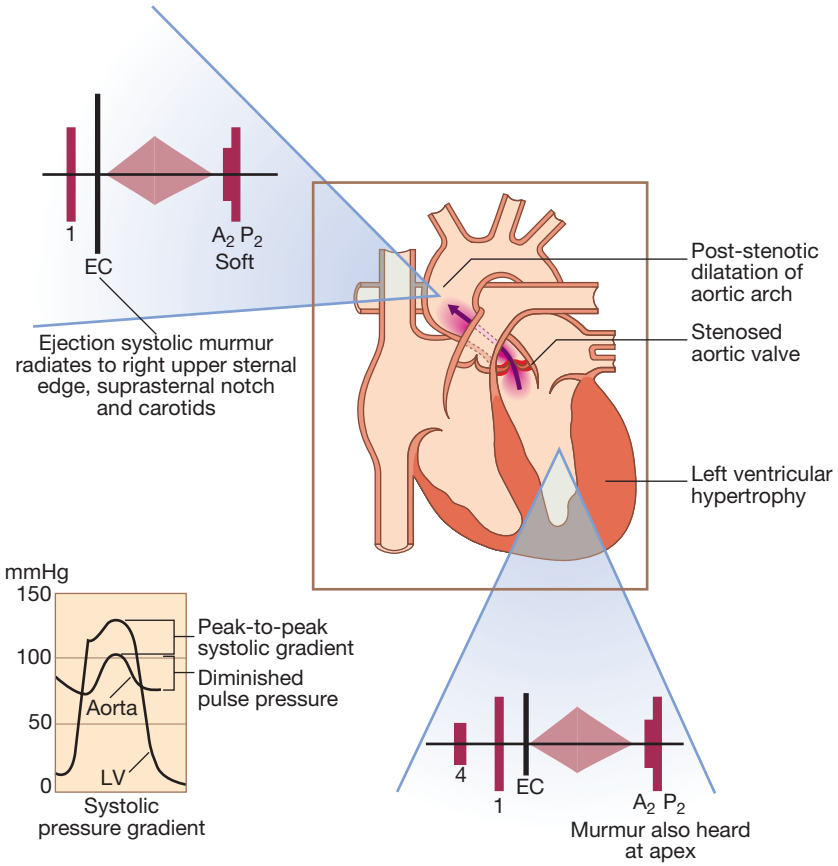

Fig. 18.89 Aortic stenosis. Pressure traces show the systolic gradient between LV and aorta. The 'diamond-shaped' murmur is heard best with the diaphragm in the aortic outflow and also at the apex. An ejection click (EC) may be present in young patients with a bicuspid aortic valve but not in older patients with calcified valves. Aortic stenosis may lead to left ventricular hypertrophy with a fourth sound at the apex and post-stenotic dilatation of the aortic arch. Figure 18.11 (p. 536) shows the typical Doppler signal with aortic stenosis.

18.107 Investigations in aortic stenosis

ECG

- Left ventricular hypertrophy (usually)
- Left bundle branch block

Chest X-ray

- May be normal; sometimes enlarged LV and dilated ascending aorta on PA view, calcified valve on lateral view

Echo

- Calcified valve with restricted opening, hypertrophied LV (see Fig. 18.91)

Doppler

- Measurement of severity of stenosis
- Detection of associated aortic regurgitation

Cardiac catheterisation

- Mainly to identify associated coronary artery disease
- May be used to measure gradient between LV and aorta

Investigations

In advanced cases, ECG features of hypertrophy (Box 18.107) are often gross (Fig. 18.90), and down-sloping ST segments and T inversion ('strain pattern') are seen in leads reflecting the LV. Nevertheless, especially in old age, the ECG can be normal, despite severe stenosis. Echocardiography demonstrates restricted valve opening (Fig. 18.91) and Doppler assessment permits calculation of the systolic gradient across the aortic valve, from which the severity of stenosis can be assessed (see Fig. 18.11, p. 536). In patients with an impaired LV, velocities across the aortic valve may be diminished because of a reduced stroke volume, while when aortic regurgitation is present, velocities are increased because of an increased stroke volume. In these circumstances, aortic valve area calculated from Doppler measurements is a more accurate assessment of severity. CT and MRI are useful in assessing the degree of valve calcification and stenosis, respectively, but are rarely necessary.

Management

Irrespective of the severity of valve stenosis, patients with asymptomatic aortic stenosis have a good immediate prognosis and conservative management is appropriate. Such patients should be kept under review, as the development of angina, syncope, symptoms of low cardiac output or heart failure has a poor prognosis and is an indication for prompt surgery. In practice, patients with moderate or severe stenosis are evaluated every 1–2 years with Doppler echocardiography to detect progression in severity; this is more rapid in older patients with heavily calcified valves.

Patients with symptomatic severe aortic stenosis should have prompt aortic valve replacement. Old age

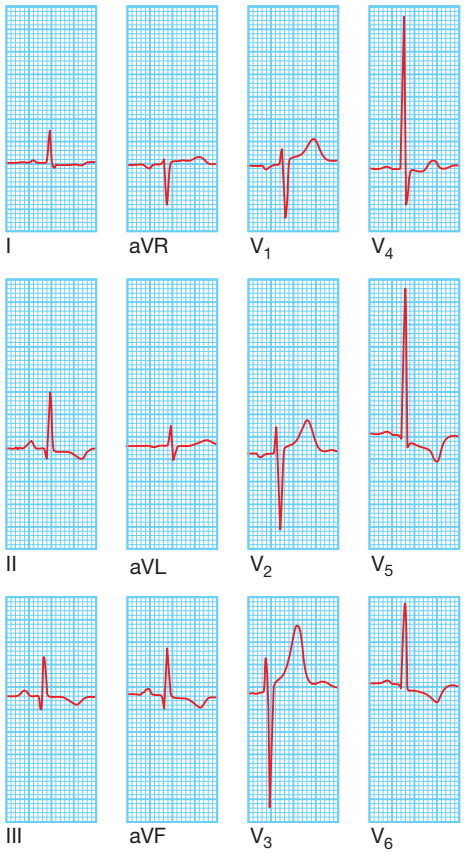

Fig. 18.90 Left ventricular hypertrophy. QRS complexes in limb leads have increased amplitude with a very large R wave in V_6 and S wave in V_2. There is ST depression and T-wave inversion in leads II, III, aVF, V_5 and V_6: a 'left ventricular strain' pattern.

18.108 Aortic stenosis in old age

- **Incidence**: the most common form of valve disease affecting the very old.
- **Symptoms**: a common cause of syncope, angina and heart failure in the very old.
- **Signs**: because of increasing stiffening in the central arteries, low pulse pressure and a slow rising pulse may not be present.
- **Surgery**: can be successful in those aged 80 yrs or more in the absence of comorbidity, but with a higher operative mortality. The prognosis without surgery is poor once symptoms have developed.
- **Valve replacement type**: a biological valve is often preferable to a mechanical one because this obviates the need for anticoagulation, and the durability of biological valves usually exceeds the patient's anticipated life expectancy.

is not a contraindication to valve replacement and results are very good in experienced centres, even for those in their eighties (Box 18.108). Delay exposes the patient to the risk of sudden death or irreversible deterioration in ventricular function. Some patients with severe aortic stenosis deny symptoms, and if this could be due to a sedentary lifestyle, a careful exercise test may reveal symptoms on modest exertion. Aortic balloon

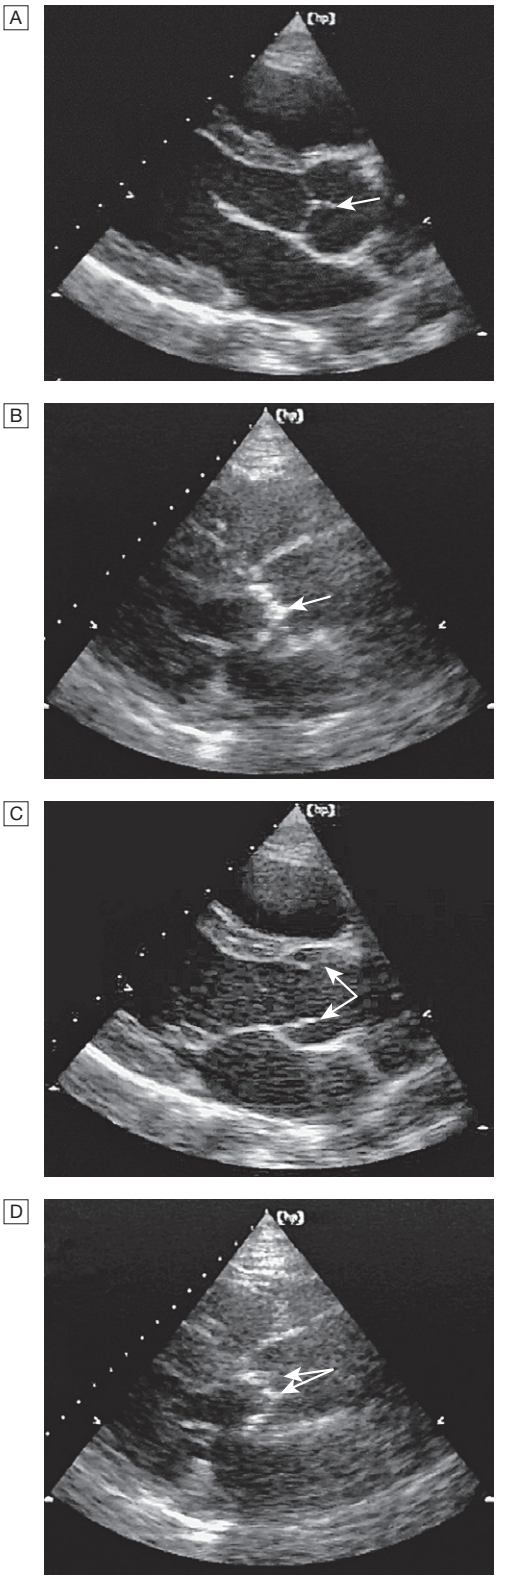

Fig. 18.91 Two-dimensional echocardiogram comparing a normal subject with a patient with calcific aortic stenosis. A Normal subject in diastole; the aortic leaflets are closed and thin, and a point of coaptation is seen (arrow). B Calcific aortic stenosis in diastole; the aortic leaflets are thick and calcified (arrow). C Normal in systole; the aortic leaflets are open (arrows). D Calcific aortic stenosis in systole; the thickened leaflets have barely moved (arrows). From Newby and Grubb 2005 – see p. 641.

valvuloplasty is useful in congenital aortic stenosis but is of no value in older patients with calcific aortic stenosis.

Anticoagulants are only required in patients who have atrial fibrillation or those who have had a valve replacement with a mechanical prosthesis.

Aortic regurgitation

Aetiology and pathophysiology

This condition is due to disease of the aortic valve cusps or dilatation of the aortic root (Box 18.109). The LV dilates and hypertrophies to compensate for the regurgitation. The stroke volume of the LV may eventually be doubled or trebled, and the major arteries are then conspicuously pulsatile. As the disease progresses, left ventricular diastolic pressure rises and breathlessness develops.

Clinical features

Until the onset of breathlessness, the only symptom may be an awareness of the heart beat (Box 18.110), particularly when lying on the left side, which results from the increased stroke volume. Paroxysmal nocturnal dyspnoea is sometimes the first symptom, and peripheral oedema or angina may occur. The characteristic murmur is best heard to the left of the sternum during held expiration (Fig. 18.92); a thrill is rare. A systolic murmur due to the increased stroke volume is common and does not

18.109 Causes of aortic regurgitation

Congenital

- Bicuspid valve or disproportionate cusps

Acquired

- Rheumatic disease
- Infective endocarditis
- Trauma
- Aortic dilatation (Marfan's syndrome, aneurysm, dissection, syphilis, ankylosing spondylitis)

18.110 Clinical features of aortic regurgitation

Symptoms

Mild to moderate aortic regurgitation

- Often asymptomatic
- Awareness of heart beat, 'palpitations'

Severe aortic regurgitation

- Breathlessness
- Angina

Signs

Pulses

- Large-volume or 'collapsing' pulse
- Low diastolic and increased pulse pressure
- Bounding peripheral pulses
- Capillary pulsation in nail beds: Quincke's sign
- Femoral bruit ('pistol shot'): Duroziez's sign
- Head nodding with pulse: de Musset's sign

Murmurs

- Early diastolic murmur
- Systolic murmur (increased stroke volume)
- Austin Flint murmur (soft mid-diastolic)

Other signs

- Displaced, heaving apex beat (volume overload)
- Pre-systolic impulse
- Fourth heart sound
- Crepitations (pulmonary venous congestion)

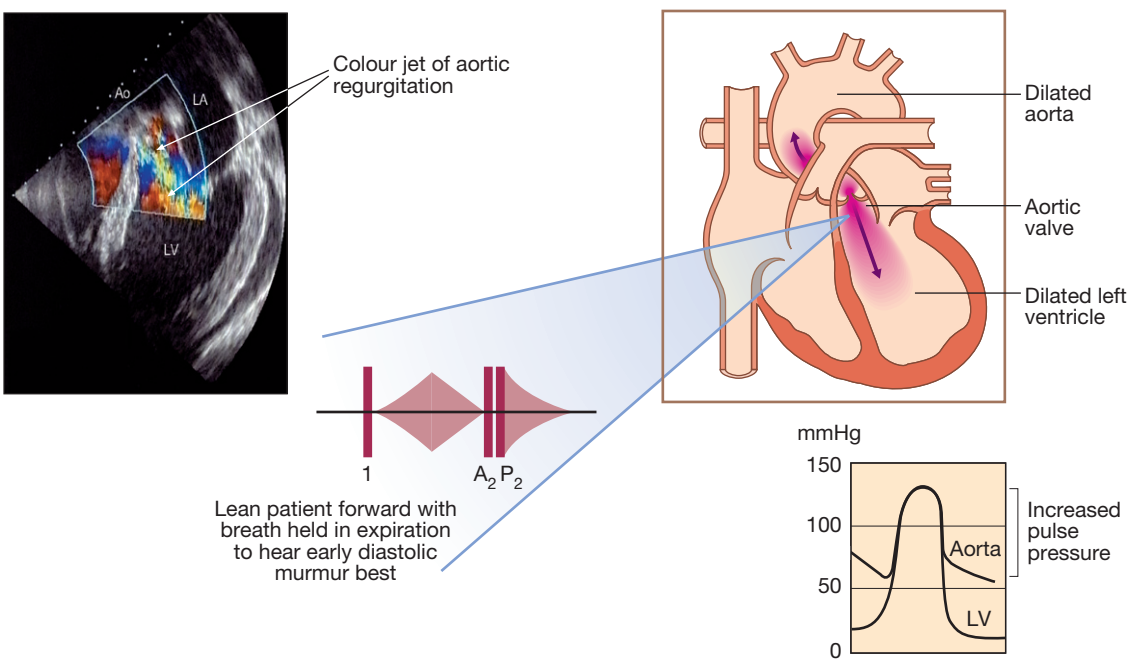

Fig. 18.92 Aortic regurgitation. The early diastolic murmur is best heard at the left sternal edge and may be accompanied by an ejection systolic ('to and fro') murmur. The aortic arch and LV may become dilated. A Doppler echocardiogram with the regurgitant jet (arrows). *Inset (Colour Doppler echo)* From Newby and Grubb 2005 – see p. 641.

necessarily indicate stenosis. The regurgitant jet causes fluttering of the mitral valve and, if severe, causes partial closure of the anterior mitral leaflet, leading to functional mitral stenosis and a soft mid-diastolic (Austin Flint) murmur.

In acute severe regurgitation (e.g. perforation of aortic cusp in endocarditis), there may be no time for compensatory left ventricular hypertrophy and dilatation to develop and the features of heart failure may predominate. In this situation, the classical signs of aortic regurgitation may be masked by tachycardia and an abrupt rise in left ventricular end-diastolic pressure; thus, the pulse pressure may be near normal and the diastolic murmur may be short or even absent.

Investigations

Regurgitation is detected by Doppler echocardiography (Box 18.111). In severe acute aortic regurgitation, the rapid rise in left ventricular diastolic pressure may cause premature mitral valve closure. Cardiac catheterisation and aortography can help in assessing the severity of regurgitation, and dilatation of the aorta and the presence of coexisting coronary artery disease. MRI is useful in assessing the degree and extent of aortic dilatation.

18.111 Investigations in aortic regurgitation

ECG

- Initially normal, later left ventricular hypertrophy and T-wave inversion

Chest X-ray

- Cardiac dilatation, maybe aortic dilatation
- Features of left heart failure

Echo

- Dilated LV
- Hyperdynamic LV
- Doppler detects reflux
- Fluttering anterior mitral leaflet

Cardiac catheterisation (may not be required)

- Dilated LV
- Aortic regurgitation
- Dilated aortic root

Management

Treatment may be required for underlying conditions, such as endocarditis or syphilis. Aortic valve replacement is indicated if aortic regurgitation causes symptoms, and this may need to be combined with aortic root replacement and coronary bypass surgery. Those with chronic aortic regurgitation can remain asymptomatic for many years because compensatory ventricular dilatation and hypertrophy occur, but should be advised to report the development of any symptoms of breathlessness or angina. Asymptomatic patients should also be followed up annually with echocardiography for evidence of increasing ventricular size. If this occurs or if the end-systolic dimension increases to 55 mm or more, then aortic valve replacement should be undertaken. Systolic BP should be controlled with vasodilating drugs, such as nifedipine or ACE inhibitors. There is conflicting evidence regarding the need for aortic valve replacement in asymptomatic patients with severe aortic regurgitation. When aortic root dilatation is the cause of aortic regurgitation (e.g. Marfan's syndrome), aortic root replacement is usually necessary.

Tricuspid valve disease

Tricuspid stenosis

Aetiology

Tricuspid stenosis is usually rheumatic in origin and is rare in developed countries. Tricuspid disease occurs in fewer than 5% of patients with rheumatic heart disease and then nearly always in association with mitral and aortic valve disease. Tricuspid stenosis and regurgitation are features of the carcinoid syndrome (p. 784).

Clinical features and investigations

Although the symptoms of mitral and aortic valve disease predominate, tricuspid stenosis may cause symptoms of right heart failure, including hepatic discomfort and peripheral oedema.

The main clinical feature is a raised JVP with a prominent *a* wave, and a slow *y* descent due to the loss of normal rapid right ventricular filling (p. 527). There is also a mid-diastolic murmur, best heard at the lower left or right sternal edge. This is generally higher-pitched than the murmur of mitral stenosis and is increased by inspiration. Right heart failure causes hepatomegaly with pre-systolic pulsation (large *a* wave), ascites and peripheral oedema. On Doppler echocardiography, the valve has similar appearances to those of rheumatic mitral stenosis.

Management

In patients who require surgery to other valves, either the tricuspid valve is replaced or valvotomy is performed at surgery. Balloon valvuloplasty can be used to treat rare cases of isolated tricuspid stenosis.

Tricuspid regurgitation

Aetiology, clinical features and investigations

Tricuspid regurgitation is common, and is most frequently 'functional' as a result of right ventricular dilatation (Box 18.112).

Symptoms are usually non-specific, with tiredness related to reduced forward flow, and oedema and hepatic enlargement due to venous congestion. The most prominent sign is a 'giant' *v* wave in the jugular venous pulse (a *cv* wave replaces the normal *x* descent). Other features include a pansystolic murmur at the left

18.112 Causes of tricuspid regurgitation

Primary

- Rheumatic heart disease
- Endocarditis, particularly in injection drug-users
- Ebstein's congenital anomaly (see Box 18.123, p. 635)

Secondary

- Right ventricular dilatation due to chronic left heart failure ('functional tricuspid regurgitation')
- Right ventricular infarction
- Pulmonary hypertension (e.g. cor pulmonale)

sternal edge and a pulsatile liver. Echocardiography may reveal dilatation of the RV. If the valve has been affected by rheumatic disease, the leaflets will appear thickened and, in endocarditis, vegetations may be seen. Ebstein's anomaly (see Box 18.123, p. 635) is a congenital abnormality in which the tricuspid valve is displaced towards the right ventricular apex, with consequent enlargement of the RA. It is commonly associated with tricuspid regurgitation.

Management

Tricuspid regurgitation due to right ventricular dilatation often improves when the cause of right ventricular overload is corrected, with diuretic and vasodilator treatment of congestive cardiac failure. Patients with a normal pulmonary artery pressure tolerate isolated tricuspid reflux well, and valves damaged by endocarditis do not usually need to be replaced. Patients undergoing mitral valve replacement, who have tricuspid regurgitation due to marked dilatation of the tricuspid annulus, benefit from valve repair with an annuloplasty ring to bring the leaflets closer together. Those with rheumatic damage may require tricuspid valve replacement.

Pulmonary valve disease

Pulmonary stenosis

This can occur in the carcinoid syndrome but is usually congenital, in which case it may be isolated or associated with other abnormalities, such as Fallot's tetralogy (p. 634).

The principal finding on examination is an ejection systolic murmur, loudest at the left upper sternum and radiating towards the left shoulder. There may be a thrill, best felt when the patient leans forward and breathes out. The murmur is often preceded by an ejection sound (click). Delay in right ventricular ejection may cause wide splitting of the second heart sound. Severe pulmonary stenosis is characterised by a loud harsh murmur, an inaudible pulmonary closure sound (P_2), an increased right ventricular heave, prominent *a* waves in the jugular pulse, ECG evidence of right ventricular hypertrophy, and post-stenotic dilatation in the pulmonary artery on the chest X-ray. Doppler echocardiography is the definitive investigation.

Mild to moderate isolated pulmonary stenosis is relatively common and does not usually progress or require treatment. Severe pulmonary stenosis (resting gradient > 50 mmHg with a normal cardiac output) is treated by percutaneous pulmonary balloon valvuloplasty or, if this is not available, by surgical valvotomy. Long-term results are very good. Post-operative pulmonary regurgitation is common but benign.

Pulmonary regurgitation

This is rare in isolation and is usually associated with pulmonary artery dilatation due to pulmonary hypertension. It may complicate mitral stenosis, producing an early diastolic decrescendo murmur at the left sternal edge that is difficult to distinguish from aortic regurgitation (Graham Steell murmur). The pulmonary hypertension may be secondary to other disease of the left side of the heart, primary pulmonary vascular disease or Eisenmenger's syndrome (p. 631). Trivial pulmonary regurgitation is a frequent finding in normal individuals and has no clinical significance.

Infective endocarditis

This is caused by microbial infection of a heart valve (native or prosthetic), the lining of a cardiac chamber or blood vessel, or a congenital anomaly (e.g. septal defect). The causative organism is usually a bacterium, but may be a rickettsia, chlamydia or fungus.

Pathophysiology

Infective endocarditis typically occurs at sites of pre-existing endocardial damage, but infection with particularly virulent or aggressive organisms (e.g. *Staphylococcus aureus*) can cause endocarditis in a previously normal heart; staphylococcal endocarditis of the tricuspid valve is a common complication of intravenous drug misuse. Many acquired and congenital cardiac lesions are vulnerable to endocarditis, particularly areas of endocardial damage caused by a high-pressure jet of blood, such as ventricular septal defect, mitral regurgitation and aortic regurgitation, many of which are haemodynamically insignificant. In contrast, the risk of endocarditis at the site of haemodynamically important low-pressure lesions, such as a large atrial septal defect, is minimal.

Infection tends to occur at sites of endothelial damage because they attract deposits of platelets and fibrin that are vulnerable to colonisation by blood-borne organisms. The avascular valve tissue and presence of fibrin and platelet aggregates help to protect proliferating organisms from host defence mechanisms. When the infection is established, vegetations composed of organisms, fibrin and platelets grow and may become large enough to cause obstruction or embolism. Adjacent tissues are destroyed and abscesses may form. Valve regurgitation may develop or increase if the affected valve is damaged by tissue distortion, cusp perforation or disruption of chordae. Extracardiac manifestations, such as vasculitis and skin lesions, are due to emboli or immune complex deposition. Mycotic aneurysms may develop in arteries at the site of infected emboli. At autopsy, infarction of the spleen and kidneys and, sometimes, an immune glomerulonephritis are found.

Microbiology

Over three-quarters of cases are caused by streptococci or staphylococci. The *viridans* group of streptococci (*Streptococcus mitis, Strep. sanguis*) are commensals in the upper respiratory tract that may enter the blood stream on chewing or teeth-brushing, or at the time of dental treatment, and are common causes of subacute endocarditis (Box 18.113). Other organisms, including *Enterococcus faecalis*, *E. faecium* and *Strep. bovis*, may enter the blood from the bowel or urinary tract. *Strep. milleri* and *Strep. bovis* endocarditis is associated with large-bowel neoplasms.

Staph. aureus has now overtaken streptococci as the most common cause of acute endocarditis. It originates from skin infections, abscesses or vascular access sites (e.g. intravenous and central lines), or from intravenous drug use. It is highly virulent and invasive, usually producing florid vegetations, rapid valve destruction and abscess formation. Other causes of acute endocarditis include *Strep. pneumoniae* and *Strep. pyogenes*.

18.113 Microbiology of infective endocarditis

Pathogen	Of native valve (n = 280)	In IV drug users (n = 87)	Of prosthetic valve	
			Early (n = 15)	Late (n = 72)
Staphylococci	124 (44%)	60 (69%)	10 (67%)	33 (46%)
Staph. aureus	106 (38%)	60 (69%)	3 (20%)	15 (21%)
Coagulase-negative	18 (6%)	0	7 (47%)	18 (25%)
Streptococci	86 (31%)	7 (8%)	0	25 (35%)
Oral	59 (21%)	3 (3%)	0	19 (26%)
Others (non-enterococcal)	27 (10%)	4 (5%)	0	6 (8%)

Adapted from Moreillon P, Que YA. Lancet 2004; 363:139–149.

Post-operative endocarditis after cardiac surgery may affect native or prosthetic heart valves or other prosthetic materials. The most common organism is a coagulase-negative staphylococcus (*Staph. epidermidis*), a normal skin commensal. There is frequently a history of wound infection with the same organism. *Staph. epidermidis* occasionally causes endocarditis in patients who have not had cardiac surgery, and its presence in blood cultures may be erroneously dismissed as contamination. Another coagulase-negative staphylococcus, *Staph. lugdenensis,* causes a rapidly destructive acute endocarditis that is associated with previously normal valves and multiple emboli. Unless accurately identified, it may also be overlooked as a contaminant.

In Q fever endocarditis due to *Coxiella burnetii*, the patient often has a history of contact with farm animals. The aortic valve is usually affected and there may also be hepatitis, pneumonia and purpura. Life-long antibiotic therapy may be required.

Gram-negative bacteria of the so-called HACEK group (*Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* spp. and *Kingella kingae*) are slow-growing, fastidious organisms that are only revealed after prolonged culture and may be resistant to penicillin.

Brucella is associated with a history of contact with goats or cattle and often affects the aortic valve.

Yeasts and fungi (*Candida, Aspergillus*) may attack previously normal or prosthetic valves, particularly in immunocompromised patients or those with indwelling intravenous lines. Abscesses and emboli are common, therapy is difficult (surgery is often required) and mortality is high. Concomitant bacterial infection may be present.

18.114 Endocarditis in old age

- **Symptoms and signs**: may be non-specific, e.g. confusion, weight loss, malaise and weakness, and the diagnosis may not be suspected.
- **Common causative organisms**: often enterococci (from the urinary tract) and *Strep. bovis* (from a colonic source).
- **Morbidity and mortality**: much higher.

Incidence

The incidence of infective endocarditis in community-based studies ranges from 5 to 15 cases per 100 000 per annum. More than 50% of patients are over 60 years of age (Box 18.114). In a large British study, the underlying condition was rheumatic heart disease in 24% of patients, congenital heart disease in 19%, and other cardiac abnormalities (e.g. calcified aortic valve, floppy mitral valve) in 25%. The remaining 32% were not thought to have a pre-existing cardiac abnormality.

Clinical features

Endocarditis can take either an acute or a more insidious 'subacute' form. However, there is considerable overlap because the clinical pattern is influenced not only by the organism, but also by the site of infection, prior antibiotic therapy and the presence of a valve or shunt prosthesis. The subacute form may abruptly develop acute life-threatening complications, such as valve disruption or emboli.

Subacute endocarditis

This should be suspected when a patient with congenital or valvular heart disease develops a persistent fever, complains of unusual tiredness, night sweats or weight loss, or develops new signs of valve dysfunction or heart failure. Less often, it presents as an embolic stroke or peripheral arterial embolism. Other features (Fig. 18.93) include purpura and petechial haemorrhages in the skin and mucous membranes, and splinter haemorrhages under the fingernails or toe nails. Osler's nodes are painful tender swellings at the fingertips that are probably the product of vasculitis; they are rare. Digital clubbing is a late sign. The spleen is frequently palpable; in *Coxiella* infections, the spleen and the liver may be considerably enlarged. Microscopic haematuria is common. The finding of any of these features in a patient with persistent fever or malaise is an indication for re-examination to detect hitherto unrecognised heart disease.

Acute endocarditis

This presents as a severe febrile illness with prominent and changing heart murmurs and petechiae. Clinical stigmata of chronic endocarditis are usually absent. Embolic events are common, and cardiac or renal failure may develop rapidly. Abscesses may be detected on echocardiography. Partially treated acute endocarditis behaves like subacute endocarditis.

Post-operative endocarditis

This may present as an unexplained fever in a patient who has had heart valve surgery. The infection usually involves the valve ring and may resemble subacute or

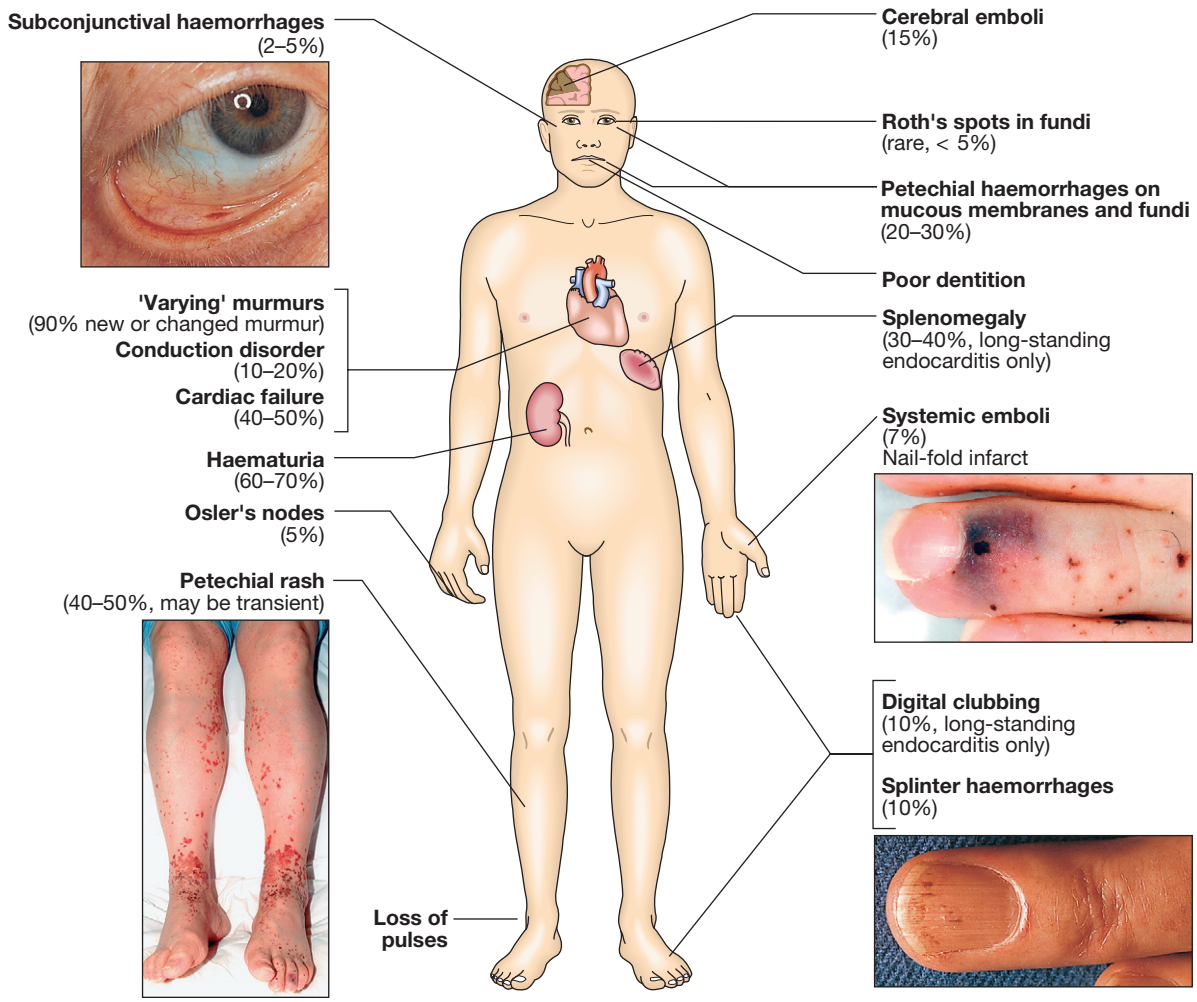

Fig. 18.93 **Clinical features which may be present in endocarditis.** *Insets (Petechial rash, nail-fold infarct)* From Newby and Grubb 2005 – see p. 641.

acute endocarditis, depending on the virulence of the organism. Morbidity and mortality are high and redo surgery is often required. The range of organisms is similar to that seen in native valve disease, but when endocarditis occurs during the first few weeks after surgery, it is usually due to infection with a coagulase-negative staphylococcus that was introduced during the peri-operative period. A clinical diagnosis of endocarditis can be made on the presence of two major, one major and three minor, or five minor criteria (Box 18.115).

Investigations

Blood culture is the crucial investigation because it may identify the infection and guide antibiotic therapy. Three to six sets of blood cultures should be taken prior to commencing therapy and should not wait for episodes of pyrexia. The first two specimens will detect bacteraemia in 90% of culture-positive cases. Aseptic technique is essential and the risk of contaminants should be minimised by sampling from different venepuncture sites. An in-dwelling line should not be used to take cultures. Aerobic and anaerobic cultures are required.

Echocardiography is key for detecting and following the progress of vegetations, for assessing valve damage

18.115 Diagnosis of infective endocarditis (modified Duke criteria)

Major criteria

Positive blood culture
- Typical organism from two cultures
- Persistent positive blood cultures taken > 12 hrs apart
- Three or more positive cultures taken over > 1 hr

Endocardial involvement
- Positive echocardiographic findings of vegetations
- New valvular regurgitation

Minor criteria
- Predisposing valvular or cardiac abnormality
- Intravenous drug misuse
- Pyrexia ≥ 38°C
- Embolic phenomenon
- Vasculitic phenomenon
- Blood cultures suggestive: organism grown but not achieving major criteria
- Suggestive echocardiographic findings

Definite endocarditis = two major, or one major and three minor, or five minor
Possible endocarditis = one major and one minor, or three minor

and for detecting abscess formation. Vegetations as small as 2–4 mm can be detected by transthoracic echocardiography, and even smaller ones (1–1.5 mm) can be visualised by transoesophageal echocardiography (TOE), which is particularly valuable for identifying abscess formation and investigating patients with prosthetic heart valves. Vegetations may be difficult to distinguish in the presence of an abnormal valve; the sensitivity of transthoracic echo is approximately 65% but that of TOE is more than 90%. Failure to detect vegetations does not exclude the diagnosis.

Elevation of the ESR, a normocytic normochromic anaemia, and leucocytosis are common but not invariable. Measurement of serum CRP is more reliable than the ESR in monitoring progress. Proteinuria may occur and microscopic haematuria is usually present.

The ECG may show the development of AV block (due to aortic root abscess formation) and occasionally infarction due to emboli. The chest X-ray may show evidence of cardiac failure and cardiomegaly.

Management

The case fatality of bacterial endocarditis is approximately 20% and even higher in those with prosthetic valve endocarditis and those infected with antibiotic-resistant organisms. A multidisciplinary approach, with cooperation between the physician, surgeon and microbiologist, increases the chance of a successful outcome. Any source of infection should be removed as soon as possible; for example, a tooth with an apical abscess should be extracted.

Empirical treatment depends on the mode of presentation, the suspected organism, and whether the patient has a prosthetic valve or penicillin allergy (Box 18.116). If the presentation is acute, flucloxacillin and gentamicin are recommended, while for a subacute or indolent presentation, benzyl penicillin and gentamicin are preferred. In those with penicillin allergy, a prosthetic valve or suspected meticillin-resistant *Staph. aureus* (MRSA) infection, triple therapy with vancomycin, gentamicin and oral rifampicin should be considered. Following identification of the causal organism, determination of the minimum inhibitory concentration (MIC) for the organism is essential to guide antibiotic therapy.

A 2-week treatment regimen may be sufficient for fully sensitive strains of *Strep. viridans* and *Strep. bovis*, provided specific conditions are met (Box 18.117). For the empirical treatment of bacterial endocarditis, penicillin plus gentamicin is the regimen of choice for most patients; when staphylococcal infection is suspected, however, vancomycin plus gentamicin is recommended.

Cardiac surgery (débridement of infected material and valve replacement) is advisable in a substantial proportion of patients, particularly those with *Staph. aureus* and fungal infections (Box 18.118). Antimicrobial therapy must be started before surgery.

Prevention

Until recently, antibiotic prophylaxis was routinely given to people at risk of infective endocarditis undergoing interventional procedures. However, as this has not been proven to be effective and the link between

18.117 Conditions for the short-course treatment of *Strep. viridans/bovis* endocarditis

- Native valve infection
- MIC ≤ 0.1 mg/L
- No adverse prognostic factors (e.g. heart failure, aortic regurgitation, conduction defect)
- No evidence of thromboembolic disease
- No vegetations > 5 mm diameter
- Clinical response within 7 days

18.116 Antimicrobial treatment of common causative organisms in infective endocarditis

Organism	Antimicrobial	Dose	Duration: Native valve	Duration: Prosthetic valve
Viridans* streptococci and *Strep. bovis				
MIC ≤ 0.1 mg/L	Benzyl penicillin IV	1.2 g 6 times daily	4 wks[1]	6 wks
	and gentamicin IV	1 mg/kg 2–3 times daily	2 wks	2 wks
MIC > 0.1 to < 0.5 mg/L	Benzyl penicillin IV	1.2 g 6 times daily	4 wks	6 wks
	and gentamicin IV	1 mg/kg 2–3 times daily	2 wks	4–6 wks
MIC ≥ 0.5 mg/L	Benzyl penicillin IV	1.2 g 6 times daily	4 wks	6 wks
	and gentamicin IV	1 mg/kg 2–3 times daily	4 wks	4–6 wks
Enterococci				
Ampicillin-sensitive	Ampicillin IV	2 g 6 times daily	4 wks	6 wks
	and gentamicin IV[2]	1 mg/kg 2–3 times daily	4 wks	6 wks
Ampicillin-resistant	Vancomycin IV	1 g twice daily	4 wk	6 wks
	and gentamicin IV[2]	1 mg/kg 2–3 times daily	4 wks	6 wks
Staphylococci				
Penicillin-sensitive	Benzyl penicillin IV	1.2 g 6 times daily	4 wks	6 wks
Penicillin-resistant Meticillin-sensitive	Flucloxacillin IV	2 g 6 times daily (< 85 kg 6-hourly)	4 wks	6 wks[3]
Penicillin-resistant Meticillin-resistant	Vancomycin IV and gentamicin IV	1 g twice daily 1 mg/kg 3 times daily	4 wks 4 wks	6 wks[3] 6 wks[3]

[1]When conditions in Box 18.117 are met, 2 wks of benzyl penicillin. [2]In high-level gentamicin resistance, consider streptomycin. [3]Consider additional rifampicin 300–600 mg twice daily orally for 2 wks. (MIC = minimum inhibitory concentration)

18.118 Indications for cardiac surgery in infective endocarditis

- Heart failure due to valve damage
- Failure of antibiotic therapy (persistent/uncontrolled infection)
- Large vegetations on left-sided heart valves with evidence or 'high risk' of systemic emboli
- Abscess formation

N.B. Patients with prosthetic valve endocarditis or fungal endocarditis often require cardiac surgery.

episodes of infective endocarditis and interventional procedures has not been demonstrated, antibiotic prophylaxis is no longer offered routinely for defined interventional procedures.

Valve replacement surgery

Diseased heart valves can be replaced with mechanical or biological prostheses. The three most commonly used types of mechanical prosthesis are the ball and cage, tilting single disc and tilting bi-leaflet valves. All generate prosthetic sounds or clicks on auscultation. Pig or allograft valves mounted on a supporting stent are the most commonly used biological valves. They generate normal heart sounds. All prosthetic valves used in the aortic position produce a systolic flow murmur.

All mechanical valves require long-term anticoagulation because they can cause systemic thromboembolism or may develop valve thrombosis or obstruction (Box 18.119); the prosthetic clicks may become inaudible if the valve malfunctions. Biological valves have the advantage of not requiring anticoagulants to maintain proper function; however, many patients undergoing valve replacement surgery, especially mitral valve replacement, will have atrial fibrillation that requires anticoagulation anyway. Biological valves are less durable than mechanical valves and may degenerate 7 or more years after implantation, particularly when used in the mitral position. They are more durable in the aortic position and in older patients, so are particularly appropriate for patients over 65 undergoing aortic valve replacement.

Symptoms or signs of unexplained heart failure in a patient with a prosthetic heart valve may be due to valve dysfunction, and urgent assessment is required. Biological valve dysfunction is usually associated with the development of a regurgitant murmur.

18.119 Prosthetic heart valves: optimal anticoagulant control

Mechanical valves	Target INR
Ball and cage (e.g. Starr–Edwards) Tilting disc (e.g. Bjork–Shiley)	3.5
Bi-leaflet (e.g. St Jude)	3.0
Biological valves with atrial fibrillation	2.5

CONGENITAL HEART DISEASE

Congenital heart disease usually manifests in childhood but may pass unrecognised and not present until adult life. Defects that are well tolerated, such as atrial septal defect, may cause no symptoms until adult life or may be detected incidentally on routine examination or chest X-ray. Congenital defects that were previously fatal in childhood can now be corrected, or at least partially, so that survival to adult life is the norm. Such patients remain well for many years but subsequently re-present in later life with related problems such as arrhythmia or ventricular dysfunction (Box 18.120).

18.120 Presentation of congenital heart disease throughout life

Birth and neonatal period	
• Cyanosis	• Heart failure
Infancy and childhood	
• Cyanosis • Heart failure • Arrhythmia	• Murmur • Failure to thrive
Adolescence and adulthood	
• Heart failure • Murmur • Arrhythmia • Cyanosis due to shunt reversal (Eisenmenger's syndrome)	• Hypertension (coarctation) • Late consequences of previous cardiac surgery, e.g. arrhythmia, heart failure

The fetal circulation

Understanding the fetal circulation helps clarify how some forms of congenital heart disease occur. The fetus has only a small flow of blood through the lungs, as it does not breathe in utero. The fetal circulation allows oxygenated blood from the placenta to pass directly to the left side of the heart through the foramen ovale without having to flow through the lungs, and also from the pulmonary artery into the aorta via the ductus arteriosus (Fig. 18.94).

Congenital defects may arise if the changes from fetal circulation to the extrauterine circulation are incomplete. Atrial septal defects occur at the site of the foramen ovale. A patent ductus arteriosus may remain if it fails to close after birth. Failure of the aorta to develop at the point of the aortic isthmus and where the ductus arteriosus attaches can lead to coarctation of the aorta.

In fetal development, the heart develops as a single tube which folds back on itself and then divides into two separate circulations. Failure of septation can lead to some forms of atrial and ventricular septal defect. Failure of alignment of the great vessels with the ventricles contributes to transposition of the great arteries, tetralogy of Fallot and truncus arteriosus.

Aetiology and incidence

The incidence of haemodynamically significant congenital cardiac abnormalities is about 0.8% of live births (Box 18.121). Maternal infection or exposure to drugs or toxins may cause congenital heart disease. Maternal rubella infection is associated with persistent ductus arteriosus, pulmonary valvular and/or artery stenosis, and atrial septal defect. Maternal alcohol misuse is associated with septal defects, and maternal lupus erythematosus with congenital complete heart block. Genetic or chromosomal abnormalities, such as Down's syndrome, may cause septal defects, and gene defects have also

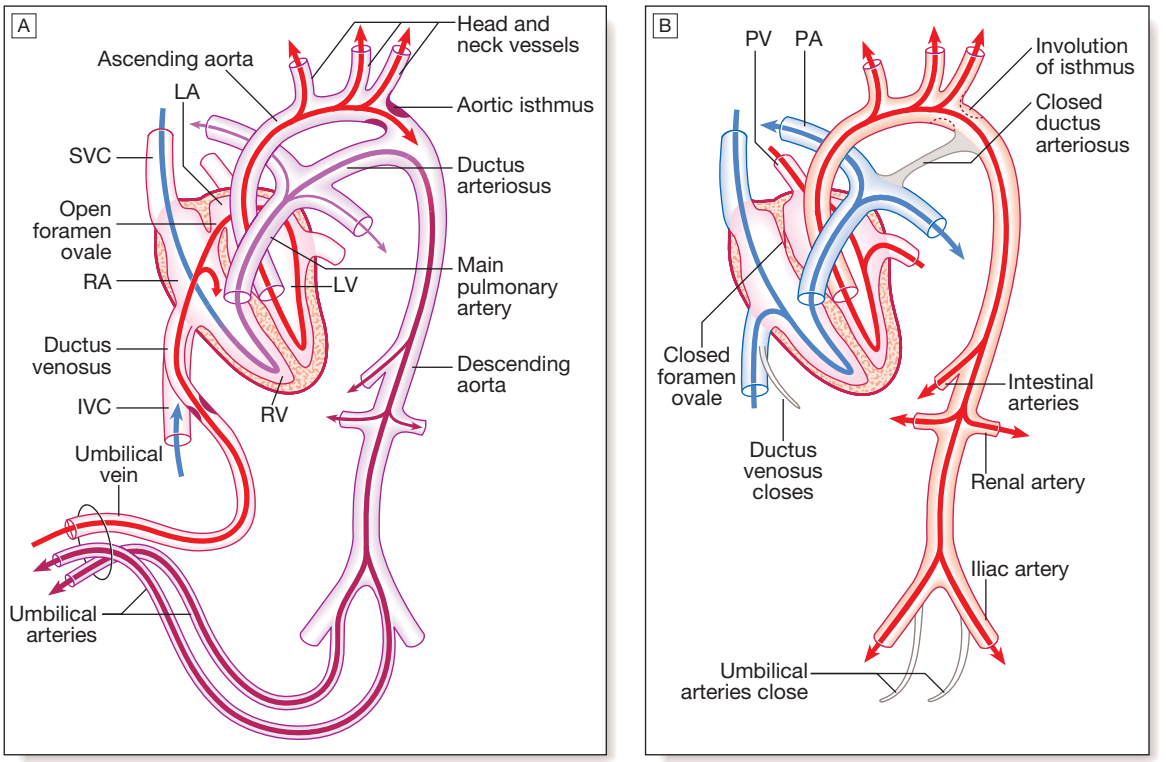

Fig. 18.94 Changes in the circulation at birth. A In the fetus, oxygenated blood comes through the umbilical vein where it enters the inferior vena cava via the ductus venosus (red). The oxygenated blood streams from the RA through the open foramen ovale to the LA and via the LV into the aorta. Venous blood from the superior vena cava (blue) crosses under the main blood stream into the RA and then, partly mixed with oxygenated blood (purple), into the RV and pulmonary artery. The pulmonary vasculature has a high resistance and so little blood passes to the lungs; most blood passes through the ductus arteriosus to the descending aorta. The aortic isthmus is a constriction in the aorta that lies in the aortic arch before the junction with the ductus arteriosus and limits the flow of oxygen-rich blood to the descending aorta. This configuration means that less oxygen-rich blood is supplied to organ systems that take up their function mainly after birth, e.g. the kidneys and intestinal tract. B At birth, the lungs expand with air and pulmonary vascular resistance falls, so that blood now flows to the lungs and back to the LA. The left atrial pressure rises above right atrial pressure and the flap valve of the foramen ovale closes. The umbilical arteries and the ductus venosus close. In the next few days, the ductus arteriosus closes under the influence of hormonal changes (particularly prostaglandins) and the aortic isthmus expands (IVC = inferior vena cava; LA = left atrium; LV = left ventricle; PA = pulmonary artery; PV = pulmonary vein; RA = right atrium; RV = right ventricle; SVC = superior vena cava). Adapted from Drews 1995 – see p. 641.

18.121 Incidence and relative frequency of congenital cardiac malformations

Lesion	% of all congenital heart defects
Ventricular septal defect	30
Atrial septal defect	10
Patent ductus arteriosus	10
Pulmonary stenosis	7
Coarctation of aorta	7
Aortic stenosis	6
Tetralogy of Fallot	6
Complete transposition of great arteries	4
Others	20

been identified as leading to specific abnormalities, such as Marfan's syndrome (p. 603) and DiGeorge's (deletion in chromosome 22q) syndrome.

Clinical features

Symptoms may be absent, or the child may be breathless or fail to attain normal growth and development. Some

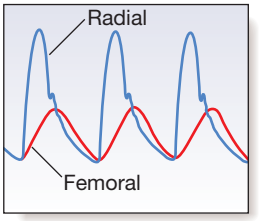

Fig. 18.95 Radiofemoral delay. The difference in pulse pressures is shown.

defects are not compatible with extrauterine life, or are so only for a short time. Clinical signs vary with the anatomical lesion. Murmurs, thrills or signs of cardiomegaly may be present. In coarctation of the aorta, radiofemoral delay may be noted (Fig. 18.95) and some female patients have the features of Turner's syndrome (p. 765). Features of other congenital conditions, such as Marfan's syndrome or Down's syndrome, may also be apparent. Cerebrovascular accidents and cerebral abscesses may complicate severe cyanotic congenital disease.

Early diagnosis is important because many types of congenital heart disease are amenable to surgery, but

this opportunity is lost if secondary changes, such as irreversible pulmonary hypertension, occur.

Central cyanosis and digital clubbing

Central cyanosis of cardiac origin occurs when desaturated blood enters the systemic circulation without passing through the lungs (i.e. a right-to-left shunt). In the neonate, the most common cause is transposition of the great arteries, in which the aorta arises from the RV and the pulmonary artery from the LV in association with a ventricular septal defect. In older children, cyanosis is usually the consequence of a ventricular septal defect combined with severe pulmonary stenosis (tetralogy of Fallot) or with pulmonary vascular disease (Eisenmenger's syndrome). Prolonged cyanosis is associated with finger and toe clubbing (p. 526).

Growth retardation and learning difficulties

These may occur with large left-to-right shunts at ventricular or great arterial level, and also with other defects, especially if they form part of a genetic syndrome. Major intellectual impairment is uncommon in children with isolated congenital heart disease; however, minor learning difficulties can occur and may complicate cardiac surgery if cerebral perfusion is compromised.

Syncope

In the presence of increased pulmonary vascular resistance or severe left or right ventricular outflow obstruction, exercise may provoke syncope as systemic vascular resistance falls but pulmonary vascular resistance rises, worsening right-to-left shunting and cerebral oxygenation. Syncope can also occur because of associated arrhythmias.

Pulmonary hypertension and Eisenmenger's syndrome

Persistently raised pulmonary flow (e.g. with left-to-right shunt) causes increased pulmonary resistance followed by pulmonary hypertension. Progressive changes, including obliteration of distal vessels, occur and are irreversible. Central cyanosis appears and digital clubbing develops. The chest X-ray shows enlarged central pulmonary arteries and peripheral 'pruning' of the pulmonary vessels. The ECG shows right ventricular hypertrophy. If severe pulmonary hypertension develops, a left-to-right shunt may reverse, resulting in right-to-left shunt and marked cyanosis (Eisenmenger's syndrome), which may be more apparent in the feet and toes than in the upper part of the body: differential cyanosis. This is more common with large ventricular septal defects or persistent ductus arteriosus than with atrial septal defects. Patients with Eisenmenger's syndrome are at particular risk from abrupt changes in afterload that exacerbate right-to-left shunting, such as vasodilatation, anaesthesia and pregnancy.

Pregnancy

During pregnancy, there is a 50% increase in plasma volume, a 40% increase in whole blood volume and a similar increase in cardiac output, so problems may arise in women with congenital heart disease (Box 18.122). Many with palliated or untreated disease will tolerate pregnancy well, however. Pregnancy is particularly hazardous in the presence of conditions associated with cyanosis or severe pulmonary hypertension; maternal mortality in patients with Eisenmenger's syndrome is more than 50%.

18.122 Pregnancy in women with congenital heart disease

- **Obstructive lesions** (e.g. severe aortic stenosis): poorly tolerated and associated with significant maternal morbidity and mortality.
- **Cyanotic conditions** (e.g. Eisenmenger's syndrome): especially poorly tolerated and pregnancy should be avoided.
- **Surgically corrected disease**: patients often tolerate pregnancy well.
- **Children of patients with congenital heart disease**: 2–5% will be born with cardiac abnormalities, especially if the mother is affected.

Persistent ductus arteriosus

Aetiology

During fetal life, before the lungs begin to function, most of the blood from the pulmonary artery passes through the ductus arteriosus into the aorta (see Fig. 18.94). Normally, the ductus closes soon after birth but sometimes fails to do so. Persistence of the ductus is associated with other abnormalities and is more common in females.

Since the pressure in the aorta is higher than that in the pulmonary artery, there will be a continuous arteriovenous shunt, the volume of which depends on the size of the ductus. As much as 50% of the left ventricular output is recirculated through the lungs, with a consequent increase in the work of the heart (Fig. 18.96).

Clinical features

With small shunts there may be no symptoms for years but, when the ductus is large, growth and development may be retarded. Usually, there is no disability in infancy

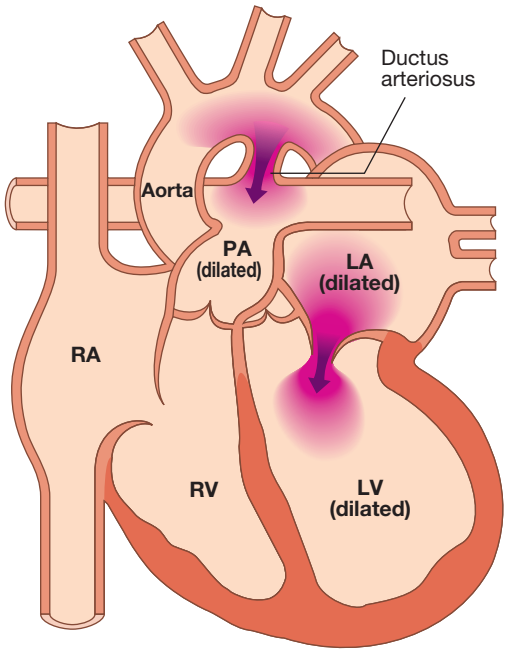

Fig. 18.96 Persistent ductus arteriosus. There is a connection between the aorta and the pulmonary artery with left-to-right shunting.

but cardiac failure may eventually ensue, dyspnoea being the first symptom. A continuous 'machinery' murmur is heard with late systolic accentuation, maximal in the second left intercostal space below the clavicle (see Fig. 18.96). It is frequently accompanied by a thrill. Pulses are increased in volume.

A large left-to-right shunt in infancy may cause a considerable rise in pulmonary artery pressure and sometimes this leads to progressive pulmonary vascular damage. Enlargement of the pulmonary artery may be detected radiologically. The ECG is usually normal.

Persistent ductus with reversed shunting

If pulmonary vascular resistance increases, pulmonary artery pressure may rise until it equals or exceeds aortic pressure. The shunt through the defect may then reverse, causing Eisenmenger's syndrome. The murmur becomes quieter, may be confined to systole or may disappear. The ECG shows evidence of right ventricular hypertrophy.

Management

A patent ductus is closed at cardiac catheterisation with an implantable occlusive device. Closure should be undertaken in infancy if the shunt is significant and pulmonary resistance not elevated, but this may be delayed until later childhood in those with smaller shunts, for whom closure remains advisable to reduce the risk of endocarditis.

Pharmacological treatment in the neonatal period

When the ductus is structurally intact, a prostaglandin synthetase inhibitor (indometacin or ibuprofen) may be used in the first week of life to induce closure. However, in the presence of a congenital defect with impaired lung perfusion (e.g. severe pulmonary stenosis and left-to-right shunt through the ductus), it may be advisable to improve oxygenation by keeping the ductus open with prostaglandin treatment. Unfortunately, these treatments do not work if the ductus is intrinsically abnormal.

Coarctation of the aorta

Aetiology

Narrowing of the aorta occurs in the region where the ductus arteriosus joins the aorta, i.e. at the isthmus just below the origin of the left subclavian artery (see Fig. 18.94). The condition is twice as common in males and occurs in 1 in 4000 children. It is associated with other abnormalities, most frequently bicuspid aortic valve and 'berry' aneurysms of the cerebral circulation (p. 1246). Acquired coarctation of the aorta is rare but may follow trauma or occur as a complication of a progressive arteritis (Takayasu's disease, p. 1116).

Clinical features and investigations

Aortic coarctation is an important cause of cardiac failure in the newborn but symptoms are often absent when it is detected in older children or adults. Headaches may occur from hypertension proximal to the coarctation, and occasionally weakness or cramps in the legs may result from decreased circulation in the lower part of the body. The BP is raised in the upper body but normal or low in the legs. The femoral pulses are weak and delayed in comparison with the radial pulse (see Fig. 18.95). A systolic murmur is usually heard posteriorly, over the coarctation. There may also be an ejection click and systolic murmur in the aortic area due to a bicuspid aortic valve. As a result of the aortic narrowing, collaterals form; they mainly involve the periscapular, internal mammary and intercostal arteries, and may result in localised bruits.

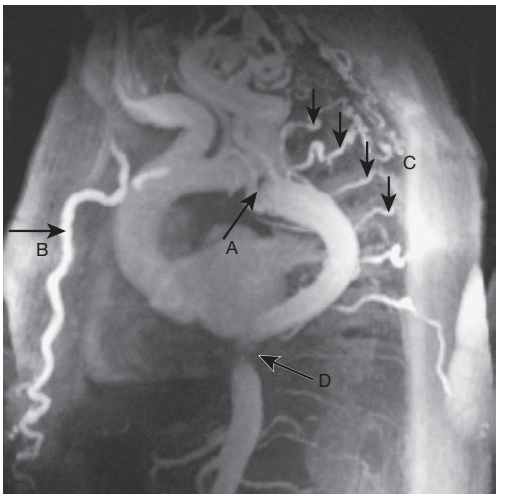

Fig. 18.97 MRI scan of coarctation of the aorta. The aorta is severely narrowed just beyond the arch at the start of the descending aorta (arrow A). Extensive collaterals have developed; a large internal mammary artery (arrow B) and several intercostal arteries (arrows C) are shown. Unusually, in this case, there is also a coarctation of the abdominal aorta (arrow D).

The chest X-ray in early childhood is often normal but later may show changes in the contour of the aorta (indentation of the descending aorta, '3 sign') and notching of the under-surfaces of the ribs from collaterals. MRI is the best imaging method. (Fig. 18.97). The ECG may show evidence of left ventricular hypertrophy, which can be confirmed by echocardiography.

Management

In untreated cases, death may occur from left ventricular failure, dissection of the aorta or cerebral haemorrhage. Surgical correction is advisable in all but the mildest cases. If this is carried out sufficiently early in childhood, persistent hypertension can be avoided. Patients repaired in late childhood or adult life often remain hypertensive or develop recurrent hypertension later on. Recurrence of stenosis may occur as the child grows and this may be managed by balloon dilatation and sometimes stenting. The latter may be used as the primary treatment. Coexistent bicuspid aortic valve, which occurs in over 50% of cases, may lead to progressive aortic stenosis or regurgitation, and also requires long-term follow-up.

Atrial septal defect

Aetiology

Atrial septal defect is one of the most common congenital heart defects and occurs twice as frequently in females. Most are 'ostium secundum' defects, involving the fossa ovalis that, in utero, was the foramen ovale (see Fig. 18.94). 'Ostium primum' defects result from a defect

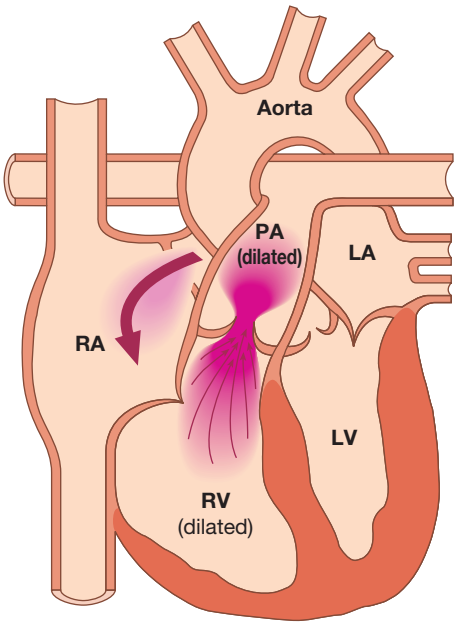

Fig. 18.98 Atrial septal defect. Blood flows across the atrial septum (arrow) from left to right. The murmur is produced by increased flow velocity across the pulmonary valve, as a result of left-to-right shunting and a large stroke volume. The density of shading is proportional to velocity of blood flow.

in the atrioventricular septum and are associated with a 'cleft mitral valve' (split anterior leaflet).

Since the normal RV is more compliant than the LV, a large volume of blood shunts through the defect from the LA to the RA, and then to the RV and pulmonary arteries (Fig. 18.98). As a result, there is gradual enlargement of the right side of the heart and of the pulmonary arteries. Pulmonary hypertension and shunt reversal sometimes complicate atrial septal defect, but are less common and tend to occur later in life than with other types of left-to-right shunt.

Clinical features and investigations

Most children are asymptomatic for many years and the condition is often detected at routine clinical examination or following a chest X-ray. Dyspnoea, chest infections, cardiac failure and arrhythmias, especially atrial fibrillation, are other possible manifestations. The characteristic physical signs are the result of the volume overload of the RV:

- wide, fixed splitting of the second heart sound: wide because of delay in right ventricular ejection (increased stroke volume and right bundle branch block) and fixed because the septal defect equalises left and right atrial pressures throughout the respiratory cycle
- a systolic flow murmur over the pulmonary valve.

In children with a large shunt, there may be a diastolic flow murmur over the tricuspid valve. Unlike a mitral flow murmur, this is usually high-pitched.

The chest X-ray typically shows enlargement of the heart and the pulmonary artery, as well as pulmonary plethora. The ECG usually shows incomplete right bundle branch block because right ventricular depolarisation is delayed as a result of ventricular dilatation

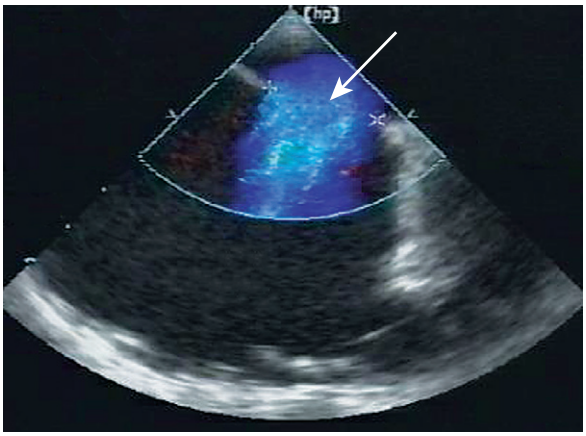

Fig. 18.99 Transoesophageal echocardiogram of an atrial septal defect. The defect is clearly seen (arrow) between the LA above and RA below. Doppler colour-flow imaging shows flow (blue) across the defect.

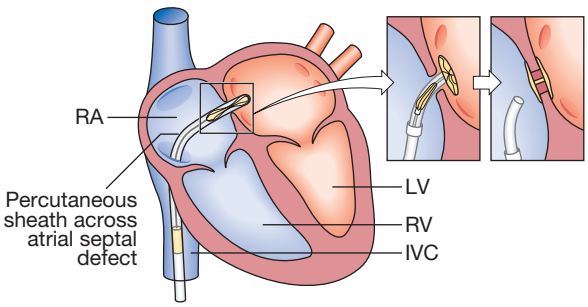

Fig. 18.100 Percutaneous close of atrial septal defect. The closure device is delivered across the inter-atrial septum and a disc deployed on either side to seal the defect.

(with a 'primum' defect, there is also left axis deviation). Echocardiography can directly demonstrate the defect and typically shows RV dilatation, RV hypertrophy and pulmonary artery dilatation. The precise size and location of the defect can be shown by transoesophageal echocardiography (Fig. 18.99).

Management

Atrial septal defects in which pulmonary flow is increased 50% above systemic flow (i.e. flow ratio of 1.5:1) are often large enough to be clinically recognisable and should be closed surgically. Closure can also be accomplished at cardiac catheterisation using implantable closure devices (Fig. 18.100). The long-term prognosis thereafter is excellent, unless pulmonary hypertension has developed. Severe pulmonary hypertension and shunt reversal are both contraindications to surgery.

Ventricular septal defect

Aetiology

Congenital ventricular septal defect occurs as a result of incomplete septation of the ventricles. Embryologically, the interventricular septum has a membranous and a muscular portion, and the latter is further divided into inflow, trabecular and outflow portions. Most congenital defects are 'perimembranous', i.e. at the junction of the membranous and muscular portions.

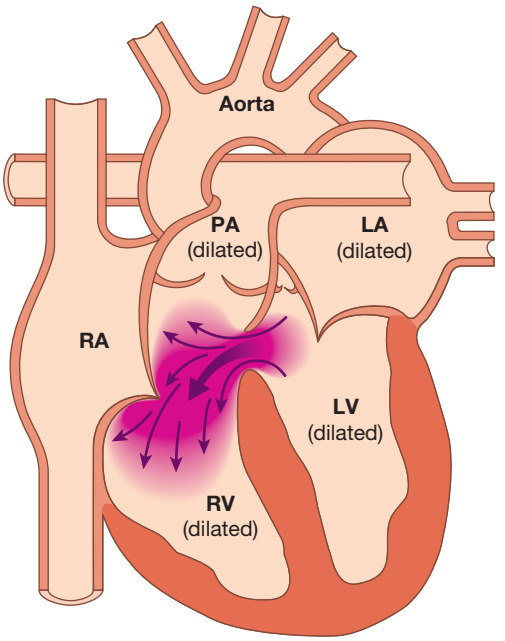

Fig. 18.101 Ventricular septal defect. In this example, a large left-to-right shunt (arrows) has resulted in chamber enlargement.

Ventricular septal defects are the most common congenital cardiac defect, occurring once in 500 live births. The defect may be isolated or part of complex congenital heart disease. Acquired ventricular septal defect may result from rupture as a complication of acute MI or, rarely, from trauma.

Clinical features

Flow from the high-pressure LV to the low-pressure RV during systole produces a pansystolic murmur, usually heard best at the left sternal edge but radiating all over the precordium (Fig. 18.101). A small defect often produces a loud murmur (maladie de Roger) in the absence of other haemodynamic disturbance. Conversely, a large defect produces a softer murmur, particularly if pressure in the RV is elevated. This may be found immediately after birth, while pulmonary vascular resistance remains high, or when the shunt is reversed in Eisenmenger's syndrome.

Congenital ventricular septal defect may present as cardiac failure in infants, as a murmur with only minor haemodynamic disturbance in older children or adults, or, rarely, as Eisenmenger's syndrome. In a proportion of infants, the murmur gets quieter or disappears due to spontaneous closure of the defect.

If cardiac failure complicates a large defect, it is usually absent in the immediate postnatal period and only becomes apparent in the first 4–6 weeks of life. In addition to the murmur, there is prominent parasternal pulsation, tachypnoea and indrawing of the lower ribs on inspiration. The chest X-ray shows pulmonary plethora and the ECG shows bilateral ventricular hypertrophy.

Management and prognosis

Small ventricular septal defects require no specific treatment. Cardiac failure in infancy is initially treated medically with digoxin and diuretics. Persisting failure is an indication for surgical repair of the defect. Percutaneous closure devices are under development.

Doppler echocardiography helps to predict the small septal defects that are likely to close spontaneously. Eisenmenger's syndrome is avoided by monitoring for signs of rising pulmonary resistance (serial ECG and echocardiography) and carrying out surgical repair, when appropriate. Surgical closure is contraindicated in fully developed Eisenmenger's syndrome when heart–lung transplantation may be the only effective treatment.

Except in Eisenmenger's syndrome, long-term prognosis is very good in congenital ventricular septal defect. Many patients with Eisenmenger's syndrome die in the second or third decade of life, but a few survive to the fifth decade without transplantation.

Tetralogy of Fallot

The RV outflow obstruction is most often subvalvular (infundibular) but may be valvular, supravalvular or a combination of these (Fig. 18.102). The ventricular septal defect is usually large and similar in aperture to the aortic orifice. The combination results in elevated right ventricular pressure and right-to-left shunting of cyanotic blood across the ventricular septal defect.

Aetiology

The embryological cause is abnormal development of the bulbar septum that separates the ascending aorta from the pulmonary artery, and which normally aligns and fuses with the outflow part of the interventricular septum. The defect occurs in about 1 in 2000 births and is the most common cause of cyanosis in infancy after the first year of life.

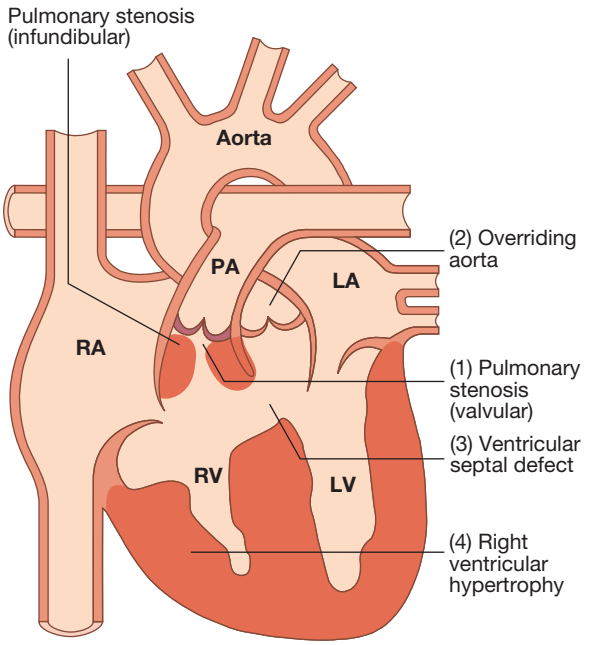

Fig. 18.102 Tetralogy of Fallot. The tetralogy comprises (1) pulmonary stenosis, (2) overriding of the ventricular septal defect by the aorta, (3) a ventricular septal defect and (4) right ventricular hypertrophy.

Clinical features

Children are usually cyanosed but this may not be the case in the neonate because it is only when right ventricular pressure rises to equal or exceed left ventricular pressure that a large right-to-left shunt develops. The subvalvular component of the RV outflow obstruction is dynamic and may increase suddenly under adrenergic stimulation. The affected child suddenly becomes increasingly cyanosed, often after feeding or a crying attack, and may become apnoeic and unconscious. These attacks are called 'Fallot's spells'. In older children, Fallot's spells are uncommon but cyanosis becomes increasingly apparent, with stunting of growth, digital clubbing and polycythaemia. Some children characteristically obtain relief by squatting after exertion, which increases the afterload of the left heart and reduces the right-to-left shunting: Fallot's sign. The natural history before the development of surgical correction was variable but most patients died in infancy or childhood.

On examination, the most characteristic feature is the combination of cyanosis with a loud ejection systolic murmur in the pulmonary area (as for pulmonary stenosis). However, cyanosis may be absent in the newborn or in patients with only mild right ventricular outflow obstruction ('acyanotic tetralogy of Fallot').

Investigations and management

The ECG shows right ventricular hypertrophy and the chest X-ray shows an abnormally small pulmonary artery and a 'boot-shaped' heart. Echocardiography is diagnostic and demonstrates that the aorta is not continuous with the anterior ventricular septum.

The definitive management is total correction of the defect by surgical relief of the pulmonary stenosis and closure of the ventricular septal defect. Primary surgical correction may be undertaken prior to the age of 5 years. If the pulmonary arteries are too hypoplastic, then palliation in the form of a Blalock–Taussig shunt may be performed, with an anastomosis created between the pulmonary artery and subclavian artery. This improves pulmonary blood flow and pulmonary artery development, and may facilitate later definitive correction.

The prognosis after total correction is good, especially if the operation is performed in childhood. Follow-up is needed to identify residual shunting, recurrent pulmonary stenosis and arrhythmias. An implantable defibrillator is sometimes recommended in adulthood.

Other causes of cyanotic congenital heart disease

There are other causes of cyanotic congenital heart disease (Box 18.123) and echocardiography is usually the definitive diagnostic procedure, supplemented, if necessary, by cardiac catheterisation.

Grown-up congenital heart disease

There are increasing numbers of children who have had surgical correction of congenital defects and who may have further problems as adults. The transition period between paediatric and adult care needs to be managed in a carefully planned manner, addressing many diverse aspects of care (Box 18.124). Those who have undergone correction of coarctation of the aorta may develop

18.123 Other causes of cyanotic congenital heart disease

Defect	Features
Tricuspid atresia	Absent tricuspid orifice, hypoplastic RV, RA-to-LA shunt, ventricular septal defect shunt, other anomalies Surgical correction may be possible
Transposition of the great vessels	Aorta arises from the morphological RV, pulmonary artery from LV Shunt via atria, ductus and possibly ventricular septal defect Palliation by balloon atrial septostomy/enlargement Surgical correction possible
Pulmonary atresia	Pulmonary valve atretic and pulmonary artery hypoplastic RA-to-LA shunt, pulmonary flow via ductus Palliation by balloon atrial septostomy Surgical correction may be possible
Ebstein's anomaly	Tricuspid valve is dysplastic and displaced into RV, RV 'atrialised' Tricuspid regurgitation and RA-to-LA shunt Wide spectrum of severity Arrhythmias Surgical repair possible but significant risk

18.124 Congenital heart disease in adolescence

- **Patients**: a heterogeneous population with residual disease and sequelae that vary according to the underlying lesion and in severity; each patient must be assessed individually.
- **Management plan**: should be agreed with the patient and include a 'cardiac destination'.
- **Risks of surgery**: non-cardiac surgery, e.g. for associated congenital abnormalities, carries increased risks and needs to be planned, with careful pre-operative assessment. Risks include thrombosis, embolism from synthetic shunts or patches, and volume overload from fluid shifts. Operative approaches should address cosmetic concerns, e.g. abdominal generator implantation may be less unsightly.
- **Exercise**: patients with mild or repaired defects can undertake moderately vigorous exercise but those with complex defects, cyanosis, ventricular dysfunction or arrhythmias require specialist evaluation and individualised advice regarding exercise.
- **Genetics**: 10–15% have a genetic basis and this should be assessed to understand the impact it may have for the patient's own future children. A family history, genetic evaluation of syndromic versus non-syndromic disorders and, sometimes, cytogenetics are required.
- **Education and employment**: may be adversely affected and occupational activity levels need to be assessed.
- **End of life**: some adolescents with complex disorders may misperceive and think they have been cured; transition to adult services may be the first time they receive information about mortality. Expectations on life expectancy need to be managed and adolescents are often willing to engage with this and play a role in decision-making.

hypertension in adult life. Those with transposition of the great arteries who have had a 'Mustard' repair, where blood is redirected at atrial level, leaving the RV connected to the aorta, may develop right ventricular failure in adult life. The RV is unsuited for function at systemic pressures and may begin to dilate and fail when patients are in their twenties or thirties.

Those who have had surgery involving the atria may develop atrial arrhythmias, and those who have ventricular scars may develop ventricular arrhythmias and need consideration for implantation of an implantable cardiac defibrillator. Such patients require careful follow-up from the teenage years throughout adult life, so that problems can be identified early and appropriate medical or surgical treatment instituted. The management of patients with grown-up congenital heart disease ('GUCH') is complex and has developed as a cardiological subspecialty.

DISEASES OF THE MYOCARDIUM

Although the myocardium is involved in most types of heart disease, the terms 'myocarditis' and 'cardiomyopathy' are usually reserved for conditions that primarily affect the heart muscle.

Myocarditis

This is an acute inflammatory condition that can have an infectious, toxic or autoimmune aetiology. Myocarditis can complicate many infections in which inflammation may be due directly to infection of the myocardium or the effects of circulating toxins. Viral infections are the most common causes, such as Coxsackie (35 cases per 1000 infections) and influenza A and B (25 cases per 1000 infections) viruses. Myocarditis may occur several weeks after the initial viral symptoms and susceptibility is increased by corticosteroid treatment, immunosuppression, radiation, previous myocardial damage and exercise. Some bacterial and protozoal infections may be complicated by myocarditis; for example, approximately 5% of patients with Lyme disease (*Borrelia burgdorferi*, p. 334) develop myopericarditis, which is often associated with AV block. Toxic aetiologies include drugs, which may directly injure the myocardium (e.g. cocaine, lithium and anti-cancer drugs, such as doxorubicin) or which may cause a hypersensitivity reaction and associated myocarditis (e.g. penicillins and sulphonamides, lead and carbon monoxide). Occasionally, autoimmune conditions, such as systemic lupus erythematosus and rheumatoid arthritis, are associated with myocarditis.

Clinical features and investigations

Myocarditis can be classified by four distinct clinical presentations:

- *Fulminant myocarditis* follows a viral prodrome or influenza-like illness, and results in severe heart failure or cardiogenic shock.
- *Acute myocarditis* presents over a longer period with heart failure; it can lead to dilated cardiomyopathy.
- *Chronic active myocarditis* is rare and associated with chronic myocardial inflammation.
- *Chronic persistent myocarditis* is characterised by focal myocardial infiltrates and can cause chest pain and arrhythmia without necessarily causing ventricular dysfunction.

In myocarditis, ECG changes are common but non-specific. Biochemical markers of myocardial injury (e.g. troponin I and T, creatine kinase) may be elevated in the early phases. Echocardiography may reveal left ventricular dysfunction that is sometimes regional (due to focal myocarditis), and cardiac MRI may show diagnostic patterns of myocardial inflammation or infiltration. Endomyocardial biopsy is sometimes used to confirm the diagnosis.

Management and prognosis

In most patients, myocarditis is self-limiting and the immediate prognosis is good. However, death may occur due to a ventricular arrhythmia or rapidly progressive heart failure. Myocarditis has been reported as a cause of sudden and unexpected death in young athletes. Some forms of myocarditis may lead to chronic low-grade myocarditis or dilated cardiomyopathy (see below); for example, in Chagas' disease (p. 360), the patient frequently recovers from the acute infection but goes on to develop a chronic dilated cardiomyopathy 10 or 20 years later.

Specific antimicrobial therapy may be used if a causative organism has been identified; this is rare, however, and in most cases only supportive therapy is available. Treatment for cardiac failure or arrhythmias may be required and patients should be advised to avoid intense physical exertion because there is some evidence that this can induce potentially fatal ventricular arrhythmias. There is no evidence for any benefit from treatment with corticosteroids and immunosuppressive agents. Rarely cardiac transplantation or temporary circulatory support with a mechanical ventricular assist device is required.

Cardiomyopathy

Cardiomyopathies are diseases of the myocardium, and are classified according to their structural and functional presentation (Fig. 18.103). They can be inherited or have infective, toxic or idiopathic aetiologies.

Dilated cardiomyopathy

This is characterised by dilatation and impaired contraction of the LV and often the RV. Left ventricular mass is increased but wall thickness is normal or reduced (see Fig. 18.103). Dilatation of the valve rings can lead to 'functional' mitral and tricuspid incompetence. Histological changes are variable but include myofibrillary loss, interstitial fibrosis and T-cell infiltrates. The differential diagnosis includes ventricular dysfunction due to coronary artery disease, and a diagnosis of dilated cardiomyopathy should only be made when this has been excluded.

The pathogenesis is not clear but dilated cardiomyopathy probably encompasses a heterogenous group of conditions. Alcohol may be an important cause in some patients. At least 25% of cases are inherited as an autosomal dominant trait and a variety of single-gene mutations have been identified. Most of these mutations

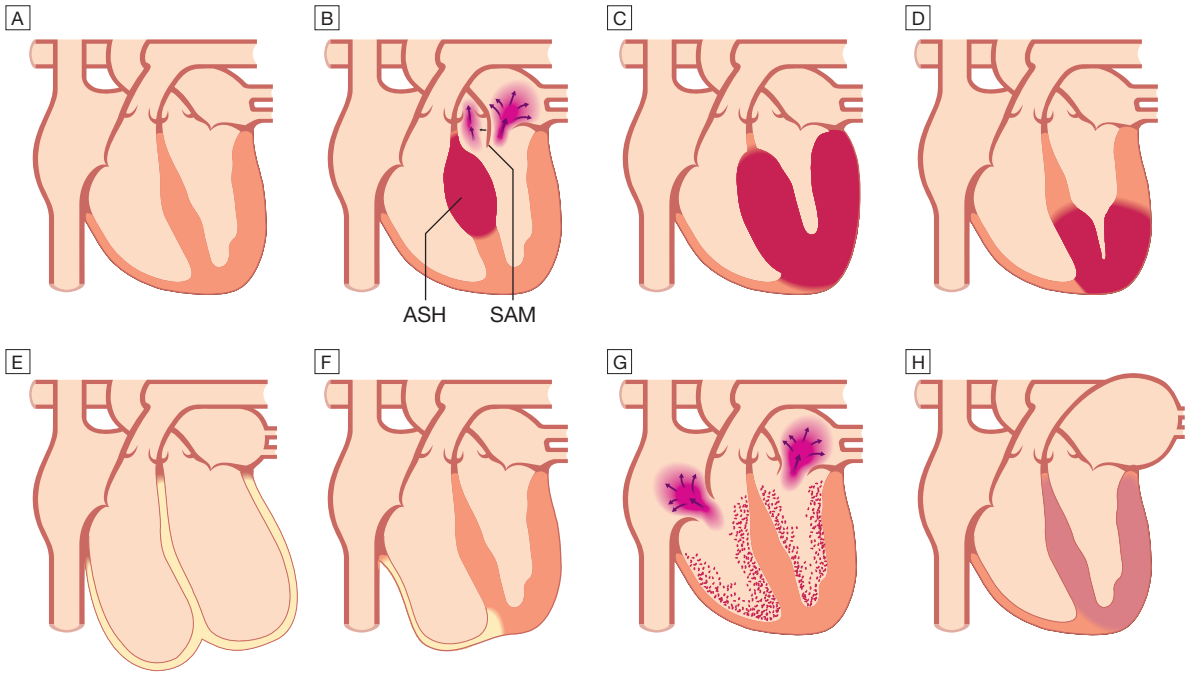

Fig. 18.103 Types of cardiomyopathy. A Normal heart. B Hypertrophic cardiomyopathy: asymmetric septal hypertrophy (ASH) with systolic anterior motion of the mitral valve (SAM), causing mitral reflux and dynamic left ventricular outflow tract obstruction. C Hypertrophic cardiomyopathy: concentric hypertrophy. D Hypertrophic cardiomyopathy: apical hypertrophy. E Dilated cardiomyopathy. F Arrhythmogenic right ventricular cardiomyopathy. G Obliterative cardiomyopathy. H Restrictive cardiomyopathy.

affect proteins in the cytoskeleton of the myocyte (e.g. dystrophin, lamin A and C, emerin and metavinculin) and many are associated with minor skeletal muscle abnormalities. Most of the X-linked inherited skeletal muscular dystrophies (e.g. Becker and Duchenne, p. 1228) are associated with cardiomyopathy. Finally, a late autoimmune reaction to viral myocarditis is thought to be the cause in a substantial subgroup of patients with dilated cardiomyopathy; a similar mechanism is thought to be responsible for the heart muscle disease that occurs in up to 10% of patients with advanced HIV infection.

In North America and Europe, symptomatic dilated cardiomyopathy has an incidence of 20 per 100 000 and a prevalence of 38 per 100 000. Men are affected more than twice as often as women. Most patients present with heart failure or are found to have the condition during routine investigation. Arrhythmia, thromboembolism and sudden death may occur at any stage; sporadic chest pain is a surprisingly frequent symptom. The ECG usually shows non-specific changes but echocardiography and cardiac MRI are useful in establishing the diagnosis. Treatment is aimed at controlling the resulting heart failure. Although some patients remain well for many years, the prognosis is variable and cardiac transplantation may be indicated. Patients with dilated cardiomyopathy and moderate or severe heart failure may be at risk of sudden arrhythmic death. This risk is substantially reduced by rigorous medical therapy with β-blockers and angiotensin receptor antagonists. Some patients may be considered for implantation of a cardiac defibrillator and/or cardiac resynchronisation therapy (p. 579).

Hypertrophic cardiomyopathy

This is the most common form of cardiomyopathy, with a prevalence of approximately 100 per 100 000. It is characterised by inappropriate and elaborate left ventricular hypertrophy with malalignment of the myocardial fibres and myocardial fibrosis. The hypertrophy may be generalised or confined largely to the interventricular septum (asymmetric septal hypertrophy, see Fig. 18.103) or other regions (e.g. apical hypertrophic cardiomyopathy, a variant which is common in the Far East).

Heart failure may develop because the stiff non-compliant ventricles impede diastolic filling. Septal hypertrophy may also cause dynamic left ventricular outflow tract obstruction (hypertrophic obstructive cardiomyopathy, HOCM) and mitral regurgitation due to abnormal systolic anterior motion of the anterior mitral valve leaflet. Effort-related symptoms (angina and breathlessness), arrhythmia and sudden death are the dominant clinical presentations.

Hypertrophic cardiomyopathy is a genetic disorder, usually with autosomal dominant transmission, a high degree of penetrance and variable expression. In most patients, it is due to a single point mutation in one of the genes that encode sarcomeric contractile proteins. There are three common groups of mutation with different phenotypes. Beta-myosin heavy chain mutations are associated with elaborate ventricular hypertrophy. Troponin mutations are associated with little, and sometimes even no, hypertrophy but marked myocardial fibre disarray, an abnormal vascular response (e.g. exercise-induced hypotension) and a high risk of sudden death. Myosin-binding protein C mutations tend to

18.125 Clinical features of hypertrophic cardiomyopathy

Symptoms

- Angina on effort
- Dyspnoea on effort
- Syncope on effort
- Sudden death

Signs

- Jerky pulse*
- Palpable left ventricular hypertrophy
- Double impulse at the apex (palpable fourth heart sound due to left atrial hypertrophy)
- Mid-systolic murmur at the base*
- Pansystolic murmur (due to mitral regurgitation) at the apex

*Signs of left ventricular outflow tract obstruction may be augmented by standing up (reduced venous return), inotropes and vasodilators (e.g. sublingual nitrate).

18.126 Risk factors for sudden death in hypertrophic cardiomyopathy

- A history of previous cardiac arrest or sustained ventricular tachycardia
- Recurrent syncope
- An adverse genotype and/or family history
- Exercise-induced hypotension
- Non-sustained ventricular tachycardia on ambulatory ECG monitoring
- Marked increase in left ventricular wall thickness

present late in life and are often associated with hypertension and arrhythmia.

Symptoms and signs are similar to those of aortic stenosis, except that, in hypertrophic cardiomyopathy, the character of the arterial pulse is jerky (Box 18.125).

The ECG is abnormal and shows features of left ventricular hypertrophy with a wide variety of often bizarre abnormalities (e.g. pseudo-infarct pattern, deep T-wave inversion). Echocardiography is diagnostic, although the diagnosis may be difficult when another cause of left ventricular hypertrophy is present (e.g. physical training – athletes' heart, hypertension) but the degree of hypertrophy is greater than expected. Genetic testing may facilitate diagnosis and, in some cases, is helpful in screening relatives of affected individuals.

The natural history is variable but clinical deterioration is often slow. The annual mortality from sudden death is 2–3% among adults and 4–6% in children and adolescents (Box 18.126). Sudden death typically occurs during or just after vigorous physical activity; indeed, hypertrophic cardiomyopathy is the most common cause of sudden death in young athletes. Ventricular arrhythmias may be responsible for many of these.

Beta-blockers, rate-limiting calcium antagonists (e.g. verapamil) and disopyramide can help to relieve symptoms and sometimes prevent syncopal attacks; however, there is no pharmacological treatment that is definitely known to improve prognosis. Arrhythmias are common and often respond to treatment with amiodarone. Outflow tract obstruction can be improved by partial surgical resection (myectomy) or by iatrogenic infarction of the basal septum (septal ablation) using a catheter-delivered alcohol solution. An implantable cardiac defibrillator should be considered in patients with clinical risk factors for sudden death (see Box 18.126). Digoxin and vasodilators may increase outflow tract obstruction and should be avoided.

Arrhythmogenic right ventricular cardiomyopathy

In this condition, patches of the right ventricular myocardium are replaced with fibrous and fatty tissue (see Fig. 18.102). It is inherited as an autosomal dominant trait and has a prevalence of approximately 10 per 100 000. The dominant clinical problems are ventricular arrhythmias, sudden death and right-sided cardiac failure. The ECG typically shows a slightly broadened QRS complex and inverted T waves in the right precordial leads. MRI is a useful diagnostic tool and is used, along with the 12-lead ECG and ambulatory ECG monitoring, to screen the first-degree relatives of affected individuals. Patients at high risk of sudden death can be offered an implantable cardiac defibrillator.

Restrictive cardiomyopathy

In this rare condition, ventricular filling is impaired because the ventricles are 'stiff' (see Fig. 18.102). This leads to high atrial pressures with atrial hypertrophy, dilatation and, later, atrial fibrillation. Amyloidosis is the most common cause in the UK, although other forms of infiltration (e.g. glycogen storage diseases), idiopathic perimyocyte fibrosis and a familial form of restrictive cardiomyopathy do occur. Diagnosis can be very difficult and requires complex Doppler echocardiography, CT or MRI, and endomyocardial biopsy. Treatment is symptomatic but the prognosis is usually poor and transplantation may be indicated.

Obliterative cardiomyopathy

This is a rare form of restrictive cardiomyopathy, involving the endocardium of one or both ventricles; it is characterised by thrombosis and fibrosis, with gradual obliteration of the ventricular cavities (e.g. endomyocardial fibroelastosis, see Fig. 18.103). The mitral and tricuspid valves become regurgitant. Heart failure and pulmonary and systemic embolism are prominent features. It can sometimes be associated with eosinophilia (e.g. eosinophilic leukaemia, Churg–Strauss syndrome, p. 1118). In tropical countries, the disease can be responsible for up to 10% of cardiac deaths. Mortality is high: 50% at 2 years. Anticoagulation and antiplatelet therapy are used, and diuretics may help symptoms of heart failure. Surgery (tricuspid and/or mitral valve replacement with decortication of the endocardium) may be helpful in selected cases.

Specific diseases of heart muscle

Many forms of specific heart muscle disease produce a clinical picture that is indistinguishable from dilated cardiomyopathy (e.g. connective tissue disorders, sarcoidosis, haemochromatosis, alcoholic heart muscle disease, Box 18.127). In contrast, amyloidosis and eosinophilic heart disease produce symptoms and signs similar to those found in restrictive or obliterative cardiomyopathy, whereas the heart disease associated with Friedreich's ataxia (p. 1199) can mimic hypertrophic cardiomyopathy.

18.127 Specific diseases of heart muscle

Infections
• Viral, e.g. Coxsackie A and B, influenza, HIV • Bacterial, e.g. diphtheria, *Borrelia burgdorferi* • Protozoal, e.g. trypanosomiasis
Endocrine and metabolic disorders
• Diabetes, hypo- and hyperthyroidism, acromegaly, carcinoid syndrome, phaeochromocytoma, inherited storage diseases
Connective tissue diseases
• Systemic sclerosis, systemic lupus erythematosus, polyarteritis nodosa
Infiltrative disorders
• Haemochromatosis, haemosiderosis, sarcoidosis, amyloidosis
Toxins
• Doxorubicin, alcohol, cocaine, irradiation
Neuromuscular disorders
• Dystrophia myotonica, Friedreich's ataxia

Treatment and prognosis are determined by the underlying disorder. Abstention from alcohol may lead to a dramatic improvement in patients with alcoholic heart muscle disease.

Cardiac tumours

Primary cardiac tumours are rare (< 0.2% of autopsies) but the heart and mediastinum may be the sites of metastases. Most primary tumours are benign (75%) and, of these, the majority are myxomas. The remainder are fibromas, lipomas, fibroelastomas and haemangiomas.

Atrial myxoma

Myxomas most commonly arise in the LA as single or multiple polypoid tumours, attached by a pedicle to the interatrial septum. They are usually gelatinous but may be solid and even calcified, with superimposed thrombus.

On examination, the first heart sound is usually loud, and there may be a murmur of mitral regurgitation with a variable diastolic sound (tumour 'plop') due to prolapse of the mass through the mitral valve. The tumour can be detected incidentally on echocardiography, or following investigation of pyrexia, syncope, arrhythmias or emboli. Occasionally, the condition presents with malaise and features suggestive of a connective tissue disorder, including a raised ESR.

Treatment is by surgical excision. If the pedicle is removed, fewer than 5% of tumours recur.

DISEASES OF THE PERICARDIUM

The normal pericardial sac contains about 50 mL of fluid, similar to lymph, which lubricates the surface of the heart. The pericardium limits distension of the heart, contributes to the haemodynamic interdependence of the ventricles, and acts as a barrier to infection. Nevertheless, congenital absence of the pericardium does not result in significant clinical or functional limitations.

18.128 Aetiology of acute pericarditis

Common	
• Viral (e.g. Coxsackie B but often not identified)	• Acute MI
Less common	
• Uraemia • Malignant disease • Trauma (e.g. blunt chest injury)	• Connective tissue disease (e.g. systemic lupus erythematosus)
Rare (in UK)	
• Bacterial infection • Rheumatic fever	• Tuberculosis

Acute pericarditis

Aetiology

Pericardial inflammation may be due to a number of pathologies (Box 18.128) but sometimes remains unexplained. Pericarditis and myocarditis often coexist, and all forms of pericarditis may produce a pericardial effusion (see below) that, depending on the aetiology, may be fibrinous, serous, haemorrhagic or purulent.

A fibrinous exudate may eventually lead to varying degrees of adhesion formation, whereas serous pericarditis often produces a large effusion of turbid, straw-coloured fluid with a high protein content.

A haemorrhagic effusion is often due to malignant disease, particularly carcinoma of the breast or bronchus, and lymphoma.

Purulent pericarditis is rare and may occur as a complication of septicaemia, by direct spread from an intrathoracic infection, or from a penetrating injury.

Clinical features

The characteristic pain of pericarditis is retrosternal, radiates to the shoulders and neck, and is typically aggravated by deep breathing, movement, a change of position, exercise and swallowing. A low-grade fever is common. A pericardial friction rub is a high-pitched superficial scratching or crunching noise, produced by movement of the inflamed pericardium, and is diagnostic of pericarditis; it is usually heard in systole but may also be audible in diastole and frequently has a 'to-and-fro' quality.

Investigations and management

The ECG shows ST elevation with upward concavity (Fig. 18.104) over the affected area, which may be widespread. PR interval depression is a very specific indicator of acute pericarditis. Later, there may be T-wave inversion, particularly if there is a degree of myocarditis.

The pain is usually relieved by aspirin (600 mg 6 times daily) but a more potent anti-inflammatory agent, such as indometacin (25 mg 3 times daily), may be required. Colchicine or corticosteroids may suppress symptoms but there is no evidence that they accelerate cure.

In viral pericarditis, recovery usually occurs within a few days or weeks but there may be recurrences (chronic relapsing pericarditis). Purulent pericarditis requires

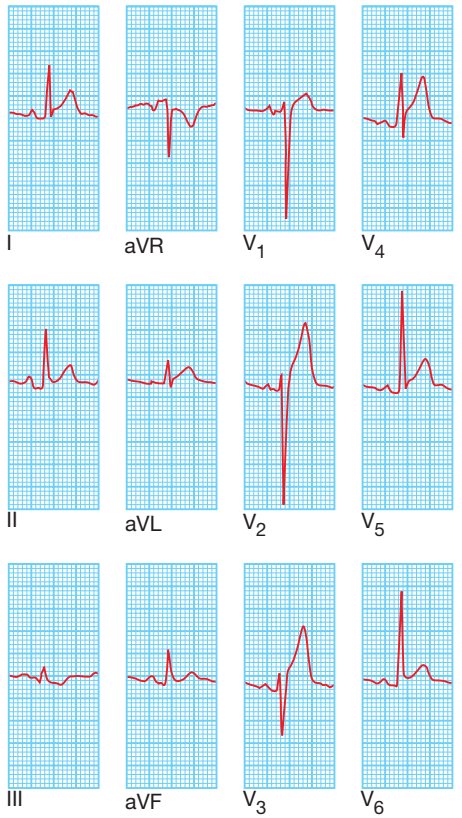

Fig. 18.104 ECG in viral pericarditis. Widespread ST elevation (leads I, II, aVL and V_1–V_6) is shown. The upward concave shape of the ST segments (see leads II and V_6) and the unusual distribution of changes (involving anterior and inferior leads) help to distinguish pericarditis from acute MI.

treatment with antimicrobial therapy, pericardiocentesis and, if necessary, surgical drainage.

Pericardial effusion

If a pericardial effusion develops, there is sometimes a sensation of retrosternal oppression. An effusion is difficult to detect clinically. The heart sounds may become quieter, although a friction rub is not always abolished.

The QRS voltages on the ECG are often reduced in the presence of a large effusion. The QRS complexes may alternate in amplitude due to a to-and-fro motion of the heart within the fluid-filled pericardial sac (electrical alternans). The chest X-ray may show an increased size of the cardiac silhouette and, when there is a large effusion, this has a globular appearance. Echocardiography is the definitive investigation and is used to monitor the size of the effusion and its effect on cardiac function (Fig. 18.105).

Cardiac tamponade

This term is used to describe acute heart failure due to compression of the heart by a large or rapidly developing effusion, and is described in detail on page 545. Typical physical findings are of a markedly raised JVP, hypotension, pulsus paradoxus (p. 532) and oliguria. Atypical presentations may occur when the effusion is loculated as a result of previous pericarditis or cardiac surgery.

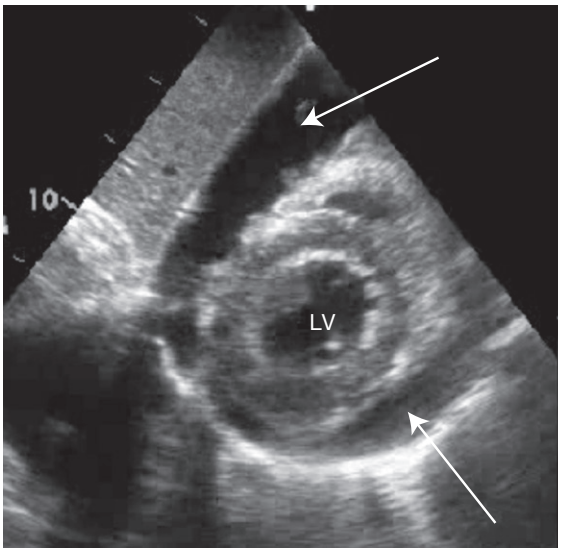

Fig. 18.105 Pericardial effusion: echocardiogram (apical view). Short axis view of the heart showing a large circumferential pericardial effusion (arrows). (LV = left ventricle)

Pericardial aspiration (pericardiocentesis)

Aspiration of a pericardial effusion is indicated for diagnostic purposes or for the treatment of cardiac tamponade. A needle is inserted under echocardiographic guidance medial to the cardiac apex or below the xiphoid process, directed upwards towards the left shoulder. The route of choice will depend on the experience of the operator, the shape of the patient and the position of the effusion. A few millilitres of fluid aspirated through the needle may be sufficient for diagnostic purposes but pericardial drainage is needed for symptom relief.

Complications of pericardiocentesis include arrhythmias, damage to a coronary artery, and bleeding with exacerbation of tamponade as a result of injury to the RV. When tamponade is due to cardiac rupture or aortic dissection, pericardial aspiration may precipitate further potentially fatal bleeding and, in these situations, emergency surgery is the treatment of choice. A viscous, loculated or recurrent effusion may also require formal surgical drainage.

Tuberculous pericarditis

Tuberculous pericarditis may complicate pulmonary tuberculosis but may also be the first manifestation of the infection. In Africa, a tuberculous pericardial effusion is a common feature of AIDS (p. 405).

The condition typically presents with chronic malaise, weight loss and a low-grade fever. An effusion usually develops and the pericardium may become thick and unyielding, leading to pericardial constriction or tamponade. An associated pleural effusion is often present.

The diagnosis may be confirmed by aspiration of the fluid and direct examination or culture for tubercle bacilli. Treatment requires specific antituberculous chemotherapy (p. 693); in addition, a 3-month course of prednisolone (initial dose 60 mg a day, tapering down rapidly) improves outcome.

Chronic constrictive pericarditis

Constrictive pericarditis is due to progressive thickening, fibrosis and calcification of the pericardium. In effect, the heart is encased in a solid shell and cannot fill properly. The calcification may extend into the myocardium, so there may also be impaired myocardial contraction. The condition often follows an attack of tuberculous pericarditis but can also complicate haemopericardium, viral pericarditis, rheumatoid arthritis and purulent pericarditis. It is often impossible to identify the original insult.

Clinical features and management

The symptoms and signs of systemic venous congestion are the hallmarks of constrictive pericarditis. Atrial fibrillation is common and there is often dramatic ascites and hepatomegaly (Box 18.129). Breathlessness is not a prominent symptom because the lungs are seldom congested.

The condition is sometimes overlooked but should be suspected in any patient with unexplained right heart failure and a small heart. A chest X-ray, which may show pericardial calcification (Fig. 18.106), and echocardiography often help to establish the diagnosis. CT scanning is useful for imaging the pericardial calcification.

Constrictive pericarditis is often difficult to distinguish from restrictive cardiomyopathy and the final diagnosis may depend on complex echo–Doppler studies and cardiac catheterisation. Surgical resection of the diseased pericardium can lead to a dramatic improvement but carries a high morbidity with disappointing results in up to 50% of patients.

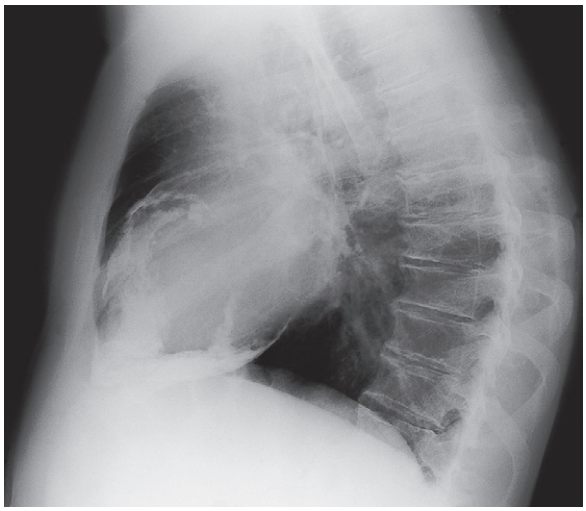

Fig. 18.106 Lateral chest X-ray from a patient with severe heart failure due to chronic constrictive pericarditis. There is heavy calcification of the pericardium.

18.129 Clinical features of constrictive pericarditis

- Fatigue
- Rapid, low-volume pulse
- Elevated JVP with a rapid *y* descent
- Kussmaul's sign (a paradoxical rise in the JVP during inspiration)
- Loud early third heart sound or 'pericardial knock'
- Hepatomegaly
- Ascites
- Peripheral oedema
- Pulsus paradoxus (excessive fall in BP during inspiration): present in some cases

Respiratory disease is responsible for a major burden of morbidity and untimely death, with conditions such as tuberculosis, pandemic influenza and pneumonia the most important in world health terms. The increasing prevalence of allergy, asthma and chronic obstructive pulmonary disease (COPD) contributes to the overall burden of chronic disease in the community. By 2025, the number of cigarette smokers worldwide is anticipated to increase to 1.5 billion, ensuring a growing burden of tobacco-related respiratory conditions.

Respiratory disease covers a breadth of pathologies, including infectious, inflammatory, neoplastic and degenerative processes. The practice of respiratory medicine thus requires collaboration with a range of disciplines. Recent advances have improved the lives of many patients with obstructive lung disease, cystic fibrosis, obstructive sleep apnoea and pulmonary hypertension, but the outlook remains poor for lung and other respiratory cancers, and for some of the fibrosing lung conditions.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

The lungs occupy the upper two-thirds of the bony thorax, bounded medially by the spine, the heart and the mediastinum and inferiorly by the diaphragm. During breathing, free movement of the lung surface relative to the chest wall is facilitated by sliding contact between the parietal and visceral pleura, which cover the inner surface of the chest wall and the lung respectively, and are normally in close apposition. Inspiration involves downward contraction of the dome-shaped diaphragm (innervated by the phrenic nerves originating from C3, 4 and 5) and upward, outward movement of the ribs on the costovertebral joints, caused by contraction of the external intercostal muscles (innervated by intercostal nerves originating from the thoracic spinal cord). Expiration is largely passive, driven by elastic recoil of the lungs.

The conducting airways from the nose to the alveoli connect the external environment with the extensive, thin and vulnerable alveolar surface. As air is inhaled through the upper airways, it is filtered in the nose, heated to body temperature and fully saturated with water vapour; partial recovery of this heat and moisture occurs on expiration. Total airway cross-section is smallest in the glottis and trachea, making the central airway particularly vulnerable to obstruction by foreign bodies and tumours. Normal breath sounds originate mainly from the rapid turbulent airflow in the larynx, trachea and main bronchi.

The multitude of small airways within the lung parenchyma has a very large combined cross-sectional area (over 300 cm^2 in the third-generation respiratory bronchioles), resulting in very slow flow rates. Airflow is normally silent here, and gas transport occurs largely by diffusion in the final generations. Major bronchial and pulmonary divisions are shown in Figure 19.1.

The acinus (Fig. 19.2) is the gas exchange unit of the lung and comprises branching respiratory bronchioles

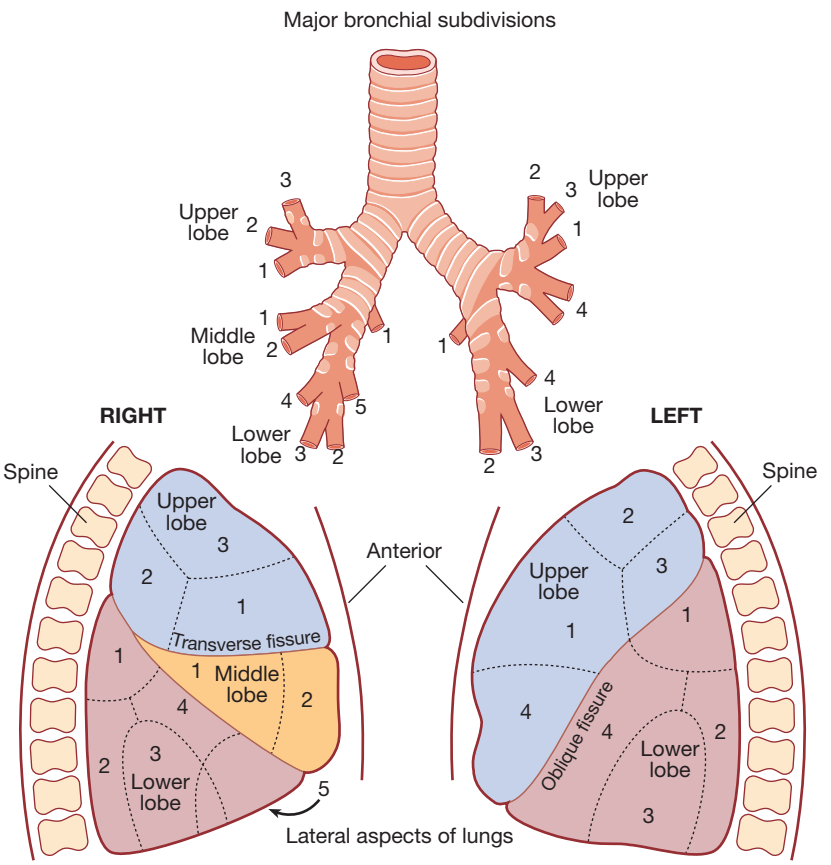

Fig. 19.1 The major bronchial divisions and the fissures, lobes and segments of the lungs. The angle of the oblique fissure means that the left upper lobe is largely anterior to the lower lobe. On the right, the transverse fissure separates the upper from the anteriorly placed middle lobe, which is matched by the lingular segment on the left side. The site of a lobe determines whether physical signs are mainly anterior or posterior. Each lobe is composed of two or more bronchopulmonary segments that are supplied by the main branches of each lobar bronchus.
Bronchopulmonary segments:
Right *Upper lobe*: (1) Anterior, (2) Posterior, (3) Apical. *Middle lobe*: (1) Lateral, (2) Medial. *Lower lobe*: (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal, (5) Medial basal.
Left *Upper lobe*: (1) Anterior, (2) Apical, (3) Posterior, (4) Lingular. *Lower lobe*: (1) Apical, (2) Posterior basal, (3) Lateral basal, (4) Anterior basal.

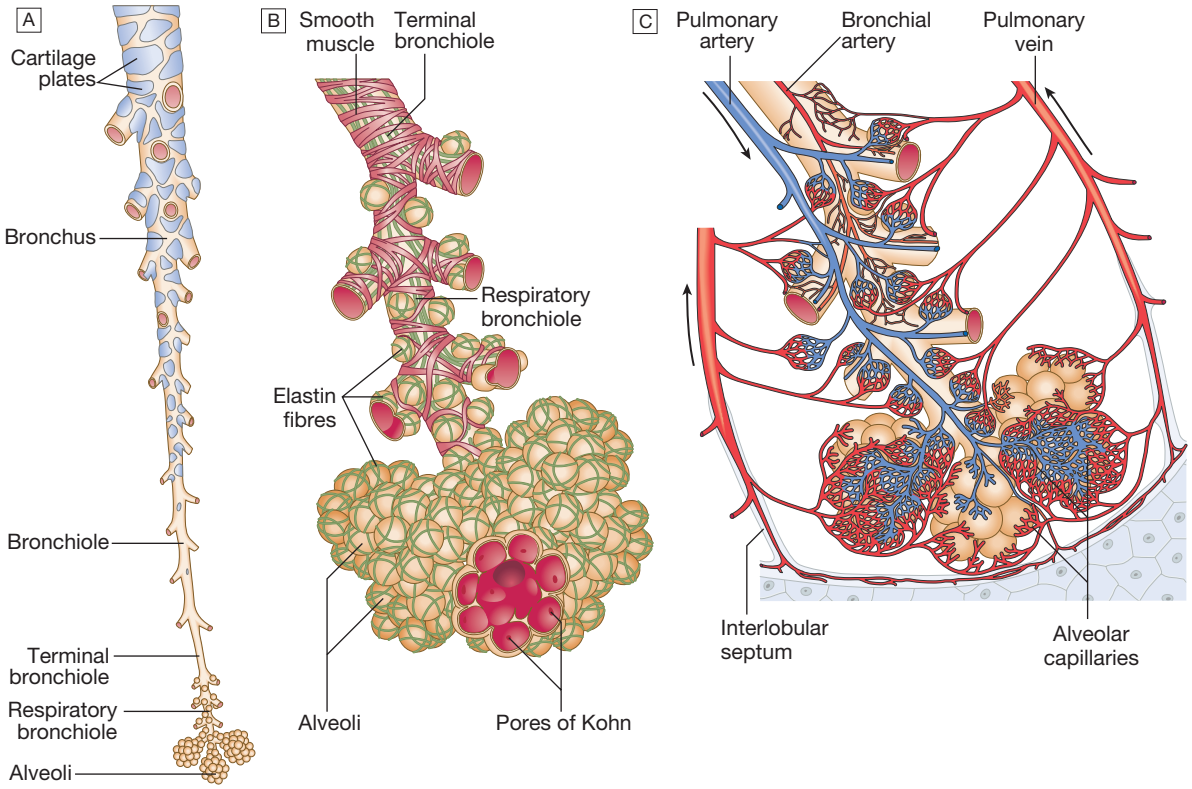

Fig. 19.2 Functional anatomy of the lung. A The tapering, branching bronchus is armoured against compression by plates of cartilage. The more distal bronchioles are collapsible, but held patent by surrounding elastic tissue. B The unit of lung supplied by a terminal bronchiole is called an acinus. The bronchiolar wall contains smooth muscle and elastin fibres. The latter also run through the alveolar walls. Gas exchange occurs in the alveoli, which are connected to each other by the pores of Kohn. C Vascular anatomy of an acinus. Both the pulmonary artery (carrying desaturated blood) and the bronchial artery (systemic supply to airway tissue) run along the bronchus. The venous drainage to the left atrium follows the interlobular septa. From www.Netter.com – see p. 731.

and clusters of alveoli. Here the air makes close contact with the blood in the pulmonary capillaries (gas-to-blood distance < 0.4 μm), and oxygen uptake and CO_2 excretion occur. The alveoli are lined with flattened epithelial cells (type I pneumocytes) and a few, more cuboidal, type II pneumocytes. The latter produce surfactant, which is a mixture of phospholipids that reduces surface tension and counteracts the tendency of alveoli to collapse under surface tension. Type II pneumocytes can divide to reconstitute type I pneumocytes after lung injury.

Lung mechanics

Healthy alveolar walls contain a fine network of elastin and collagen fibres (see Fig. 19.2). The volume of the lungs at the end of a tidal ('normal') breath out is called the functional residual capacity (FRC). At this volume, the inward elastic recoil of the lungs (resulting from elastin fibres and surface tension in the alveolar lining fluid) is balanced by the resistance of the chest wall to inward distortion from its resting shape, causing negative pressure in the pleural space. Elastin fibres allow the lung to be easily distended at physiological lung volumes, but collagen fibres cause increasing stiffness as full inflation is approached so that, in health, the maximum inspiratory volume is limited by the lung (rather than the chest wall). Within the lung, the weight of tissue compresses the dependent regions and distends the uppermost parts, so a greater portion of an inhaled breath passes to the basal regions, which also receive the greatest blood flow as a result of gravity. Elastin fibres in alveolar walls maintain small airway patency by radial traction on the airway walls. Even in health, however, these small airways narrow during expiration because they are surrounded by alveoli at higher pressure, but are prevented from collapsing by radial elastic traction. The volume that can be exhaled is thus limited purely by the capacity of the expiratory muscles to distort the chest wall inwards. In emphysema, loss of alveolar walls leaves the small airways unsupported, and their collapse on expiration causes air trapping and high end-expiratory volume (p. 673).

Control of breathing

The respiratory motor neurons in the posterior medulla oblongata are the origin of the respiratory cycle. Their activity is modulated by multiple external inputs in health and in disease (see Fig. 19.10, p. 657):

- Central chemoreceptors in the ventrolateral medulla sense the pH of the cerebrospinal fluid (CSF) and are indirectly stimulated by a rise in arterial PCO_2.
- The carotid bodies sense hypoxaemia but are mainly activated by arterial PO_2 values below 8 KPa (60 mmHg). They are also sensitised to hypoxia by raised arterial PCO_2.
- Muscle spindles in the respiratory muscles sense changes in mechanical load.

- Vagal sensory fibres from the lung may be stimulated by stretch, by inhaled toxins or by disease processes in the interstitium.
- Cortical (volitional) and limbic (emotional) influences can override the automatic control of breathing.

Ventilation/perfusion matching and the pulmonary circulation

To achieve optimal gas exchange within the lungs, the regional distribution of ventilation and perfusion must be matched. At segmental and subsegmental level, hypoxia constricts pulmonary arterioles and airway CO_2 dilates bronchi, helping to maintain good regional matching of ventilation and perfusion. Lung disease may create regions of relative underventilation or underperfusion, which disturb this regional matching, causing respiratory failure (p. 663). In addition to causing ventilation–perfusion mismatch, diseases that destroy capillaries or thicken the alveolar capillary membrane (e.g. emphysema or fibrosis) can impair gas diffusion directly.

The pulmonary circulation in health operates at low pressure (approximately 24/9 mmHg), and can accommodate large increases in flow with minimal rise in pressure, such as during exercise. Pulmonary hypertension occurs when vessels are destroyed by emphysema, obstructed by thrombus, involved in interstitial inflammation or thickened by pulmonary vascular disease. The right ventricle responds by hypertrophy, with right axis deviation and P pulmonale on the ECG. Pulmonary hypertension with hypoxia and hypercapnia is associated with generalised salt and water retention ('cor pulmonale'), with elevation of the jugular venous pressure (JVP) and peripheral oedema. This is thought to result mainly from a failure of the hypoxic and hypercapnic kidney to excrete sufficient salt and water.

Lung defences

Upper airway defences

Large airborne particles are trapped by nasal hairs, and smaller particles settling on the mucosa are cleared towards the oropharynx by the columnar ciliated epithelium which covers the turbinates and septum (Fig. 19.3). During cough, expiratory muscle effort against a closed glottis results in high intrathoracic pressure, which is then released explosively. The flexible posterior tracheal wall is pushed inwards by the high surrounding pressure, which reduces tracheal cross-section and thus maximises the airspeed to achieve effective expectoration. The larynx also acts as a sphincter, protecting the airway during swallowing and vomiting.

Lower airway defences

The sterility, structure and function of the lower airways are maintained by close cooperation between the innate and adaptive immune responses (pp. 72 and 76).

The innate response in the lungs is characterised by a number of non-specific defence mechanisms. Inhaled particulate matter is trapped in airway mucus and cleared by the mucociliary escalator. Cigarette smoke increases mucus secretion but reduces mucociliary clearance and predisposes towards lower respiratory tract infections, including pneumonia. Defective mucociliary transport is also a feature of several rare diseases, including Kartagener's syndrome, Young's syndrome and ciliary dysmotility syndrome, which are characterised by repeated sino-pulmonary infections and bronchiectasis.

Airway secretions contain an array of antimicrobial peptides (such as defensins, immunoglobulin A (IgA) and lysozyme), antiproteinases and antioxidants. Many assist with the opsonisation and killing of bacteria, and the regulation of the powerful proteolytic enzymes secreted by inflammatory cells. In particular, α_1-antiproteinase (A1Pi) regulates neutrophil elastase, and deficiency of this may be associated with premature emphysema.

19.1 Respiratory function in old age

- **Reserve capacity**: a significant reduction in function can occur with ageing with only minimal effect on normal breathing, but the ability to combat acute disease is reduced.
- **Decline in FEV_1**: the FEV_1/FVC (forced expiratory volume/forced vital capacity, p. 652) ratio falls by around 0.2% per year from 70% at the age of 40–45 years, due to a decline in elastic recoil in the small airways with age. Smoking accelerates this decline threefold on average. Symptoms usually occur only when FEV_1 drops below 50% of predicted.
- **Increasing ventilation–perfusion mismatch**: the reduction in elastic recoil causes a tendency for the small airways to collapse during expiration, particularly in dependent areas of the lungs, thus reducing ventilation.
- **Reduced ventilatory responses to hypoxia and hypercapnia**: older people may be less tachypnoeic for any given fall in PaO_2 or rise in $PaCO_2$.
- **Impaired defences against infection**: due to reduced numbers of glandular epithelial cells, which lead to a reduction in protective mucus.
- **Decline in maximum oxygen uptake**: due to a combination of impairments in muscle, and the respiratory and cardiovascular systems. This leads to a reduction in cardiorespiratory reserve and exercise capacity.
- **Loss of chest wall compliance**: due to reduced intervertebral disc spaces and ossification of the costal cartilages; respiratory muscle strength and endurance also decline. These changes only become important in the presence of other respiratory disease.

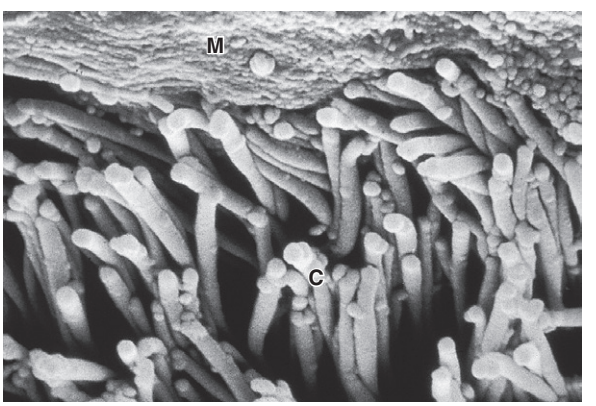

Fig. 19.3 The mucociliary escalator. Scanning electron micrograph of the respiratory epithelium showing large numbers of cilia (C) overlaid by the mucus 'raft' (M).

Macrophages engulf microbes, organic dusts and other particulate matter. They are unable to digest inorganic agents, such as asbestos or silica, which lead to their death and the release of powerful proteolytic enzymes that cause parenchymal damage. Neutrophil numbers in the airway are low, but the pulmonary circulation contains a marginated pool that may be recruited rapidly in response to bacterial infection. This may explain the prominence of lung injury in sepsis syndromes and trauma.

Adaptive immunity is characterised by the specificity of the response and the development of memory. Lung dendritic cells facilitate antigen presentation to T and B lymphocytes.

INVESTIGATION OF RESPIRATORY DISEASE

A detailed history, thorough examination and basic haematological and biochemical tests usually indicate the likely diagnosis and differential. A number of other investigations are normally required to confirm the diagnosis and/or monitor disease activity.

Imaging

The 'plain' chest X-ray

This is performed on the majority of patients suspected of having chest disease. A postero-anterior (PA) film provides information on the lung fields, heart, mediastinum, vascular structures and thoracic cage (Fig. 19.4). Additional information may be obtained from a lateral film, particularly if pathology is suspected behind the heart shadow or deep in the diaphragmatic sulci. An approach to interpreting the chest X-ray is given in Box 19.2, and common abnormalities are listed in Box 19.3.

19.2 How to interpret a chest X-ray

Name, date, orientation	Films are postero-anterior (PA) unless marked AP to denote that they are antero-posterior
Lung fields	Equal translucency? Check horizontal fissure from right hilum to sixth rib at the anterior axillary line Masses? Consolidation? Cavitation?
Lung apices	Check behind the clavicles: Masses? Consolidation? Cavitation?
Trachea	Central? (Midway between the clavicular heads) Paratracheal mass? Goitre?
Heart	Normal shape? Cardiothoracic ratio (should be < half the intrathoracic diameter) Retrocardiac mass?
Hila	Left should be higher than right Shape? (Should be concave laterally; if convex, consider mass or lymphadenopathy) Density?
Diaphragm	Right should be higher than left Hyperinflation? (No more than 10 ribs should be visible posteriorly above the diaphragm)
Costophrenic angles	Acute and well defined? (Pleural fluid or thickening, if not)
Soft tissues	Breast shadows in females Chest wall for masses or subcutaneous emphysema
Bones	Ribs, vertebrae, scapulae and clavicles Any fracture visible at bone margins or lucencies?

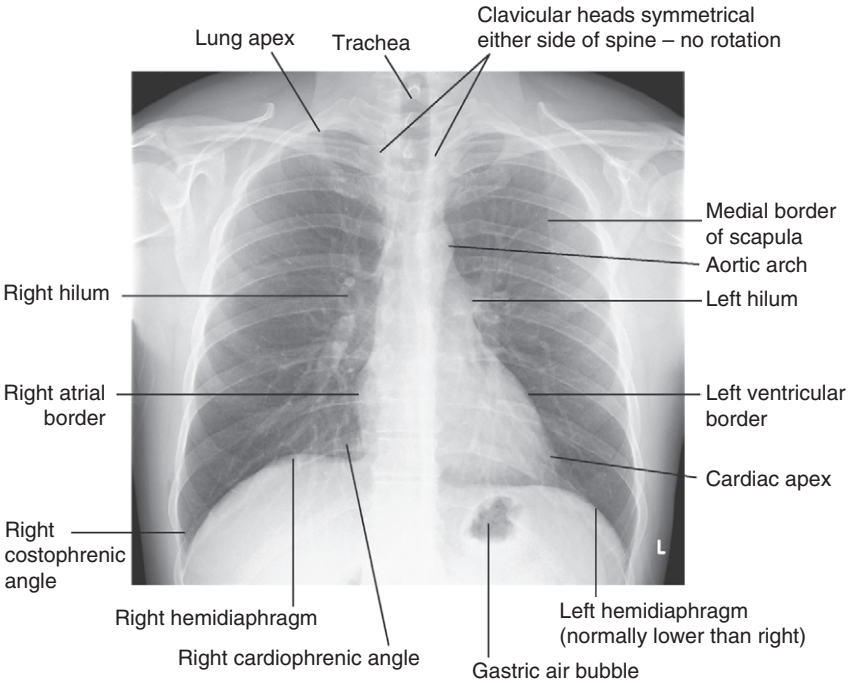

Fig. 19.4 The normal chest X-ray. The lung markings consist of branching and tapering lines radiating out from the hila. Where airways and vessels turn towards the film, they can appear as open or filled circles (see upper pole of right hilum). The scapulae may overlie the lung fields; trace the edge of bony structures to avoid mistaking them for pleural or pulmonary shadows. To check for hyperinflation, count the ribs; if more than 10 are visible posteriorly above the diaphragm, the lungs are hyperinflated. From Innes 2009 – see p. 731.

19.3 Common chest X-ray abnormalities

Pulmonary and pleural shadowing

- **Consolidation**: infection, infarction, inflammation, and rarely bronchoalveolar cell carcinoma
- **Lobar collapse**: mucus plugging, tumour, compression by lymph nodes
- **Solitary nodule**: see page 660
- **Multiple nodules**: miliary tuberculosis (TB), dust inhalation, metastatic malignancy, healed varicella pneumonia, rheumatoid disease
- **Ring shadows, tramlines and tubular shadows**: bronchiectasis
- **Cavitating lesions**: tumour, abscess, infarct, pneumonia (*Staphylococcus/Klebsiella*), granulomatosis with polyangiitis
- **Reticular, nodular and reticulonodular shadows**: diffuse parenchymal lung disease, infection
- **Pleural abnormalities**: fluid, plaques, tumour

Increased translucency

- Bullae
- Oligaemia
- Pneumothorax

Hilar abnormalities

- **Unilateral hilar enlargement:** TB, bronchial carcinoma, lymphoma
- **Bilateral hilar enlargement:** sarcoid, lymphoma, TB, silicosis

Other abnormalities

- Hiatus hernia
- Surgical emphysema

Increased shadowing may represent accumulation of fluid, lobar collapse or consolidation. Uncomplicated consolidation should not change the position of the mediastinum and the presence of an air bronchogram means that proximal bronchi are patent. Collapse (implying obstruction of the lobar bronchus) is accompanied by loss of volume and displacement of the mediastinum towards the affected side (Fig. 19.5).

The presence of ring shadows (thickened bronchi seen end-on), tramline shadows (thickened bronchi side-on) or tubular shadows (bronchi filled with secretions) suggests bronchiectasis, but computed tomography is a much more sensitive test than plain X-ray in bronchiectasis. The presence of pleural fluid is suggested by a dense basal shadow, which, in the erect patient, ascends towards the axilla (p. 645). In large pulmonary embolism, relative oligaemia may cause a lung field to appear abnormally dark.

Computed tomography

Computed tomography (CT) provides detailed images of the pulmonary parenchyma, mediastinum, pleura and bony structures. The displayed range of densities can be adjusted to highlight different structures, such as the lung parenchyma, the mediastinal vascular structures or bone. Sophisticated software facilitates three-dimensional reconstruction of the thorax and virtual bronchoscopy.

CT is superior to chest radiography in determining the position and size of a pulmonary lesion and whether calcification or cavitation is present. It is now routinely used in the assessment of patients with suspected lung

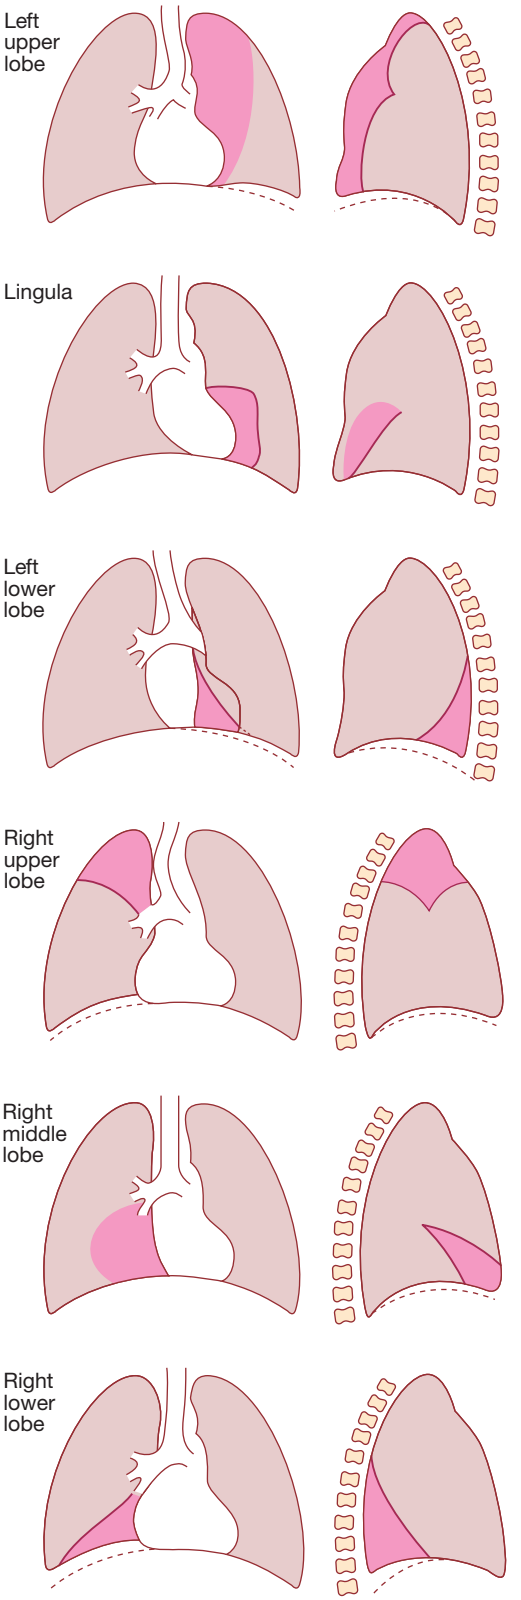

Fig. 19.5 Radiological features of lobar collapse caused by bronchial obstruction. The dotted line in the drawings represents the normal position of the diaphragm. The dark pink area represents the extent of shadowing seen on the X-ray.

cancer and facilitates guided percutaneous needle biopsy. Information on tumour stage may be gained by examining the mediastinum, liver and adrenal glands.

High-resolution CT (HRCT) uses thin sections to provide detailed images of the pulmonary parenchyma and is particularly useful in assessing diffuse parenchymal lung disease, identifying bronchiectasis (Fig. 19.30, p. 679), and assessing type and extent of emphysema.

Assessment of the pulmonary circulation

CT pulmonary angiography (CTPA) has become the investigation of choice in the diagnosis of pulmonary thromboembolism (see Fig. 19.69, p. 679), when it may either confirm the suspected embolism or highlight an alternative diagnosis. It has largely replaced the radioisotope-based ventilation–perfusion scan, although the latter continues to provide useful information in the pre-operative assessment of patients being considered for lung resection. In pulmonary hypertension, Doppler echocardiographic assessment of tricuspid regurgitant jets allows accurate non-invasive measurement of pulmonary artery pressure in most cases. Right heart catheterisation is still used in the investigation of patients with pulmonary hypertension in specialised centres, as it permits accurate measurement of response to pulmonary vasodilators.

Positron emission tomography

Positron emission tomography (PET) scanners exploit the ability of malignant tissue to absorb and metabolise glucose avidly. The radiotracer ^{18}F-fluorodeoxyglucose (FDG) is infused and rapidly taken up by malignant tissue. It is then phosphorylated but cannot be metabolised further, becoming 'trapped' in the cell. PET is useful in the investigation of pulmonary nodules, and in staging mediastinal lymph nodes and distal metastatic disease in patients with lung cancer. The negative predictive value is high; however, the positive predictive value is poor. Co-registration of PET and CT (PET-CT) enhances localisation and characterisation of metabolically active deposits (Fig. 19.6). Future advances will see the combination of PET and magnetic resonance imaging (MRI).

Ultrasound

Ultrasound is used to assess the pleural space for pleural fluid, which appears as a hypoechoic space. It also allows direct visualisation of the diaphragm and solid organs such as the liver, spleen and kidneys, thereby allowing safe pleural aspiration, biopsy and intercostal chest drain insertion. Ultrasound can also be used to guide needle biopsy of superficial lymph node or chest wall masses and provides useful information on the shape and movement of the diaphragm. Endobronchial ultrasound (EBUS) is described below.

Endoscopic examination

Laryngoscopy

The larynx may be inspected directly with a fibreoptic laryngoscope and this is useful in cases of suspected vocal cord dysfunction, when paradoxical movement of the vocal cords may mimic asthma. Left-sided lung tumours may involve the left recurrent laryngeal nerve, paralysing the left vocal cord and leading to a hoarse voice and a 'bovine' cough.

Bronchoscopy

The trachea and the first 3–4 generations of bronchi may be inspected using a flexible bronchoscope. Flexible bronchoscopy is usually performed under local anaesthesia with sedation, on an outpatient basis. Abnormal tissue in the bronchial lumen or wall can be biopsied, and bronchial brushings, washings or aspirates can be taken for cytological or bacteriological examination. Small biopsy specimens of lung tissue, taken by forceps passed through the bronchial wall (transbronchial biopsies), may be helpful in the diagnosis of bronchocentric disorders such as sarcoid, hypersensitivity pneumonitis and diffuse malignancy, but are generally too small to be of diagnostic value in other diffuse parenchymal pulmonary disease (p. 706). Transbronchial needle aspiration (TBNA) may be used to sample mediastinal lymph nodes and to stage lung cancer.

Rigid bronchoscopy requires general anaesthesia and is reserved for specific situations, such as massive haemoptysis or removal of foreign bodies (see Fig. 19.9, p. 655). Endobronchial laser therapy and endobronchial stenting may be easier with rigid bronchoscopy.

Assessment of the mediastinum

The sampling of mediastinal lymph nodes is essential in the diagnosis and staging of lung cancer and may confirm the diagnosis of non-malignant conditions, such as tuberculosis or sarcoidosis. Endobronchial

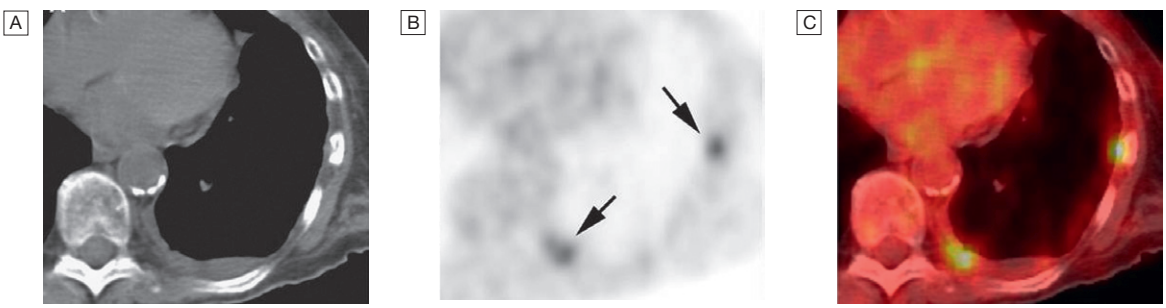

Fig. 19.6 Computed tomography and positron emission tomography combined to reveal intrathoracic metastases. A In a patient with lung cancer, CT shows some posterior pleural thickening. B PET scanning reveals FDG uptake in two pleural lesions (arrows). C The lesions are highlighted in yellow in the combined PET/CT image. From http://radiology.rsnajnls.org – see p. 731.

ultrasound (EBUS), using a specialised bronchoscope, allows directed needle aspiration from peribronchial nodes and is used increasingly to determine disease extent. Lymph nodes down to the main carina can also be sampled using a mediastinoscope passed through a small incision at the suprasternal notch under general anaesthetic. Lymph nodes in the lower mediastinum may be biopsied via the oesophagus using endoscopic ultrasound (EUS), an oesophageal endoscope equipped with an ultrasound transducer and biopsy needle.

Investigation of pleural disease

Core biopsy of the pleura, guided by either ultrasound or CT, has largely replaced the traditional 'blind' method of pleural biopsy using an Abram's needle. Thoracoscopy, which involves the insertion of an endoscope through the chest wall, facilitates biopsy under direct vision and is performed by many surgeons and an increasing number of physicians.

Immunological and serological tests

The presence of pneumococcal antigen (revealed by counter-immunoelectrophoresis) in sputum, blood or urine may be of diagnostic importance in pneumonia. Influenza viruses can be detected in throat swab samples by fluorescent antibody techniques. In blood, high or rising antibody titres to specific organisms (such as *Legionella*, *Mycoplasma*, *Chlamydia* or viruses) may eventually clinch a diagnosis suspected on clinical grounds but early diagnosis of *Legionella* is best done by urine antigen testing. Precipitating antibodies may indicate a reaction to fungi such as *Aspergillus* (p. 697) or to antigens involved in hypersensitivity pneumonitis (p. 719). Total levels of immunoglobulin E (IgE), and levels of IgE directed against specific antigens, can be useful in assessing the contribution of allergy to respiratory disease.

Skin tests

The tuberculin test (p. 695) may be of value in the diagnosis of tuberculosis. Skin hypersensitivity tests are useful in the investigation of allergic diseases (p. 89).

Microbiological investigations

Sputum, pleural fluid, throat swabs, blood, and bronchial washings and aspirates can be examined for bacteria, fungi and viruses. In some cases, as when *Mycobacterium tuberculosis* is isolated, the information is diagnostically conclusive but, in others, the findings must be interpreted in conjunction with the results of clinical and radiological examination.

The use of hypertonic saline to induce expectoration of sputum is useful in facilitating the collection of specimens for microbiology, particularly in patients in whom more invasive procedures, such as bronchoscopy, are not possible. The technique also allows assessment of the inflammatory cell population of the airway, which is a useful research tool in many conditions, including asthma, COPD and interstitial lung disease.

Histopathology and cytology

Histopathological examination of biopsies of pleura, lymph node or lung often allows a 'tissue diagnosis' to be made. This is particularly important in suspected malignancy or in characterising the pathological changes in interstitial lung disease. Important causative organisms, such as *M. tuberculosis*, *Pneumocystis jirovecii* or fungi, may be identified in bronchial washings, brushings or transbronchial biopsies.

Cytological examination of exfoliated cells in pleural fluid or bronchial brushings and washings, or of fine needle aspirates from lymph nodes or pulmonary lesions, can support a diagnosis of malignancy but, if this is indeterminate, a larger tissue biopsy is often necessary. Differential cell counts in bronchial lavage fluid may help to distinguish pulmonary changes due to sarcoidosis (p. 709) from those caused by idiopathic pulmonary fibrosis (p. 706) or hypersensitivity pneumonitis (p. 719).

Respiratory function testing

Respiratory function tests are used to aid diagnosis, assess functional impairment, and monitor treatment or progression of disease. Airway narrowing, lung volume and gas exchange capacity are quantified and compared with normal values adjusted for age, gender, height and ethnic origin. In diseases characterised by airway narrowing (e.g. asthma, bronchitis and emphysema), maximum expiratory flow is limited by dynamic compression of small intrathoracic airways, some of which may close completely during expiration, limiting the volume that can be expired ('obstructive' defect). Hyperinflation of the chest results, and can become extreme if elastic recoil is also lost due to parenchymal destruction, as in emphysema. In contrast, diseases that cause interstitial inflammation and/or fibrosis lead to progressive loss of lung volume ('restrictive' defect) with normal expiratory flow rates. Typical laboratory traces are illustrated in Figure 19.7.

Measurement of airway obstruction

Airway narrowing is assessed by asking patients to blow out as hard and as fast as they can into a peak flow meter or a spirometer. Peak flow meters are cheap and convenient for home monitoring of peak expiratory flow (PEF) in the detection and monitoring of asthma, but results are effort-dependent. More accurate and reproducible measures are obtained by inhaling fully, then exhaling at maximum effort into a spirometer. The forced expired volume in 1 second (FEV_1) is the volume exhaled in the first second, and the forced vital capacity (FVC) is the total volume exhaled. FEV_1 is disproportionately reduced in airflow obstruction, resulting in FEV_1/FVC ratios of less than 70%. In this situation, spirometry should be repeated following inhaled short-acting β_2-adrenoceptor agonists (e.g. salbutamol); a large improvement in FEV_1 (over 400 mL) and variability in peak flow over time are features of asthma (p. 668).

To distinguish large airway narrowing (e.g. tracheal stenosis or compression) from small airway narrowing, flow/volume loops are recorded using spirometry. These display flow in relation to lung volume (rather than time) during maximum expiration and inspiration, and the pattern of flow reveals the site of airflow obstruction (see Fig. 19.7).

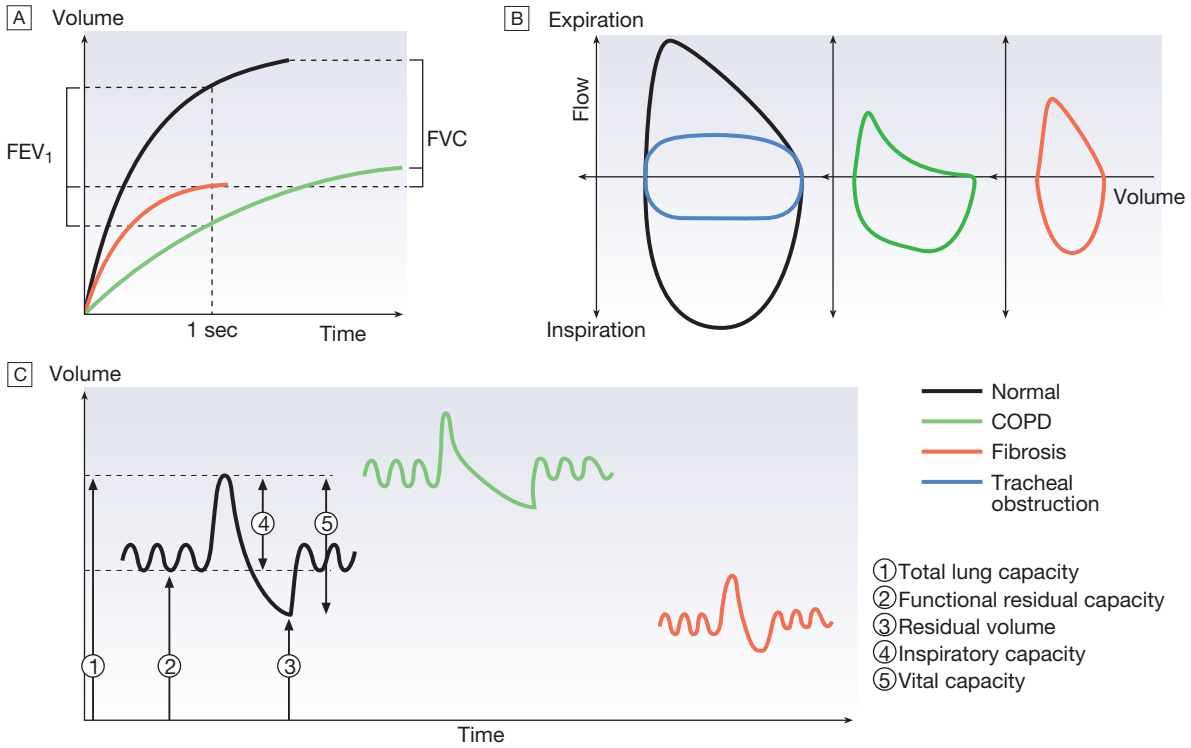

Fig. 19.7 Respiratory function tests in health and disease. A Volume/time traces from forced expiration in a normal subject, in COPD and in fibrosis. COPD causes slow, prolonged and limited exhalation. In fibrosis, forced expiration results in rapid expulsion of a reduced forced vital capacity (FVC). Forced expiratory volume (FEV_1) is reduced in both diseases but is disproportionately reduced, compared to FVC, in COPD. B The same data plotted as flow/volume loops. In COPD, collapse of intrathoracic airways limits flow, particularly during mid- and late expiration. The blue trace illustrates large airway obstruction, which particularly limits peak flow rates. C Lung volume measurement. Volume/time graphs during quiet breathing with a single maximal breath in and out. COPD causes hyperinflation with increased residual volume. Fibrosis causes a proportional reduction in all lung volumes.

Lung volumes

Tidal volume and vital capacity (VC – the maximum amount of air that can be expelled from the lungs after the deepest possible breath) can be measured by spirometry. Total lung capacity (TLC – the total amount of air in the lungs after taking the deepest breath possible) can be measured by asking the patient to rebreathe an inert non-absorbed gas (usually helium) and recording how much the test gas is diluted by lung gas. This measures the volume of intrathoracic gas that mixes with tidal breaths. Alternatively, lung volume may be measured by body plethysmography, which determines the pressure/volume relationship of the thorax. This method measures total intrathoracic gas volume, including poorly ventilated areas such as bullae.

Transfer factor

To measure the capacity of the lungs to exchange gas, patients inhale a test mixture of 0.3% carbon monoxide, which is taken up avidly by haemoglobin in pulmonary capillaries. After a short breath-hold, the rate of disappearance of CO into the circulation is calculated from a sample of expirate, and expressed as the TL_{CO} or carbon monoxide transfer factor. Helium is also included in the test breath to allow calculation of the volume of lung examined by the test breath. Transfer factor expressed per unit lung volume is termed K_{CO}. Common respiratory function abnormalities are summarised in Box 19.4.

19.4 How to interpret respiratory function abnormalities

	Asthma	Chronic bronchitis	Emphysema	Pulmonary fibrosis
FEV_1	↓↓	↓↓	↓↓	↓
VC	↓	↓	↓	↓↓
FEV_1/VC	↓	↓	↓	→/↑
TL_{CO}	→	→	↓↓	↓↓
K_{CO}	→/↑	→	↓	→/↓
TLC	→/↑	↑	↑↑	↓
RV	→/↑	↑	↑↑	↓

(RV = residual volume; see text for other abbreviations)

Arterial blood gases and oximetry

The measurement of hydrogen ion concentration, PaO_2 and $PaCO_2$, and derived bicarbonate concentration in an arterial blood sample is essential to assess the degree and type of respiratory failure, and for measuring acid–base status. This is discussed in detail on pages 663 and 442. Interpretation of results is made easier by blood gas diagrams (Fig. 19.8), which indicate whether any acidosis or alkalosis is due to acute or chronic respiratory derangements of $PaCO_2$, or to metabolic causes. Pulse oximeters with finger or ear probes measure the

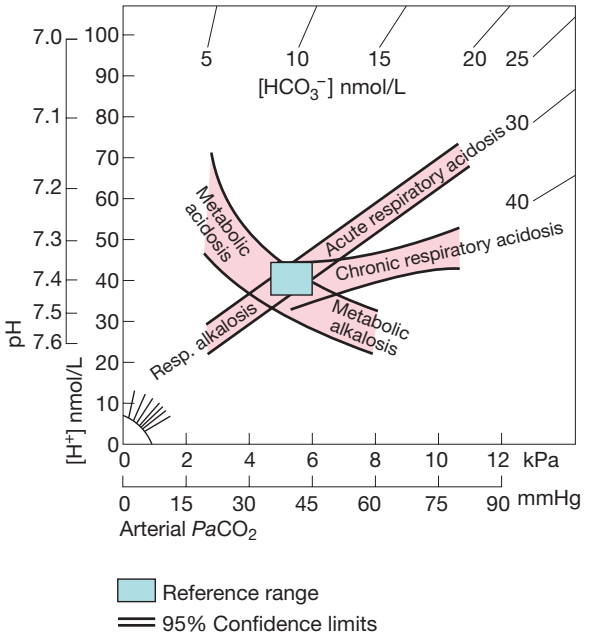

Fig. 19.8 Changes in blood [H⁺], $PaCO_2$ and plasma [HCO_3^-] in acid–base disorders. The rectangle indicates normal limits for [H⁺] and $PaCO_2$. The bands represent 95% confidence limits of single disturbances in human blood. To determine the likely cause of an acid–base disorder, plot the values of [H⁺] and $PaCO_2$ from an arterial blood gas measurement. The diagram indicates whether any acidosis or alkalosis results primarily from a respiratory disorder of $PaCO_2$ or from a metabolic derangement. Adapted from Flenley 1971 – see p. 732.

difference in absorbance of light by oxygenated and deoxygenated blood to calculate its oxygen saturation (SaO_2). This allows non-invasive continuous assessment of oxygen saturation in patients, which is useful in assessing hypoxaemia and its response to therapy.

Exercise tests

Resting measurements may be unhelpful in early disease or in patients complaining only of exercise-induced symptoms. Exercise testing with spirometry before and after can help demonstrate exercise-induced asthma. Walk tests include the self-paced 6-minute walk and the externally paced incremental 'shuttle' test, where patients walk at increasing pace between two cones 10 m apart. These provide simple, repeatable assessments of disability and response to treatment. Cardiopulmonary bicycle exercise testing, with measurement of metabolic gas exchange, ventilation and ECG changes, is useful for quantifying exercise limitation and detecting occult cardiovascular or respiratory limitation in a breathless patient.

PRESENTING PROBLEMS IN RESPIRATORY DISEASE

Cough

Cough is the most frequent symptom of respiratory disease and is caused by stimulation of sensory nerves in the mucosa of the pharynx, larynx, trachea and bronchi. Acute sensitisation of the normal cough reflex occurs in a number of conditions, and it is typically induced by changes in air temperature or exposure to irritants, such as cigarette smoke or perfumes. The characteristics of cough originating at various levels of the respiratory tract are detailed in Box 19.5.

19.5 Cough

Origin	Common causes	Clinical features
Pharynx	Post-nasal drip	History of chronic rhinitis
Larynx	Laryngitis, tumour, whooping cough, croup	Voice or swallowing altered, harsh or painful cough Paroxysms of cough, often associated with stridor
Trachea	Tracheitis	Raw retrosternal pain with cough
Bronchi	Bronchitis (acute) and COPD Asthma Eosinophilic bronchitis Bronchial carcinoma	Dry or productive, worse in mornings Usually dry, worse at night Features similar to asthma but AHR absent Persistent (often with haemoptysis)
Lung parenchyma	Tuberculosis Pneumonia Bronchiectasis Pulmonary oedema Interstitial fibrosis	Productive (often with haemoptysis) Dry initially, productive later Productive, changes in posture induce sputum production Often at night (may be productive of pink, frothy sputum) Dry and distressing
Drug side-effect	ACE inhibitors	Dry cough

(ACE = angiotensin-converting enzyme; AHR = airway hyper-reactivity; COPD = chronic obstructive pulmonary disease)
Based on Crompton GK. The respiratory system. In: Munro JF, Campbell IW. Macleod's clinical examination. 10th edn. Edinburgh: Churchill Livingstone; 2000 (p. 119); copyright Elsevier.

The explosive quality of a normal cough is lost in patients with respiratory muscle paralysis or vocal cord palsy. Paralysis of a single vocal cord gives rise to a prolonged, low-pitched, inefficient 'bovine' cough accompanied by hoarseness. Coexistence of an inspiratory noise (stridor) indicates partial obstruction of a major airway (e.g. laryngeal oedema, tracheal tumour, scarring, compression or inhaled foreign body) and requires urgent investigation and treatment. Sputum production is common in patients with acute or chronic cough, and its nature and appearance can provide clues to the aetiology (p. 644).

Causes of cough

Acute transient cough is most commonly caused by viral lower respiratory tract infection, post-nasal drip resulting from rhinitis or sinusitis, aspiration of a foreign

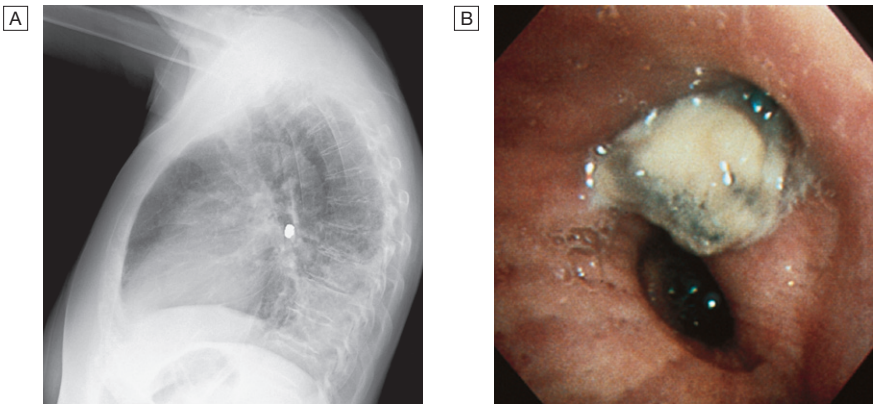

Fig. 19.9 Inhaled foreign body. A Chest X-ray showing a tooth lodged in a main bronchus. B Bronchoscopic appearance of inhaled foreign body (tooth) with a covering mucous film.

body, or throat-clearing secondary to laryngitis or pharyngitis. When cough occurs in the context of more serious diseases, such as pneumonia, aspiration, congestive heart failure or pulmonary embolism, it is usually easy to diagnose from other clinical features.

Patients with chronic cough present more of a challenge, especially when physical examination, chest X-ray and lung function studies are normal. In this context, it is most often explained by cough-variant asthma (where cough may be the principal or exclusive clinical manifestation), post-nasal drip secondary to nasal or sinus disease, or gastro-oesophageal reflux with aspiration. Diagnosis of the latter may require ambulatory oesophageal pH monitoring or a prolonged trial of anti-reflux therapy (p. 865). Between 10% and 15% of patients (particularly women) taking angiotensin-converting enzyme (ACE) inhibitors develop a drug-induced chronic cough. *Bordetella pertussis* infection in adults (p. 682) can also result in protracted cough and should be suspected in those in close contact with children. While most patients with a bronchogenic carcinoma have an abnormal chest X-ray on presentation, fibreoptic bronchoscopy or thoracic CT is advisable in most adults (especially smokers) with otherwise unexplained cough of recent onset, as this may reveal a small endobronchial tumour or unexpected foreign body (Fig. 19.9). In a small percentage of patients, dry cough may be the presenting feature of interstitial lung disease.

Breathlessness

Breathlessness or dyspnoea can be defined as the feeling of an uncomfortable need to breathe. It is unusual among sensations, as it has no defined receptors, no localised representation in the brain, and multiple causes both in health (e.g. exercise) and in diseases of the lungs, heart or muscles.

Pathophysiology

Stimuli to breathing resulting from disease processes are shown in Figure 19.10. Respiratory diseases can stimulate breathing and dyspnoea by:

- stimulating intrapulmonary sensory nerves (e.g. pneumothorax, interstitial inflammation and pulmonary embolus)
- increasing the mechanical load on the respiratory muscles (e.g. airflow obstruction or pulmonary fibrosis)
- causing hypoxia, hypercapnia or acidosis, which stimulate chemoreceptors.

In cardiac failure, pulmonary congestion reduces lung compliance and can also obstruct the small airways. Reduced cardiac output also limits oxygen supply to the skeletal muscles during exercise, causing early lactic acidaemia and further stimulating breathing via the central chemoreceptors.

Breathlessness and the effects of treatment can be quantified using a symptom scale. Patients tend to report breathlessness in proportion to the sum of the above stimuli to breathe. Individual patients differ greatly in the intensity of breathlessness reported for a given set of circumstances, but breathlessness scores during exercise within individuals are reproducible, and can be used to monitor the effects of therapy.

Differential diagnosis

Patients with breathlessness present either with chronic exertional symptoms or as an emergency with acute breathlessness, when symptoms are prominent even at rest. The causes can be classified accordingly (Box 19.6).

Chronic exertional breathlessness

The cause of breathlessness is often apparent from a careful clinical history. Key questions include:

How is your breathing at rest and overnight?

In COPD, there is a fixed, structural limit to maximum ventilation, and a tendency for progressive hyperinflation during exercise. Breathlessness is mainly apparent when walking, and patients usually report minimal symptoms at rest and overnight. In contrast, patients with significant asthma are often woken from their sleep by breathlessness with chest tightness and wheeze.

Orthopnoea, however, is common in COPD, as well as in heart disease, because airflow obstruction is made worse by cranial displacement of the diaphragm by the abdominal contents when recumbent, so many patients choose to sleep propped up. It may thus not be a useful differentiating symptom, unless there is a clear history of previous angina or infarction to suggest cardiac disease.

How much can you do on a good day?

Noting 'breathless on exertion' is not enough; the approximate distance the patient can walk on the level should be documented, along with capacity to climb

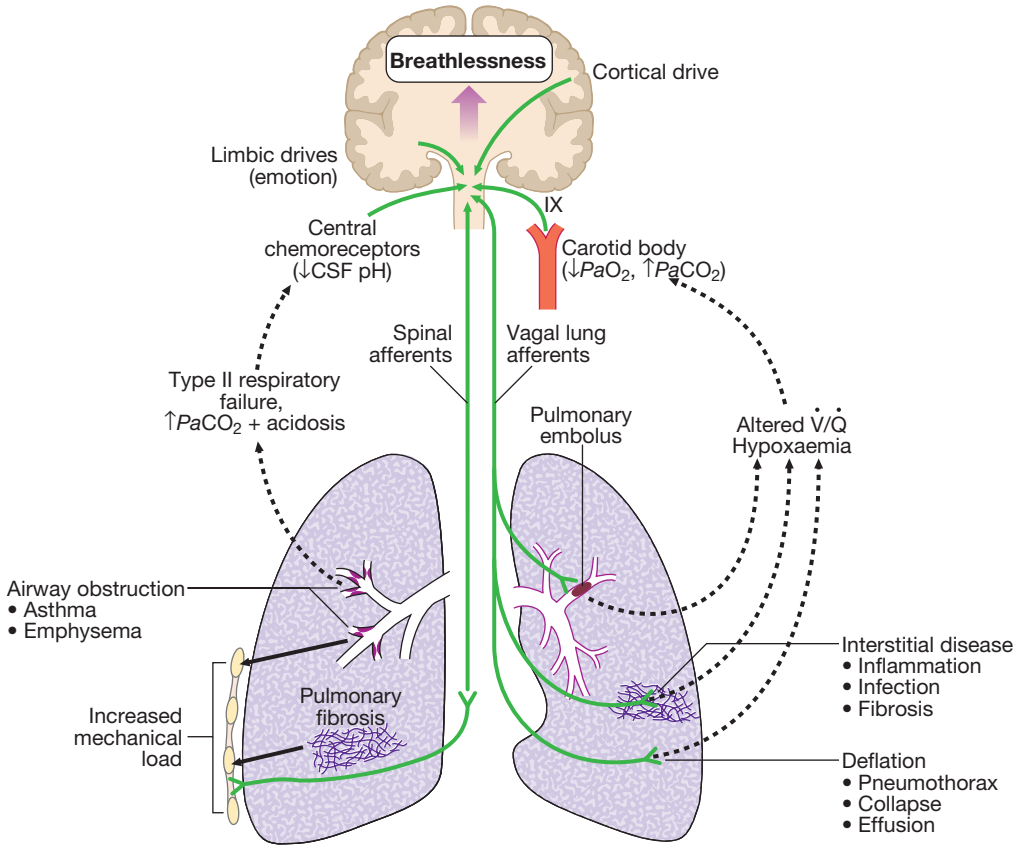

Fig. 19.10 Respiratory stimuli contributing to breathlessness. Mechanisms by which disease can stimulate the respiratory motor neurons in the medulla. Breathlessness is usually felt in proportion to the sum of these stimuli. Further explanation is given on page 543. ($\dot{V}/\dot{Q}$ = ventilation/perfusion match)

19.6 Causes of breathlessness

System	Acute dyspnoea	Chronic exertional dyspnoea
Cardiovascular	*Acute pulmonary oedema (p. 543)	Chronic heart failure (p. 543) Myocardial ischaemia (angina equivalent) (p. 544)
Respiratory	*Acute severe asthma *Acute exacerbation of COPD *Pneumothorax *Pneumonia *Pulmonary embolus ARDS Inhaled foreign body (especially in children) Lobar collapse Laryngeal oedema (e.g. anaphylaxis)	*COPD *Chronic asthma Bronchial carcinoma Interstitial lung disease (sarcoidosis, fibrosing alveolitis, extrinsic allergic alveolitis, pneumoconiosis) Chronic pulmonary thromboembolism Lymphatic carcinomatosis (may cause intolerable breathlessness) Large pleural effusion(s)
Others	Metabolic acidosis (e.g. diabetic ketoacidosis, lactic acidosis, uraemia, overdose of salicylates, ethylene glycol poisoning) Psychogenic hyperventilation (anxiety or panic-related)	Severe anaemia Obesity Deconditioning

*Denotes a common cause. (ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)

inclines or stairs. Variability within and between days is a hallmark of asthma; in mild asthma, the patient may be free of symptoms and signs when well. Gradual, progressive loss of exercise capacity over months and years, with consistent disability over days, is typical of COPD. When asthma is suspected, the degree of variability is best documented by home peak flow monitoring.

Relentless, progressive breathlessness that is also present at rest, often accompanied by a dry cough, suggests interstitial fibrosis. Impaired left ventricular function can also cause chronic exertional breathlessness, cough and wheeze. A history of angina, hypertension or myocardial infarction raises the possibility of a cardiac cause. This may be confirmed by a displaced apex beat,

a raised JVP and cardiac murmurs (although these signs can occur in severe cor pulmonale). The chest X-ray may show cardiomegaly, and an electrocardiogram (ECG) and echocardiogram may provide evidence of left ventricular disease. Measurement of arterial blood gases may help, as, in the absence of an intracardiac shunt or pulmonary oedema, the PaO_2 in cardiac disease is normal and the $PaCO_2$ is low or normal.

Did you have breathing problems in childhood or at school?

When present, a history of childhood wheeze increases the likelihood of asthma, although this history may be absent in late-onset asthma. A history of atopic allergy also increases the likelihood of asthma.

Do you have other symptoms along with your breathlessness?

Digital or perioral paraesthesiae and a feeling that 'I cannot get a deep enough breath in' are typical features of psychogenic hyperventilation, but this cannot be diagnosed until investigations have excluded other potential causes. Additional symptoms include lightheadedness, central chest discomfort or even carpopedal spasm due to acute respiratory alkalosis. These alarming symptoms may provoke further anxiety and exacerbate hyperventilation. Psychogenic breathlessness rarely disturbs sleep, frequently occurs at rest, may be provoked by stressful situations and may even be relieved by exercise. The Nijmegen questionnaire can be used to score some of the typical symptoms of hyperventilation (Box 19.7). Arterial blood gases show normal PO_2, low PCO_2 and alkalosis.

Pleuritic chest pain in a patient with chronic breathlessness, particularly if it occurs in more than one site over time, should raise suspicion of thromboembolic disease. Thromboembolism may occasionally present as chronic breathlessness with no other specific features, and should always be considered before a diagnosis of psychogenic hyperventilation is made.

Morning headache is an important symptom in patients with breathlessness, as it may signal the onset of carbon dioxide retention and respiratory failure. This is particularly significant in patients with musculoskeletal disease impairing respiratory function (e.g. kyphoscoliosis or muscular dystrophy).

Acute severe breathlessness

This is one of the most common and dramatic medical emergencies. The history and a rapid but careful examination will usually suggest a diagnosis which can be confirmed by routine investigations, including chest X-ray, ECG and arterial blood gases. Specific features that aid the diagnosis of the important causes are shown in Box 19.8.

19.7 Factors suggesting psychogenic hyperventilation

- 'Inability to take a deep breath'
- Frequent sighing/erratic ventilation at rest
- Short breath-holding time in the absence of severe respiratory disease
- Difficulty in performing and/or inconsistent spirometry measures
- High score (over 26) on Nijmegen questionnaire
- Induction of symptoms during submaximal hyperventilation
- Resting end-tidal $CO_2 < 4.5\%$
- Associated digital paraesthesiae

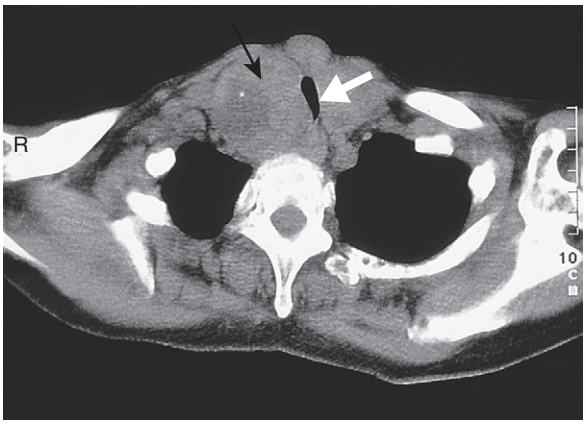

Fig. 19.11 CT showing retrosternal multinodular goitre (small arrow) causing acute severe breathlessness and stridor due to tracheal compression (large arrow).

History

It is important to establish the rate of onset and severity of the breathlessness and whether associated cardiovascular symptoms (chest pain, palpitations, sweating and nausea) or respiratory symptoms (cough, wheeze, haemoptysis, stridor – Fig. 19.11) are present. A previous history of repeated episodes of left ventricular failure, asthma or exacerbations of COPD is valuable. In the severely ill patient, it may be necessary to obtain the history from accompanying witnesses. In children, the possibility of inhalation of a foreign body (see Fig. 19.9) or acute epiglottitis should always be considered.

Clinical assessment

The following should be assessed and documented:

- level of consciousness
- degree of central cyanosis
- evidence of anaphylaxis (urticaria or angioedema)
- patency of the upper airway
- ability to speak (in single words or sentences)
- cardiovascular status (heart rate and rhythm, blood pressure and degree of peripheral perfusion).

Pulmonary oedema is suggested by pink, frothy sputum and bi-basal crackles; asthma or COPD by wheeze and prolonged expiration; pneumothorax by a silent resonant hemithorax; and pulmonary embolus by severe breathlessness with normal breath sounds. The peak expiratory flow should be measured whenever possible. Leg swelling may suggest cardiac failure or, if asymmetrical, venous thrombosis. Arterial blood gases, a chest X-ray and an ECG should be obtained to confirm the clinical diagnosis, and high concentrations of oxygen given pending results. Urgent endotracheal intubation (p. 194) may become necessary if the conscious level declines or if severe respiratory acidosis is present.

19.8 Differential diagnosis of acute breathlessness

Condition	History	Signs	CXR	ABG	ECG
Pulmonary oedema	Chest pain, palpitations, orthopnoea, cardiac history*	Central cyanosis, ↑JVP, sweating, cool extremities, basal crackles*	Cardiomegaly, oedema/pleural effusions*	↓PaO_2 ↓$PaCO_2$	Sinus tachycardia, ischaemia*, arrhythmia
Massive pulmonary embolus	Risk factors, chest pain, pleurisy, syncope*, dizziness*	Central cyanosis, ↑JVP*, absence of signs in the lung*, shock (tachycardia, hypotension)	Often normal Prominent hilar vessels, oligaemic lung fields*	↓PaO_2 ↓$PaCO_2$	Sinus tachycardia, RBBB, $S_1Q_3T_3$ pattern ↑T(V_1–V_4)
Acute severe asthma	History of asthma, asthma medications, wheeze*	Tachycardia, pulsus paradoxus, cyanosis (late), JVP →*, ↓peak flow, wheeze*	Hyperinflation only (unless complicated by pneumothorax)*	↓PaO_2 ↓$PaCO_2$ (↑$PaCO_2$ in extremis)	Sinus tachycardia (bradycardia in extremis)
Acute exacerbation of COPD	Previous episodes*, smoker. If in type II respiratory failure, may be drowsy	Cyanosis, hyperinflation*, signs of CO_2 retention (flapping tremor, bounding pulses)*	Hyperinflation*, bullae, complicating pneumothorax	↓ or ↓↓PaO_2 ↑$PaCO_2$ in type II failure ± ↑H^+, ↑HCO_3 in chronic type II failure	Normal, or signs of right ventricular strain
Pneumonia	Prodromal illness*, fever*, rigors*, pleurisy*	Fever, confusion, pleural rub*, consolidation*, cyanosis (if severe)	Pneumonic consolidation*	↓PaO_2 ↓$PaCO_2$ (↑ in extremis)	Tachycardia
Metabolic acidosis	Evidence of diabetes mellitus or renal disease, aspirin or ethylene glycol overdose	Fetor (ketones), hyperventilation without heart or lung signs*, dehydration*, air hunger	Normal	PaO_2 normal ↓↓$PaCO_2$, ↑H^+	
Psychogenic	Previous episodes, digital or perioral dysaesthesia	No cyanosis, no heart or lung signs, carpopedal spasm	Normal	PaO_2 normal* ↓↓$PaCO_2$, ↓H^+*	

*Valuable discriminatory feature. (ABG = arterial blood gases; RBBB = right bundle branch block)

Chest pain

Chest pain is a frequent manifestation of both cardiac (p. 539) and respiratory disease (Box 19.9). Pleurisy, a sharp chest pain aggravated by deep breathing or coughing, is a common feature of pulmonary infection or infarction; it may also occur with malignancy. On examination, rib movement may be restricted and a pleural rub may be present. Malignant involvement of the chest wall or ribs can cause gnawing, continuous local pain in the chest wall. Central chest pain suggests heart disease but also occurs with tumours affecting the mediastinum, oesophageal disease (p. 865) or disease of the thoracic aorta (p. 603). Massive pulmonary embolus may cause ischaemic cardiac pain, as well as severe breathlessness. Tracheitis produces raw upper retrosternal pain, exacerbated by the accompanying cough. Musculoskeletal chest wall pain is usually exacerbated by movement and associated with local tenderness.

Haemoptysis

Coughing up blood, irrespective of the amount, is an alarming symptom and patients nearly always seek medical advice. Care should be taken to establish that it is true haemoptysis and not haematemesis, or gum or nose bleeding. Haemoptysis must always be assumed to have a serious cause until this is excluded (Box 19.10).

Many episodes of haemoptysis remain unexplained, even after full investigation, and are likely to be due to simple bronchial infection. A history of repeated small haemoptysis, or blood-streaking of sputum, is highly suggestive of bronchial carcinoma. Fever, night sweats and weight loss suggest tuberculosis. Pneumococcal pneumonia often causes 'rusty'-coloured sputum but can cause frank haemoptysis, as can all suppurative pneumonic infections, including lung abscess (p. 687). Bronchiectasis (p. 678) and intracavitary mycetoma (p. 698) can cause catastrophic bronchial haemorrhage, and in these patients there may be a history of previous tuberculosis or pneumonia in early life. Finally, pulmonary thromboembolism is a common cause of haemoptysis and should always be considered.

Physical examination may reveal additional clues. Finger clubbing suggests bronchial carcinoma or bronchiectasis; other signs of malignancy, such as cachexia, hepatomegaly and lymphadenopathy, should also be sought. Fever, pleural rub and signs of consolidation occur in pneumonia or pulmonary infarction; a minority of patients with pulmonary infarction also have unilateral leg swelling or pain suggestive of deep venous thrombosis. Rashes, haematuria and digital infarcts

19.9 Differential diagnosis of chest pain

Central

Cardiac
- Myocardial ischaemia (angina)
- Myocardial infarction
- Myocarditis
- Pericarditis
- Mitral valve prolapse syndrome

Aortic
- Aortic dissection
- Aortic aneurysm

Oesophageal
- Oesophagitis
- Oesophageal spasm
- Mallory–Weiss syndrome

Massive pulmonary embolus

Mediastinal
- Tracheitis
- Malignancy

Anxiety/emotion[1]

Peripheral

Lungs/pleura
- Pulmonary infarct
- Pneumonia
- Pneumothorax
- Malignancy
- Tuberculosis
- Connective tissue disorders

Musculoskeletal[2]
- Osteoarthritis
- Rib fracture/injury
- Costochondritis (Tietze's syndrome)
- Intercostal muscle injury
- Epidemic myalgia (Bornholm disease)

Neurological
- Prolapsed intervertebral disc
- Herpes zoster
- Thoracic outlet syndrome

[1]May also cause peripheral chest pain. [2]Can sometimes cause central chest pain.

19.10 Causes of haemoptysis

Bronchial disease
- Carcinoma*
- Bronchiectasis*
- Acute bronchitis*
- Bronchial adenoma
- Foreign body

Parenchymal disease
- Tuberculosis*
- Suppurative pneumonia
- Parasites (e.g. hydatid disease, flukes)
- Lung abscess
- Trauma
- Actinomycosis
- Mycetoma

Lung vascular disease
- Pulmonary infarction*
- Goodpasture's syndrome (p. 497)
- Polyarteritis nodosa
- Idiopathic pulmonary haemosiderosis

Cardiovascular disease
- Acute left ventricular failure*
- Mitral stenosis
- Aortic aneurysm

Blood disorders
- Leukaemia
- Haemophilia
- Anticoagulants

*More common causes.

point to an underlying systemic disease, such as a vasculitis, which may be associated with haemoptysis.

Management

In severe acute haemoptysis, the patient should be nursed upright (or on the side of the bleeding, if this is known), given high-flow oxygen and resuscitated as required. Bronchoscopy in the acute phase is difficult and often merely shows blood throughout the bronchial tree. If radiology shows an obvious central cause, then rigid bronchoscopy under general anaesthesia may allow intervention to stop bleeding; however, the source often cannot be visualised. Intubation with a divided endotracheal tube may allow protected ventilation of the unaffected lung to stabilise the patient. Bronchial arteriography and embolisation (Fig. 19.12), or even emergency surgery, can be life-saving in the acute situation.

In the vast majority of cases, however, the haemoptysis itself is not life-threatening and a logical sequence of investigations can be followed:

- chest X-ray, which may provide evidence of a localised lesion, including tumour (malignant or benign), pneumonia, mycetoma or tuberculosis
- full blood count (FBC) and clotting screen
- bronchoscopy after acute bleeding has settled, which may reveal a central bronchial carcinoma (not visible on the chest X-ray) and permit biopsy and tissue diagnosis
- CTPA, which may reveal underlying pulmonary thromboembolic disease or alternative causes not seen on the chest X-ray (e.g. pulmonary arteriovenous malformation or small or hidden tumours).

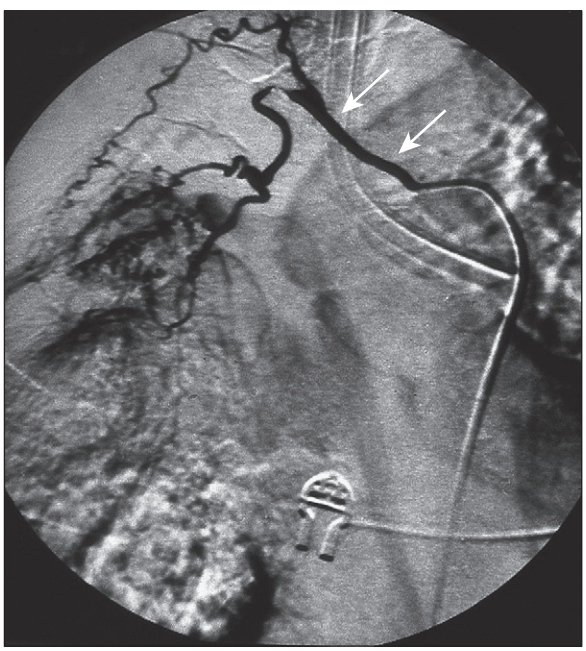

Fig. 19.12 Bronchial artery angiography. An angiography catheter has been passed via the femoral artery and aorta into an abnormally dilated right bronchial artery (arrows). Contrast is seen flowing into the lung. This patient had post-tuberculous bronchiectasis and presented with massive haemoptysis. Bronchial artery embolisation was successfully performed.

The incidental pulmonary nodule

The incidental finding of a pulmonary nodule (a rounded opacity measuring up to 3 cm in diameter) is common, particularly with the widespread use of thoracic CT scanning (Fig. 19.13). The differential diagnosis is extensive (Box 19.11), and whilst the majority are benign, it is important to identify a potentially treatable malignancy.

A lesion may be confidently described as benign if it appears unchanged over 2 years. If previous images are available and this can be established, no further investigation may be necessary. Otherwise, the likelihood of malignancy is assessed by considering the characteristics of the patient, including age, smoking history and any history of prior malignancy, and the appearance of the nodule in terms of its size, margin, density and location (Box 19.12). Further investigation is required in the majority of cases.

Pulmonary nodules are invariably beyond the vision of the bronchoscope and, with the notable exception of pulmonary infection (e.g. tuberculosis), bronchoscopy is usually unrewarding as the yield from blind washings is low. Endoscopic bronchoscopic ultrasound may overcome this but, for the time being, tissue is most commonly obtained using percutaneous needle biopsy under ultrasound or CT guidance. Needle biopsy may be complicated by pneumothorax in around 20% of cases and although only 3% require intercostal drainage, this technique should only be contemplated in individuals with an FEV_1 of more than 35% predicted. Haemorrhage into the lung or pleural space, air embolism and tumour seeding are rare but recognised complications.

PET scanning provides useful information about nodules of at least 1 cm in diameter, in which the presence of high metabolic activity is strongly suggestive of malignancy, while an inactive 'cold' nodule is consistent with benign disease. False-positive results may occur with some infectious or inflammatory nodules, and false-negative results with neuro-endocrine tumours and bronchiolo-alveolar cell carcinomas. Detection of neuro-endocrine tumours may be improved by the use of ^{68}Ga-Dotatoc in place of FDG.

Where tissue biopsy is contraindicated and the lesion is too small to be confidently assessed by PET, interval thoracic CT scanning may be considered. The period between scans is based upon the average tumour doubling time (Box 19.13). Changes may be difficult to assess visually and specially adapted computer programs allow more detailed topographical assessment. However, the risks of radiation exposure inherent in this approach, and the fact that further nodules are likely to be detected, need to be considered. In some circumstances, if the nodule is highly likely to be malignant and the patient is fit for surgery, the best option may be to proceed to surgical resection.

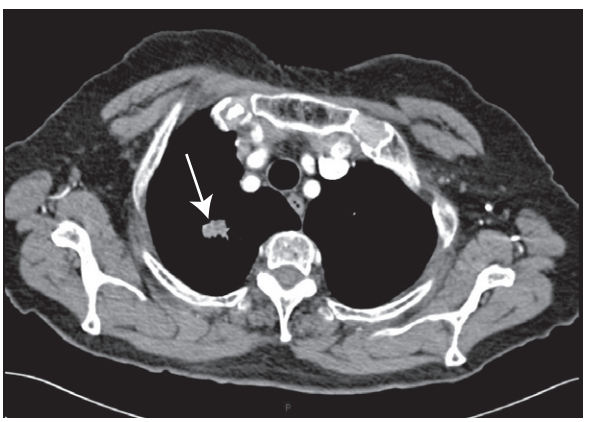

Fig. 19.13 Thoracic CT scan showing a solitary pulmonary nodule identified in the right upper lobe (arrow).

19.11 Causes of pulmonary nodules

Common causes

- Bronchial carcinoma
- Single metastasis
- Localised pneumonia
- Lung abscess
- Tuberculoma
- Pulmonary infarct

Uncommon causes

- Benign tumours
- Lymphoma
- Arteriovenous malformation
- Hydatid cyst (p. 380)
- Bronchogenic cyst
- Rheumatoid nodule
- Pulmonary sequestration
- Pulmonary haematoma
- Wegener's granuloma
- 'Pseudotumour' – fluid collection in a fissure
- Aspergilloma (usually surrounded by air 'halo')

19.12 Clinical and radiographic features distinguishing benign from malignant nodules

Feature	Risk of malignancy
Patient characteristics	
Age	Increases with age and is uncommon < age of 40
Smoking history	Increases in proportion to duration and amount smoked
Other	Increased by history of lung cancer in first-degree relative, and by exposure to asbestos, silica, uranium and radon
Characteristics of nodule	
Size	Nearly all > 3 cm but fewer than 1% < 4 mm are malignant
Margin	Usually smooth in benign lesions Spiculated suggests malignancy
Calcification or fat	Laminated or central deposition of calcification suggests granuloma 'Popcorn' pattern is suggestive of hamartoma Fat may suggest hamartoma or lipoid granuloma
Location	70% of lung cancers occur in upper lobes Benign lesions are equally distributed throughout upper and lower lobes

Note Linear or sheet-like lung opacities are unlikely to represent neoplasms and do not require follow-up. Some nodular opacities may be sufficiently typical of scarring that follow-up is not warranted.
Adapted from Fleischer Society Statement. Radiology 2005; 237:395–400.

19.13 Recommendations for follow-up of incidental nodules smaller than 8 mm[1]

Nodule size (mm) (average of length and width)	No or minimal history of smoking/ other risk factors	Smoker/other risk factors
≤ 4	No follow-up needed[2]	Follow-up CT at 12 mths; if unchanged, no further follow-up
4–6	Follow-up at 12 mths; if unchanged, no further follow-up	Initial follow-up CT at 6–12 mths, then at 18–24 mths if no change
6–8	Initial follow-up CT at 6–12 mths, then at 18–24 mths if no change	Initial follow-up CT at 3–6 mths, then at 9–12 mths if no change
> 8	Follow-up CT at around 3, 9 and 24 mths, dynamic contrast-enhanced CT, PET and/or biopsy	As for low-risk patient

[1]Excludes younger patients, and those with unexplained fever or known/ suspected malignant disease.
[2]Very low risk of malignancy (< 1%). Non-solid (ground glass) or partly solid nodules may require longer follow-up to exclude indolent adenocarcinoma.
Adapted from Radiology 2005; 237:395–400.

19.14 Causes of pleural effusion

Common causes

- Pneumonia ('para-pneumonic effusion')
- Tuberculosis
- Pulmonary infarction*
- Malignant disease
- Cardiac failure*
- Subdiaphragmatic disorders (subphrenic abscess, pancreatitis etc.)

Uncommon causes

- Hypoproteinaemia* (nephrotic syndrome, liver failure, malnutrition)
- Connective tissue diseases* (particularly systemic lupus erythematosus (SLE) and rheumatoid arthritis)
- Post-myocardial infarction syndrome
- Acute rheumatic fever
- Meigs' syndrome (ovarian tumour plus pleural effusion)
- Myxoedema*
- Uraemia*
- Asbestos-related benign pleural effusion

*May cause bilateral effusions.

Pleural effusion

The accumulation of serous fluid within the pleural space is termed pleural effusion. The accumulation of frank pus is termed empyema (p. 662), that of blood is haemothorax, and that of chyle is a chylothorax. In general, pleural fluid accumulates as a result of either increased hydrostatic pressure or decreased osmotic pressure ('transudative' effusion, as seen in cardiac, liver or renal failure), or from increased microvascular pressure due to disease of the pleura or injury in the adjacent lung ('exudative' effusion). The causes of the majority of pleural effusions (Boxes 19.14 and 19.15) are identified by a thorough history, examination and relevant investigations.

Clinical assessment

Symptoms (pain on inspiration and coughing) and signs of pleurisy (a pleural rub) often precede the development of an effusion, especially in patients with underlying pneumonia, pulmonary infarction or connective tissue disease. However, when breathlessness is the only symptom, depending on the size and rate of accumulation, the onset may be insidious. The physical signs are detailed on page 645.

Investigations

Radiological investigations

The classical appearance of pleural fluid on the erect PA chest film is of a curved shadow at the lung base, blunting the costophrenic angle and ascending towards the axilla (p. 645). Fluid appears to track up the lateral chest wall. In fact, fluid surrounds the whole lung at this level, but casts a radiological shadow only where the X-ray beam passes tangentially across the fluid against the lateral chest wall. Around 200 mL of fluid is required in order for it to be detectable on a PA chest X-ray. Previous scarring or adhesions in the pleural space can cause localised effusions. Pleural fluid localised below the lower lobe ('subpulmonary effusion') simulates an elevated hemidiaphragm. Pleural fluid localised within an oblique fissure may produce a rounded opacity that may be mistaken for a tumour.

Ultrasound is more accurate than plain chest X-ray for determining the presence of fluid. A clear hypoechoic space is consistent with a transudate and the presence of moving floating densities suggests an exudate. The presence of septation suggests an evolving empyema or resolving haemothorax. CT scanning is indicated where malignant disease is suspected.

Pleural aspiration and biopsy

In some conditions (e.g. left ventricular failure), it should not be necessary to sample fluid unless atypical features are present; appropriate treatment should be administered and the effusion re-evaluated. However, in most other circumstances, diagnostic sampling is required. Simple aspiration provides information on the colour and texture of fluid and these alone may immediately suggest an empyema or chylothorax. The presence of blood is consistent with pulmonary infarction or malignancy, but may result from a traumatic tap. Biochemical analysis allows classification into transudate and exudates (Box 19.16) and Gram stain may suggest parapneumonic effusion. The predominant cell type provides useful information and cytological examination is essential. A low pH suggests infection but may also be seen in rheumatoid arthritis, ruptured oesophagus or advanced malignancy.

Ultrasound- or CT-guided pleural biopsy provides tissue for pathological and microbiological analysis. Where necessary, video-assisted thoracoscopy allows visualisaton of the pleura and direct guidance of a biopsy.

19.15 Pleural effusion: main causes and features

Cause	Appearance of fluid	Type of fluid	Predominant cells in fluid	Other diagnostic features
Tuberculosis	Serous, usually amber-coloured	Exudate	Lymphocytes (occasionally polymorphs)	Positive tuberculin test Isolation of *M. tuberculosis* from pleural fluid (20%) Positive pleural biopsy (80%) Raised adenosine deaminase
Malignant disease	Serous, often blood-stained	Exudate	Serosal cells and lymphocytes Often clumps of malignant cells	Positive pleural biopsy (40%) Evidence of malignancy elsewhere
Cardiac failure	Serous, straw-coloured	Transudate	Few serosal cells	Other signs of cardiac failure Response to diuretics
Pulmonary infarction	Serous or blood-stained	Exudate (rarely transudate)	Red blood cells Eosinophils	Evidence of pulmonary infarction Obvious source of embolism Factors predisposing to venous thrombosis
Rheumatoid disease	Serous Turbid if chronic	Exudate	Lymphocytes (occasionally polymorphs)	Rheumatoid arthritis: rheumatoid factor and anti-CCP antibodies Cholesterol in chronic effusion; very low glucose in pleural fluid
SLE	Serous	Exudate	Lymphocytes and serosal cells	Other signs of SLE Antinuclear factor or anti-DNA positive
Acute pancreatitis	Serous or blood-stained	Exudate	No cells predominate	Higher amylase in pleural fluid than in serum
Obstruction of thoracic duct	Milky	Chyle	None	Chylomicrons

(anti-CCP = anti-cyclic citrullinated peptide; SLE = systemic lupus erythematosus)

19.16 Light's criteria for distinguishing pleural transudate from exudate

Exudate is likely if one or more of the following criteria are met:
- Pleural fluid protein : serum protein ratio > 0.5
- Pleural fluid LDH : serum LDH ratio > 0.6
- Pleural fluid LDH > two-thirds of the upper limit of normal serum LDH

(LDH = lactate dehydrogenase)

Management

Therapeutic aspiration may be required to palliate breathlessness but removing more than 1.5 L at a time is associated with a small risk of re-expansion pulmonary oedema. An effusion should never be drained to dryness before establishing a diagnosis, as biopsy may be precluded until further fluid accumulates. Treatment of the underlying cause – for example, heart failure, pneumonia, pulmonary embolism or subphrenic abscess – will often be followed by resolution of the effusion. The management of pleural effusion in pneumonia, tuberculosis and malignancy is dealt with below.

Empyema

This is a collection of pus in the pleural space, which may be as thin as serous fluid or so thick that it is impossible to aspirate, even through a wide-bore needle. Microscopically, neutrophil leucocytes are present in large numbers. An empyema may involve the whole pleural space or only part of it ('loculated' or 'encysted' empyema) and is usually unilateral. It is always secondary to infection in a neighbouring structure, usually the lung, most commonly due to the bacterial pneumonias and tuberculosis. Over 40% of patients with community-acquired pneumonia develop an associated pleural effusion ('para-pneumonic' effusion) and about 15% of these become secondarily infected. Other causes are infection of a haemothorax following trauma or surgery, oesophageal rupture, and rupture of a subphrenic abscess through the diaphragm.

Both pleural surfaces are covered with a thick, shaggy, inflammatory exudate. The pus in the pleural space is often under considerable pressure, and if the condition is not adequately treated, pus may rupture into a bronchus, causing a bronchopleural fistula and pyopneumothorax, or track through the chest wall with the formation of a subcutaneous abscess or sinus, so-called empyema necessitans.

Clinical assessment

An empyema should be suspected in patients with pulmonary infection if there is severe pleuritic chest pain or persisting or recurrent pyrexia, despite appropriate antibiotic treatment. In other cases, the primary infection may be so mild that it passes unrecognised and the first definite clinical features are due to the empyema itself. Once an empyema has developed, systemic features are prominent (Box 19.17).

19.17 Clinical features of empyema

Systemic features

- Pyrexia, usually high and remittent
- Rigors, sweating, malaise and weight loss
- Polymorphonuclear leucocytosis, high CRP

Local features

- Pleural pain; breathlessness; cough and sputum, usually because of underlying lung disease; copious purulent sputum if empyema ruptures into a bronchus (bronchopleural fistula)
- Clinical signs of pleural effusion

Fig. 19.14 Chest X-ray showing a 'D'-shaped shadow in the left mid-zone, consistent with an empyema. In this case, an intercostal chest drain has been inserted but the loculated collection of pus remains.

Investigations

Chest X-ray appearances may be indistinguishable from those of pleural effusion, although pleural adhesions may confine the empyema to form a 'D'-shaped shadow against the inside of the chest wall (Fig. 19.14). When air is present as well as pus (pyopneumothorax), a horizontal 'fluid level' marks the air/liquid interface. Ultrasound shows the position of the fluid, the extent of pleural thickening and whether fluid is in a single collection or multiloculated, containing fibrin and debris (Fig. 19.15). CT provides information on the pleura, underlying lung parenchyma and patency of the major bronchi.

Ultrasound or CT is used to identify the optimal site for aspiration, which is best performed using a wide-bore needle. If the fluid is thick and turbid pus, empyema is confirmed. Other features suggesting empyema are a fluid glucose of less than 3.3 mmol/L (60 mg/dL), lactate dehydrogenase (LDH) of more than 1000 U/L, or a fluid pH of less than 7.0 (H^+ over 100 nmol/L). However, pH measurement should be avoided if pus is thick, as it damages blood gas machines. The pus is frequently sterile on culture if antibiotics have already been given. The distinction between tuberculous and non-tuberculous disease can be difficult and often requires pleural biopsy, histology and culture.

Management

An empyema will only heal if infection is eradicated and the empyema space is obliterated, allowing apposition of the visceral and parietal pleural layers. This

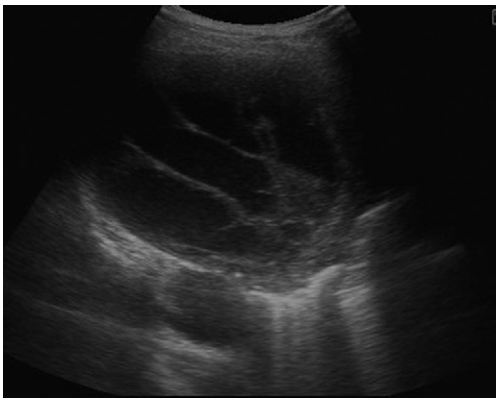

Fig. 19.15 Pleural ultrasound showing septation.

can only occur if re-expansion of the compressed lung is secured at an early stage by removal of all the pus from the pleural space. When the pus is sufficiently thin, this is most easily achieved by the insertion of a wide-bore intercostal tube into the most dependent part of the empyema space. If the initial aspirate reveals turbid fluid or frank pus, or if loculations are seen on ultrasound, the tube should be put on suction (–5 to –10 cm H_2O) and flushed regularly with 20 mL normal saline. If the organism causing the empyema can be identified, the appropriate antibiotic should be given for 2–4 weeks. Empirical antibiotic treatment (e.g. intravenous co-amoxiclav or cefuroxime with metronidazole) should be used if the organism is unknown. Intrapleural fibrinolytic therapy is of no benefit.

An empyema can often be aborted if these measures are started early, but if the intercostal tube is not providing adequate drainage – for example, when the pus is thick or loculated, surgical intervention is required to clear the empyema cavity of pus and break down any adhesions. Surgical 'decortication' of the lung may also be required if gross thickening of the visceral pleura is preventing re-expansion of the lung. Surgery is also necessary if a bronchopleural fistula develops.

Despite the widespread availability of antibiotics that are effective against pneumonia, empyema remains a significant cause of morbidity and mortality.

Respiratory failure

The term 'respiratory failure' is used when pulmonary gas exchange fails to maintain normal arterial oxygen and carbon dioxide levels. Its classification into types I and II is defined by the absence or presence of hypercapnia (raised $PaCO_2$).

Pathophysiology

When disease impairs ventilation of part of a lung (e.g. in asthma or pneumonia), perfusion of that region results in hypoxic and CO_2-laden blood entering the pulmonary veins. Increased ventilation of neighbouring regions of normal lung can increase CO_2 excretion, correcting arterial CO_2 to normal, but cannot augment oxygen uptake because the haemoglobin flowing through these regions is already fully saturated. Admixture of blood from the underventilated and normal regions thus results in hypoxia with normocapnia,

19.18 How to interpret blood gas abnormalities in respiratory failure

	Type I		Type II	
	Hypoxia (PaO_2 < 8.0 kPa (60 mmHg)) Normal or low $PaCO_2$ (< 6.6 kPa (50 mmHg))		Hypoxia (PaO_2 < 8.0 kPa (60 mmHg)) Raised $PaCO_2$ (> 6.6 kPa (50 mmHg))	
	Acute	**Chronic**	**Acute**	**Chronic**
H^+	→	→	↑	→ or ↑
Bicarbonate	→	→	→	↑
Causes	Acute asthma Pulmonary oedema Pneumonia Lobar collapse Pneumothorax Pulmonary embolus ARDS	COPD Lung fibrosis Lymphangitis carcinomatosa Right-to-left shunts	Acute severe asthma Acute exacerbation of COPD Upper airway obstruction Acute neuropathies/paralysis Narcotic drugs Primary alveolar hypoventilation Flail chest injury	COPD Sleep apnoea Kyphoscoliosis Myopathies/muscular dystrophy Ankylosing spondylitis

(ARDS = acute respiratory distress syndrome; COPD = chronic obstructive pulmonary disease)

which is called 'type I respiratory failure'. Diseases causing this include all those that impair ventilation locally with sparing of other regions (Box 19.18).

Arterial hypoxia with hypercapnia (type II respiratory failure) is seen in conditions that cause generalised, severe ventilation–perfusion mismatch, leaving insufficient normal lung to correct $PaCO_2$, or a disease that reduces total ventilation. The latter includes not just diseases of the lung but also disorders affecting any part of the neuromuscular mechanism of ventilation (see Box 19.18).

Management of acute respiratory failure

Prompt diagnosis and management of the underlying cause is crucial. In type I respiratory failure, high concentrations of oxygen (40–60% by mask) will usually relieve hypoxia by increasing the alveolar PO_2 in poorly ventilated lung units. Occasionally, however (e.g. severe pneumonia affecting several lobes), mechanical ventilation may be needed to relieve hypoxia. Patients who need high concentrations of oxygen for more than a few hours should receive humidified oxygen.

Acute type II respiratory failure is an emergency requiring immediate intervention. It is useful to distinguish between patients with high ventilatory drive (rapid respiratory rate and accessory muscle recruitment) who cannot move sufficient air, and those with reduced or inadequate respiratory effort. In the former, particularly if inspiratory stridor is present, acute upper airway obstruction from foreign body inhalation or laryngeal obstruction (angioedema, carcinoma or vocal cord paralysis) must be considered, as the Heimlich manœuvre (p. 728), immediate intubation or emergency tracheostomy may be life-saving.

More commonly, the problem is in the lungs, with severe generalised bronchial obstruction from COPD or asthma, acute respiratory distress syndrome (ARDS) arising from a variety of insults (p. 191), or occasionally tension pneumothorax (p. 728). In all such cases, high-concentration (e.g. 60%) oxygen should be administered, pending a rapid examination of the respiratory system and measurement of arterial blood gases. Patients with the trachea deviated away from a silent and resonant hemithorax are likely to have tension pneumothorax, and air should be aspirated from the pleural space and a chest drain inserted as soon as possible. Patients with generalised wheeze, scanty breath sounds bilaterally or a history of asthma or COPD should be treated with nebulised salbutamol 2.5 mg with oxygen, repeated until bronchospasm is relieved. Failure to respond to initial treatment, declining conscious level and worsening respiratory acidosis (H^+ > 50 nmol/L (pH < 7.3), $PaCO_2$ > 6.6 kPa (50 mmHg)) on blood gases are all indications that supported ventilation is required (p. 193).

A small percentage of patients with severe chronic COPD and type II respiratory failure develop abnormal tolerance to raised $PaCO_2$ and may become dependent on hypoxic drive to breathe. In these patients only, lower concentrations of oxygen (24–28% by Venturi mask) should be used to avoid precipitating worsening respiratory depression (see below). In all cases, regular monitoring of arterial blood gases is important to assess progress.

Patients with acute type II respiratory failure who have reduced drive or conscious level may be suffering from sedative poisoning, CO_2 narcosis or a primary failure of neurological drive (e.g. following intracerebral haemorrhage or head injury). History from a witness may be invaluable, and reversal of specific drugs with (for example) opiate antagonists is occasionally successful, but should not delay intubation and supported mechanical ventilation in appropriate cases.

Chronic and 'acute on chronic' type II respiratory failure

The most common cause of chronic type II respiratory failure is severe COPD. Although $PaCO_2$ may be persistently raised, there is no persisting acidaemia because the kidneys retain bicarbonate, correcting arterial pH to normal. This 'compensated' pattern, which may also occur in chronic neuromuscular disease or kyphoscoliosis, is maintained until there is a further acute illness (see Box 19.18), such as an exacerbation of COPD which precipitates an episode of 'acute on chronic' respiratory failure, with acidaemia and initial respiratory distress

followed by drowsiness and eventually coma. These patients have lost their chemo-sensitivity to elevated $PaCO_2$, and so they may paradoxically depend on hypoxia for respiratory drive, and are at risk of respiratory depression if given high concentrations of oxygen – for example, during ambulance transfers or in emergency departments. Moreover, in contrast to acute severe asthma, some patients with 'acute on chronic' type II respiratory failure due to COPD may not be distressed, despite being critically ill with severe hypoxaemia, hypercapnia and acidaemia. While the physical signs of CO_2 retention (confusion, flapping tremor, bounding pulses and so on) can be helpful if present, they may not be, so arterial blood gases are mandatory in the assessment of initial severity and response to treatment.

Management

The principal aims of treatment in acute on chronic type II respiratory failure are to achieve a safe PaO_2 (> 7.0 kPa (52 mmHg)) without increasing $PaCO_2$ and acidosis, while identifying and treating the precipitating condition. In these patients, it is not necessary to achieve a normal PaO_2; even a small increase will often have a greatly beneficial effect on tissue oxygen delivery, since their PaO_2 values are often on the steep part of the oxygen saturation curve (p. 184). The risks of worsening hypercapnia and coma must be balanced against those of severe hypoxaemia, which include potentially fatal arrhythmias or severe cerebral complications. Immediate treatment is shown in Box 19.19. Patients who are conscious and have adequate respiratory drive may benefit from non-invasive ventilation (NIV), which has been shown to reduce the need for intubation and shorten hospital stay. Patients who are drowsy and have low respiratory drive require an urgent decision regarding intubation and ventilation, as this is likely to be the only effective treatment, even though weaning off the ventilator may be difficult in severe disease. The decision is challenging, and important factors to consider include patient and family wishes, presence of a potentially remediable precipitating condition, prior functional capacity and quality of life. The various types of non-invasive (via a face or nasal mask) or invasive (via an endotracheal tube) ventilation are detailed on pages 193–196.

Respiratory stimulant drugs, such as doxapram, tend to cause unacceptable distress due to increased dyspnoea, and have been largely superseded by intubation and mechanical ventilation in patients with CO_2 narcosis, as they provide only minor and transient improvements in arterial blood gases.

19.19 Assessment and management of 'acute on chronic' type II respiratory failure

Initial assessment

Patient may not appear distressed, despite being critically ill

- Conscious level (response to commands, ability to cough)
- CO_2 retention (warm periphery, bounding pulses, flapping tremor)
- Airways obstruction (wheeze, prolonged expiration, hyperinflation, intercostal indrawing, pursed lips)
- Cor pulmonale (peripheral oedema, raised JVP, hepatomegaly, ascites)
- Background functional status and quality of life
- Signs of precipitating cause (see Box 19.17)

Investigations

- Arterial blood gases (severity of hypoxaemia, hypercapnia, acidaemia, bicarbonate)
- Chest X-ray

Management

- Maintenance of airway
- Treatment of specific precipitating cause
- Frequent physiotherapy ± pharyngeal suction
- Nebulised bronchodilators
- Controlled oxygen therapy
  - Start with 24% Venturi mask
  - Aim for a PaO_2 > 7 kPa (52 mmHg) (a PaO_2 < 5 (37 mmHg) is dangerous)
- Antibiotics if evidence of infection
- Diuretics if evidence of fluid overload

Progress

- If $PaCO_2$ continues to rise or a safe PaO_2 cannot be achieved without severe hypercapnia and acidaemia, mechanical ventilatory support may be required

Home ventilation for chronic respiratory failure

NIV is of great value in the long-term treatment of respiratory failure due to spinal deformity, neuromuscular disease and central alveolar hypoventilation. Some patients with advanced lung disease, e.g. cystic fibrosis, also benefit from NIV for respiratory failure. In these conditions, the onset of type II respiratory failure can be very gradual. Morning headache (due to elevated $PaCO_2$) and fatigue are common symptoms but, in many cases, the diagnosis is only revealed by sleep studies or morning blood gas analysis. In the initial stages, ventilation is insufficient for metabolic needs only during sleep, when there is a physiological decline in ventilatory drive. Over time, however, CO_2 retention becomes chronic, with renal compensation of acidosis. Treatment by home-based NIV overnight is often sufficient to restore the daytime PCO_2 to normal, and to relieve fatigue and headache. In advanced disease (e.g. muscular dystrophies or cystic fibrosis), daytime NIV may also be required.

Lung transplantation

Lung transplantation is an established treatment for carefully selected patients with advanced lung disease unresponsive to medical treatment (Box 19.20).

19.20 Indications for lung transplantation

Parenchymal lung disease

- Cystic fibrosis
- Emphysema
- Pulmonary fibrosis
- Obliterative bronchiolitis
- Langerhans cell histiocytosis (p. 715)
- Lymphangioleiomyomatosis (p. 715)

Pulmonary vascular disease

- Primary pulmonary hypertension
- Thromboembolic pulmonary hypertension
- Veno-occlusive disease
- Eisenmenger's syndrome (p. 631)

Single-lung transplantation may be used for selected patients with advanced emphysema or lung fibrosis. This is contraindicated in patients with chronic bilateral pulmonary infection, such as cystic fibrosis and bronchiectasis, because the transplanted lung is vulnerable to cross-infection in the context of post-transplant immunosuppression and for these individuals bilateral lung transplantation is the standard procedure. Combined heart–lung transplantation is still occasionally needed for patients with advanced congenital heart disease such as Eisenmenger's syndrome, and is preferred by some surgeons for the treatment of primary pulmonary hypertension unresponsive to medical therapy.

The prognosis following lung transplantation is improving steadily with modern immunosuppressive drugs: over 50% 10-year survival in some UK centres. However, chronic rejection resulting in obliterative bronchiolitis continues to afflict some recipients. Corticosteroids are used to manage acute rejection, but drugs that inhibit cell-mediated immunity specifically, such as ciclosporin, mycophenolate and tacrolimus (p. 94), are used to prevent chronic rejection. Azithromycin, statins and total lymphoid irradiation are employed to treat obliterative bronchiolitis, but late organ failure remains a significant problem.

The major factor limiting the availability of lung transplantation is the shortage of donor lungs. To improve organ availability, techniques to recondition the lungs in vitro after removal from the donor are being developed.

OBSTRUCTIVE PULMONARY DISEASES

Asthma

Asthma is a chronic inflammatory disorder of the airways, in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyper-responsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction within the lung that is often reversible, either spontaneously or with treatment.

Epidemiology

The prevalence of asthma increased steadily over the latter part of the last century, first in the developed and then in the developing world (Fig. 19.16). Current estimates suggest that asthma affects 300 million people worldwide, with a predicted additional 100 million people affected by 2025. The socio-economic impact is enormous, as poor control leads to days lost from school or work, unscheduled health-care visits and hospital admissions.

Although the development and course of the disease, and the response to treatment, are influenced by genetic determinants, the rapid rise in prevalence implies that environmental factors are critically important in the development and expression of the disease. To date, studies have explored the potential role of indoor and outdoor allergens, microbial exposure, diet, vitamins, breastfeeding, tobacco smoke, air pollution and obesity but no clear consensus has emerged.

Pathophysiology

Airway hyper-reactivity (AHR) – the tendency for airways to narrow excessively in response to triggers that have little or no effect in normal individuals – is integral to the diagnosis of asthma and appears to be related, although not exclusively, to airway inflammation (Fig. 19.17). Other factors likely to be important in the behaviour of airway smooth muscle include the degree of airway narrowing and neurogenic mechanisms.

The relationship between atopy (the propensity to produce IgE) and asthma is well established, and in many individuals there is a clear relationship between sensitisation and allergen exposure, as demonstrated by skin prick reactivity or elevated serum specific IgE. Common examples of allergens include house dust mites, pets such as cats and dogs, pests such as cockroaches, and fungi. Inhalation of an allergen into the airway is followed by an early and late-phase bronchoconstrictor response (Fig. 19.18). Allergic mechanisms

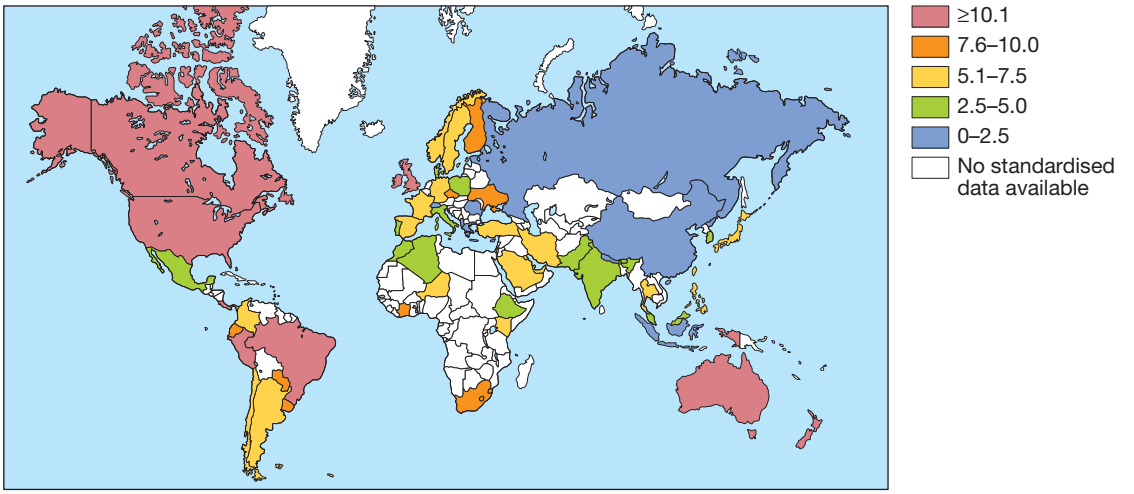

Fig. 19.16 World map showing the prevalence of clinical asthma (proportion of population (%)). From WHO – see p. 732; data drawn from the European Community Respiratory Health Study (ECRHS) and the International Study of Asthma and Allergies in Childhood (ISAAC).

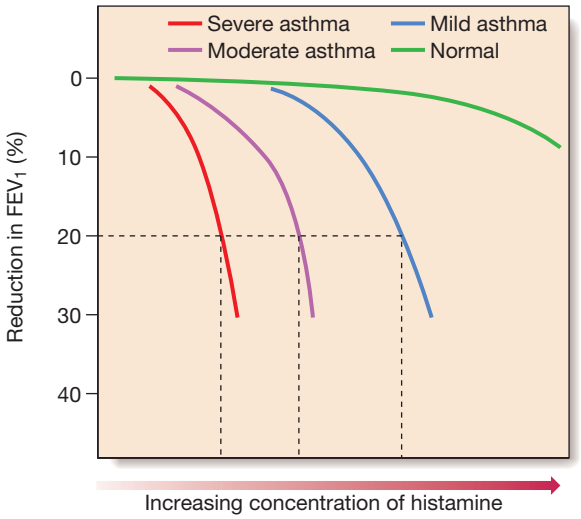

Fig. 19.17 Airway hyper-reactivity in asthma. This is demonstrated by bronchial challenge tests with sequentially increasing concentrations of either histamine, methacholine or mannitol. The reactivity of the airways is expressed as the concentration or dose of either chemical required to produce a specific decrease (usually 20%) in the FEV_1 (PC_{20} or PD_{20} respectively).

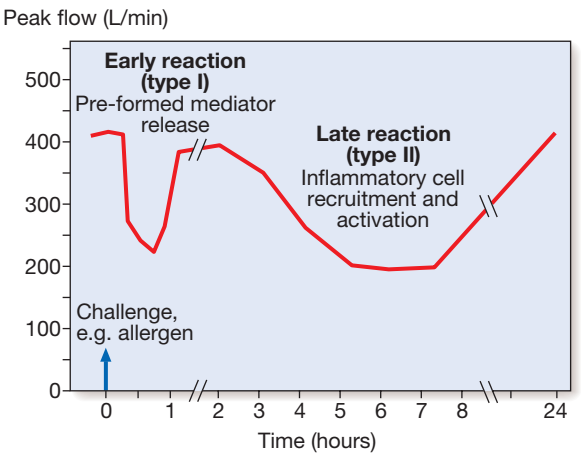

Fig. 19.18 Changes in peak flow following allergen challenge. A similar biphasic response is observed following a variety of different challenges. Occasionally, an isolated late response is seen with no early reaction.

are also implicated in some cases of occupational asthma (p. 715).

In cases of aspirin-sensitive asthma, the ingestion of salicylates results in inhibition of the cyclo-oxygenase enzymes, preferentially shunting the metabolism of arachidonic acid through the lipoxygenase pathway with resultant production of the asthmogenic cysteinyl leukotrienes. In exercise-induced asthma, hyperventilation results in water loss from the pericellular lining fluid of the respiratory mucosa, which, in turn, triggers mediator release. Heat loss from the respiratory mucosa may also be important.

In persistent asthma, a chronic and complex inflammatory response ensues, characterised by an influx of numerous inflammatory cells, the transformation and participation of airway structural cells, and the secretion of an array of cytokines, chemokines and growth factors. Examination of the inflammatory cell profile in induced sputum samples demonstrates that, although asthma is predominantly characterised by airway eosinophilia, neutrophilic inflammation predominates in some patients, while, in others, scant inflammation is observed: so-called 'pauci-granulocytic' asthma.

With increasing severity and chronicity of the disease, remodelling of the airway may occur, leading to fibrosis of the airway wall, fixed narrowing of the airway and a reduced response to bronchodilator medication.

Clinical features

Typical symptoms include recurrent episodes of wheezing, chest tightness, breathlessness and cough. Asthma is commonly mistaken for a cold or chest infection which is taking time to resolve (e.g. longer than 10 days). Classical precipitants include exercise, particularly in cold weather, exposure to airborne allergens or pollutants, and viral upper respiratory tract infections. Wheeze apart, there is often very little to find on examination. An inspection for nasal polyps and eczema should be performed. Rarely, a vasculitic rash may suggest Churg–Strauss syndrome (p. 1118).

Patients with mild intermittent asthma are usually asymptomatic between exacerbations. Individuals with persistent asthma report ongoing breathlessness and wheeze, but these are variable, with symptoms fluctuating over the course of one day, or from day to day or month to month.

Asthma characteristically displays a diurnal pattern, with symptoms and lung function being worse in the early morning. Particularly when poorly controlled, symptoms such as cough and wheeze disturb sleep and have led to the term 'nocturnal asthma'. Cough may be the dominant symptom in some patients, and the lack of wheeze or breathlessness may lead to a delay in reaching the diagnosis of so-called 'cough-variant asthma'.

Some patients with asthma have a similar inflammatory response in the upper airway. Careful enquiry should be made as to a history of sinusitis, sinus headache, a blocked or runny nose, and loss of sense of smell.

Although the aetiology of asthma is often elusive, an attempt should be made to identify any agents that may contribute to the appearance or aggravation of the condition. Particular enquiry should be made about potential allergens, such as exposure to a pet cat, guinea pig, rabbit or horse, pest infestation, exposure to moulds following water damage to a home or building, and any potential occupational agents.

In some circumstances, the appearance of asthma is triggered by medications. Beta-blockers, even when administered topically as eye drops, may induce bronchospasm, as may aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs). The classical aspirin-sensitive patient is female and presents in middle age with asthma, rhinosinusitis and nasal polyps. Aspirin-sensitive patients may also report symptoms following alcohol (in particular, white wine) and foods containing salicylates. Other medications implicated include the oral contraceptive pill, cholinergic agents and prostaglandin F2α. Betel nuts contain arecoline, which is structurally similar to methacholine and can aggravate asthma. An important minority of patients develop a

particularly severe form of asthma, and this appears to be more common in women. Allergic triggers are less important and airway neutrophilia predominates.

Diagnosis

The diagnosis of asthma is predominantly clinical and based on a characteristic history. Supportive evidence is provided by the demonstration of variable airflow obstruction, preferably by using spirometry (Box 19.21) to measure FEV_1 and VC. This identifies the obstructive defect, defines its severity, and provides a baseline for bronchodilator reversibility (Fig. 19.19). If spirometry is not available, a peak flow meter may be used. Patients should be instructed to record peak flow readings after rising in the morning and before retiring in the evening. A diurnal variation in PEF of more than 20% (the lowest values typically being recorded in the morning) is considered diagnostic, and the magnitude of variability provides some indication of disease severity (Fig. 19.20). A trial of corticosteroids (e.g. 30 mg daily for 2 weeks) may be useful in establishing the diagnosis, by demonstrating an improvement in either FEV_1 or PEF.

It is not uncommon for patients whose symptoms are suggestive of asthma to have normal lung function. In these circumstances, the demonstration of AHR by challenge tests may be useful to confirm the diagnosis (see Fig. 19.17). AHR is sensitive but non-specific: it has a high negative predictive value but positive results may be seen in other conditions, such as COPD, bronchiectasis and cystic fibrosis. When symptoms are predominantly related to exercise, an exercise challenge may be followed by a drop in lung function (Fig. 19.21).

19.21 How to make a diagnosis of asthma

Compatible clinical history *plus either/or*:

- $FEV_1 \geq 15\%$* (and 200 mL) increase following administration of a bronchodilator/trial of corticosteroids
- > 20% diurnal variation on ≥ 3 days in a week for 2 weeks on PEF diary
- $FEV_1 \geq 15\%$ decrease after 6 mins of exercise

*Global Initiative for Asthma (GINA) definition accepts an increase of 12%.

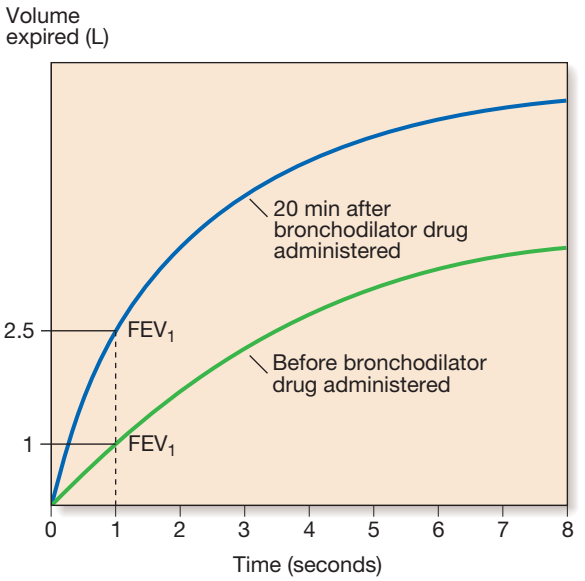

Fig. 19.19 Reversibility test. Forced expiratory manœuvres before and 20 minutes after inhalation of a β_2-adrenoceptor agonist. Note the increase in FEV_1 from 1.0 to 2.5 L.

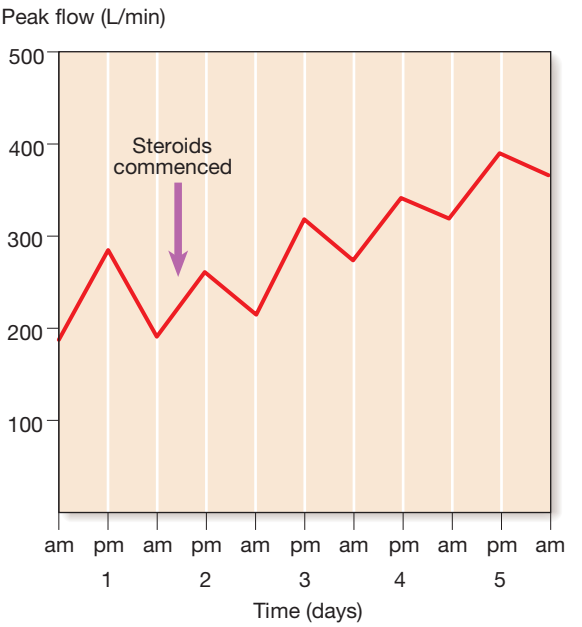

Fig. 19.20 Serial recordings of peak expiratory flow (PEF) in a patient with asthma. Note the sharp overnight fall (morning dip) and subsequent rise during the day. Following the introduction of corticosteroids, there is an improvement in PEF rate and loss of morning dipping.

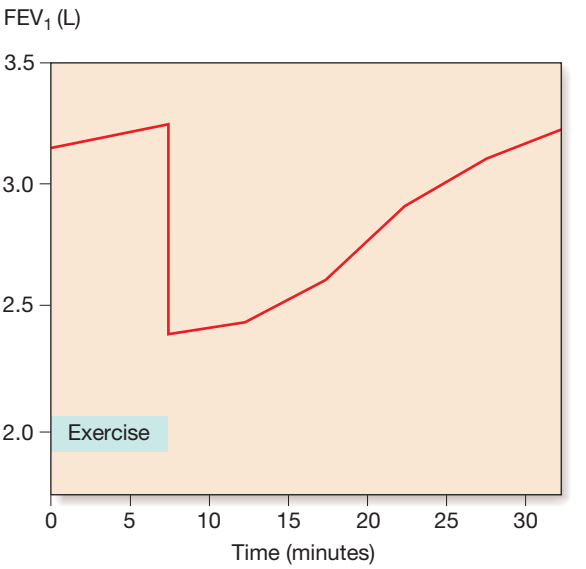

Fig. 19.21 Exercise-induced asthma. Serial recordings of FEV_1 in a patient with bronchial asthma before and after 6 minutes of strenuous exercise. Note initial rise on completion of exercise, followed by sudden fall and gradual recovery. Adequate warm-up exercise or pre-treatment with a β_2-adrenoceptor agonist, nedocromil sodium or a leukotriene antagonist can protect against exercise-induced symptoms.

Other investigations

- *Measurement of allergic status*: the presence of atopy may be demonstrated by skin prick tests. Similar information may be provided by the measurement of total and allergen-specific IgE. A full blood picture may show the peripheral blood eosinophilia.
- *Radiological examination*: chest X-ray appearances are often normal or show hyperinflation of lung fields. Lobar collapse may be seen if mucus occludes a large bronchus and, if accompanied by the presence of flitting infiltrates, may suggest that asthma has been complicated by allergic bronchopulmonary aspergillosis (p. 697). An HRCT scan may be useful to detect bronchiectasis.
- *Assessment of eosinophilic airway inflammation*: an induced sputum differential eosinophil count of greater than 2% or exhaled breath nitric oxide concentration (FE_{NO}) may support the diagnosis but is non-specific.

Management

Setting goals

Asthma is a chronic condition but may be controlled with appropriate treatment in the majority of patients. The goal of treatment should be to obtain and maintain complete control (Box 19.22), but aims may be modified according to the circumstances and the patient. Unfortunately, surveys consistently demonstrate that the majority of individuals with asthma report suboptimal control, perhaps reflecting the poor expectations of patients and their clinicians.

Whenever possible, patients should be encouraged to take responsibility for managing their own disease. A full explanation of the nature of the condition, the relationship between symptoms and inflammation, the importance of key symptoms such as nocturnal waking, the different types of medication, and, if appropriate, the use of PEF to guide management decisions, should be given. A variety of tools/questionnaires have been validated to assist in assessing asthma control. Written action plans can be helpful in developing self-management skills.

Avoidance of aggravating factors

This is particularly important in the management of occupational asthma (p. 715) but may also be relevant in atopic patients, when removing or reducing exposure to relevant antigens, such as a pet, may effect improvement. House dust mite exposure may be minimised by replacing carpets with floorboards and using mite-impermeable bedding. So far, improvements in asthma control following such measures have been difficult to demonstrate. Many patients are sensitised to several ubiquitous aeroallergens, making avoidance strategies largely impractical. Measures to reduce fungal exposure and eliminate cockroaches may be applicable in specific circumstances, and medications known to precipitate or aggravate asthma should be avoided. Smoking cessation (p. 100) is particularly important, as smoking not only encourages sensitisation, but also induces a relative corticosteroid resistance in the airway.

The stepwise approach to the management of asthma (Fig. 19.22)

Step 1: Occasional use of inhaled short-acting β_2-adrenoreceptor agonist bronchodilators

For patients with mild intermittent asthma (symptoms less than once a week for 3 months and fewer than two nocturnal episodes per month), it is usually sufficient to prescribe an inhaled short-acting β_2-agonist, such as salbutamol or terbutaline, to be used as required. However, many patients (and their physicians) underestimate the severity of asthma. A history of a severe exacerbation should lead to a step-up in treatment.

A variety of different inhaled devices are available and the choice of device should be guided by patient preference and competence in its use. The metered-dose inhaler remains the most widely prescribed (Fig. 19.23).

Step 2: Introduction of regular preventer therapy

Regular anti-inflammatory therapy (preferably inhaled corticosteroids (ICS), such as beclometasone, budesonide (BUD), fluticasone or ciclesonide) should be started in addition to inhaled β_2-agonists taken on an as-required basis for any patient who:

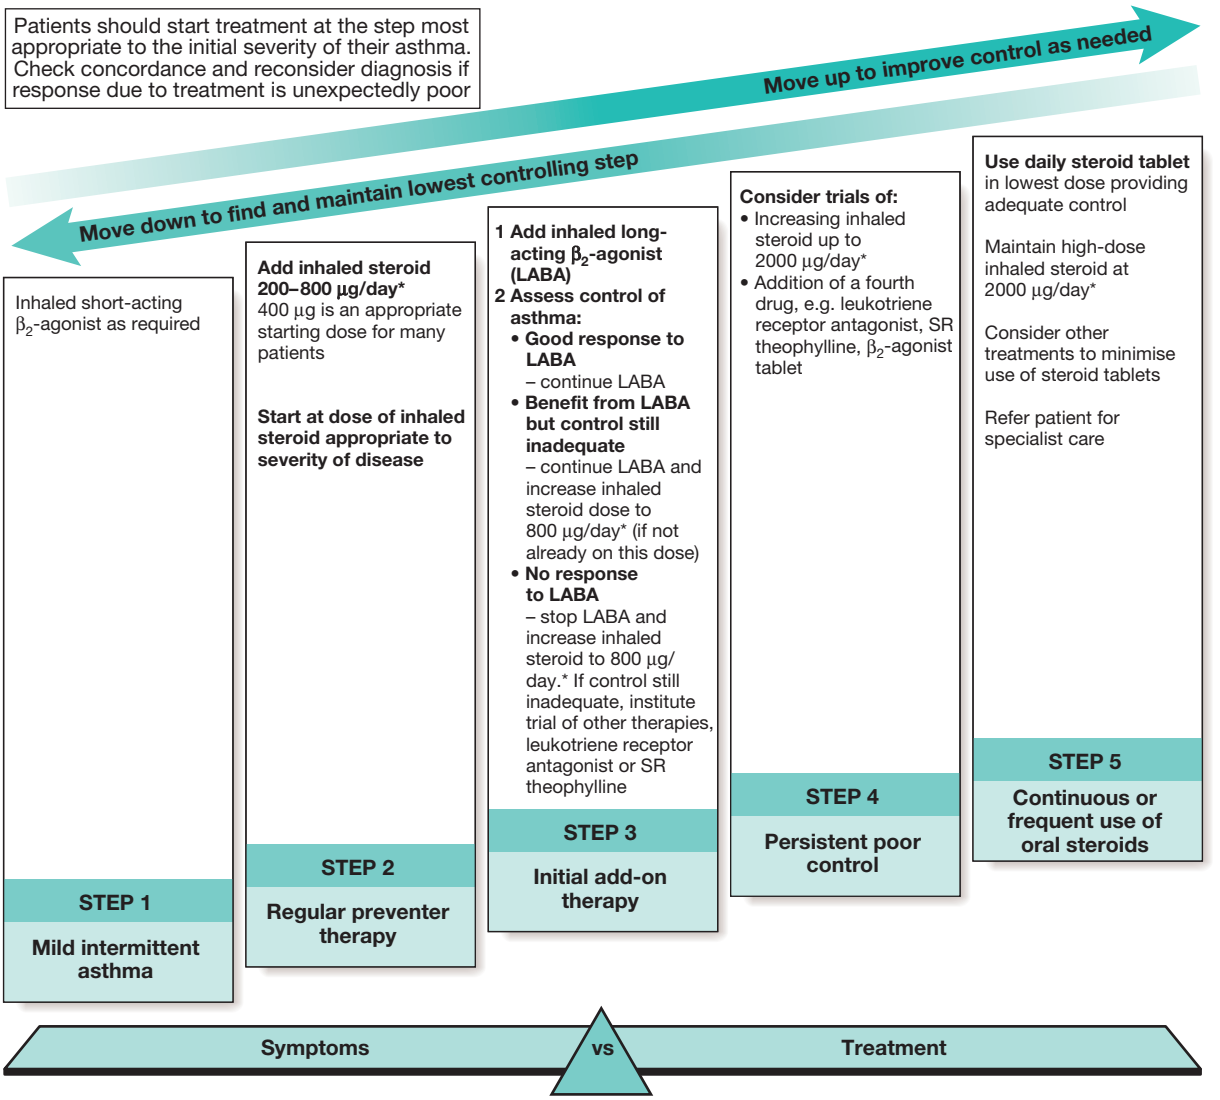
- has experienced an exacerbation of asthma in the last 2 years (Box 19.23)
- uses inhaled β_2-agonists three times a week or more
- reports symptoms three times a week or more
- is awakened by asthma one night per week.

For adults, a reasonable starting dose is 400 µg beclometasone dipropionate (BDP) or equivalent per day in adults, although higher doses may be required in smokers. Alternative but much less effective preventive

19.22 Levels of asthma control*

Characteristic	Controlled	Partly controlled (any present in any week)	Uncontrolled
Daytime symptoms	None (≤ twice/wk)	> twice/wk	≥ 3 features of partly controlled asthma present in any wk
Limitations of activities	None	Any	
Nocturnal symptoms/awakening	None	Any	
Need for rescue/'reliever' treatment	None (≤ twice/wk)	> twice/wk	
Lung function (PEF or FEV_1)	Normal	< 80% predicted or personal best (if known) on any day	
Exacerbation	None	≥ 1/yr	1 in any wk

*Based on GINA guidelines.



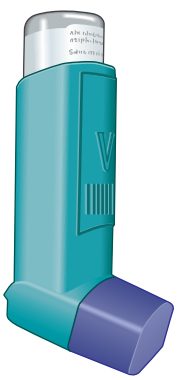


Fig. 19.22 Management approach in adults based on asthma control. *Beclometasone dipropionate (BDP) or equivalent. From British Thoracic Society and SIGN – see p. 732.

- Remove the cap and shake the inhaler
- Breathe out gently and place the mouthpiece into the mouth
- Incline the head backwards to minimise oropharyngeal deposition
- Simultaneously, begin a slow deep inspiration, depress the canister and continue to inhale
- Hold the breath for 10 seconds

Fig. 19.23 How to use a metered-dose inhaler.

agents include chromones, leukotriene receptor antagonists, and theophyllines.

Step 3: Add-on therapy

If a patient remains poorly controlled, despite regular use of ICS, a thorough review should be undertaken of adherence, inhaler technique and ongoing exposure to modifiable aggravating factors. A further increase in the dose of ICS may benefit some patients but, in general, add-on therapy should be considered in adults taking 800 µg/day BDP (or equivalent).

Long-acting β_2-agonists (LABAs), such as salmeterol and formoterol (duration of action of at least 12 hours), represent the first choice of add-on therapy. They have consistently been demonstrated to improve asthma control and to reduce the frequency and severity of exacerbations when compared to increasing the dose of ICS alone. Fixed combination inhalers of ICS and LABAs have been developed; these are more convenient, increase compliance and prevent patients using a LABA

EBM 19.23 Inhaled corticosteroids and asthma

'Regular therapy with low-dose budesonide reduces the risk of severe exacerbations in patients with mild persistent asthma.'

- Pauwels RA, et al. Lancet 2003; 361:1066–1067.

19.24 Asthma in pregnancy

- **Unpredictable clinical course**: one-third worsen, one-third remain stable and one-third improve.
- **Labour and delivery**: 90% have no symptoms.
- **Safety data**: good for β_2-agonists, inhaled steroids, theophyllines, oral prednisolone, and chromones.
- **Oral leukotriene receptor antagonists**: no evidence that these harm the fetus and they should not be stopped in women who have previously demonstrated significant improvement in asthma control prior to pregnancy.
- **Steroids**: women on maintenance prednisolone > 7.5 mg/day should receive hydrocortisone 100 mg 3–4 times daily during labour.
- **Prostaglandin F2α**: may induce bronchospasm and should be used with extreme caution.
- **Breastfeeding**: use medications as normal.
- **Uncontrolled asthma**: associated with maternal (hyperemesis, hypertension, pre-eclampsia, vaginal haemorrhage, complicated labour) and fetal (intrauterine growth restriction and low birth weight, preterm birth, increased perinatal mortality, neonatal hypoxia) complications.

as monotherapy – the latter may be accompanied by an increased risk of life-threatening attacks or asthma death. The onset of action of formoterol is similar to that of salbutamol such that, in carefully selected patients, a fixed combination of budesonide and formoterol may be used as both rescue and maintenance therapy.

Oral leukotriene receptor antagonists (e.g. montelukast 10 mg daily) are generally less effective than LABA as add-on therapy, but may facilitate a reduction in the dose of ICS and control exacerbations. Oral theophyllines may be considered in some patients but their unpredictable metabolism, propensity for drug interactions and prominent side-effects limit their widespread use.

Step 4: Poor control on moderate dose of inhaled steroid and add-on therapy: addition of a fourth drug

In adults, the dose of ICS may be increased to 2000 μg BDP/BUD (or equivalent) daily. A nasal corticosteroid preparation should be used in patients with prominent upper airway symptoms. Oral therapy with leukotriene receptor antagonists, theophyllines or a slow-release β_2-agonist may be considered. If the trial of add-on therapy is ineffective, it should be discontinued. Oral itraconazole may be contemplated in patients with allergic bronchopulmonary aspergillosis (p. 697).

Step 5: Continuous or frequent use of oral steroids

At this stage, prednisolone therapy (usually administered as a single daily dose in the morning) should be prescribed in the lowest amount necessary to control symptoms. Patients on long-term corticosteroid tablets (> 3 months) or receiving more than three or four courses per year will be at risk of systemic side-effects (p. 776). Osteoporosis can be prevented in this group by giving bisphosphonates (p. 1123). In atopic patients, omalizumab, a monoclonal antibody directed against IgE, may prove helpful in reducing symptoms and allowing a reduction in the prednisolone dose. Steroid-sparing therapies, such as methotrexate, ciclosporin or oral gold, may be considered.

Step-down therapy

Once asthma control is established, the dose of inhaled (or oral) corticosteroid should be titrated to the lowest dose at which effective control of asthma is maintained. Decreasing the dose of ICS by around 25–50% every 3 months is a reasonable strategy for most patients.

Exacerbations of asthma

The course of asthma may be punctuated by exacerbations with increased symptoms, deterioration in lung function, and an increase in airway inflammation. Exacerbations are most commonly precipitated by viral infections, but moulds (*Alternaria* and *Cladosporium*), pollens (particularly following thunderstorms) and air pollution are also implicated. Most attacks are characterised by a gradual deterioration over several hours to days but some appear to occur with little or no warning: so-called brittle asthma. An important minority of patients appear to have a blunted perception of airway narrowing and fail to appreciate the early signs of deterioration.

Management of mild to moderate exacerbations

Doubling the dose of ICS does not prevent an impending exacerbation. Short courses of 'rescue' oral corticosteroids (prednisolone 30–60 mg daily) therefore are often required to regain control. Tapering of the dose to withdraw treatment is not necessary, unless given for more than 3 weeks.

Indications for 'rescue' courses include:

- symptoms and PEF progressively worsening day by day, with a fall of PEF below 60% of the patient's personal best recording
- onset or worsening of sleep disturbance by asthma
- persistence of morning symptoms until midday
- progressively diminishing response to an inhaled bronchodilator
- symptoms sufficiently severe to require treatment with nebulised or injected bronchodilators.

Management of acute severe asthma

Box 19.25 highlights the immediate assessment requirements in acute asthma. Measurement of PEF is

19.25 Immediate assessment of acute severe asthma

Acute severe asthma

- PEF 33–50% predicted (< 200 L/min)
- Respiratory rate ≥ 25 breaths/min
- Heart rate ≥ 110 beats/min
- Inability to complete sentences in 1 breath

Life-threatening features

- PEF < 33% predicted (< 100 L/min)
- *Sp*O_2 < 92% or *Pa*O_2 < 8 kPa (60 mmHg) (especially if being treated with oxygen)
- Normal or raised *Pa*CO_2
- Silent chest
- Cyanosis
- Feeble respiratory effort
- Bradycardia or arrhythmias
- Hypotension
- Exhaustion
- Confusion
- Coma

Near-fatal asthma

- Raised *Pa*CO_2 and/or requiring mechanical ventilation with raised inflation pressures

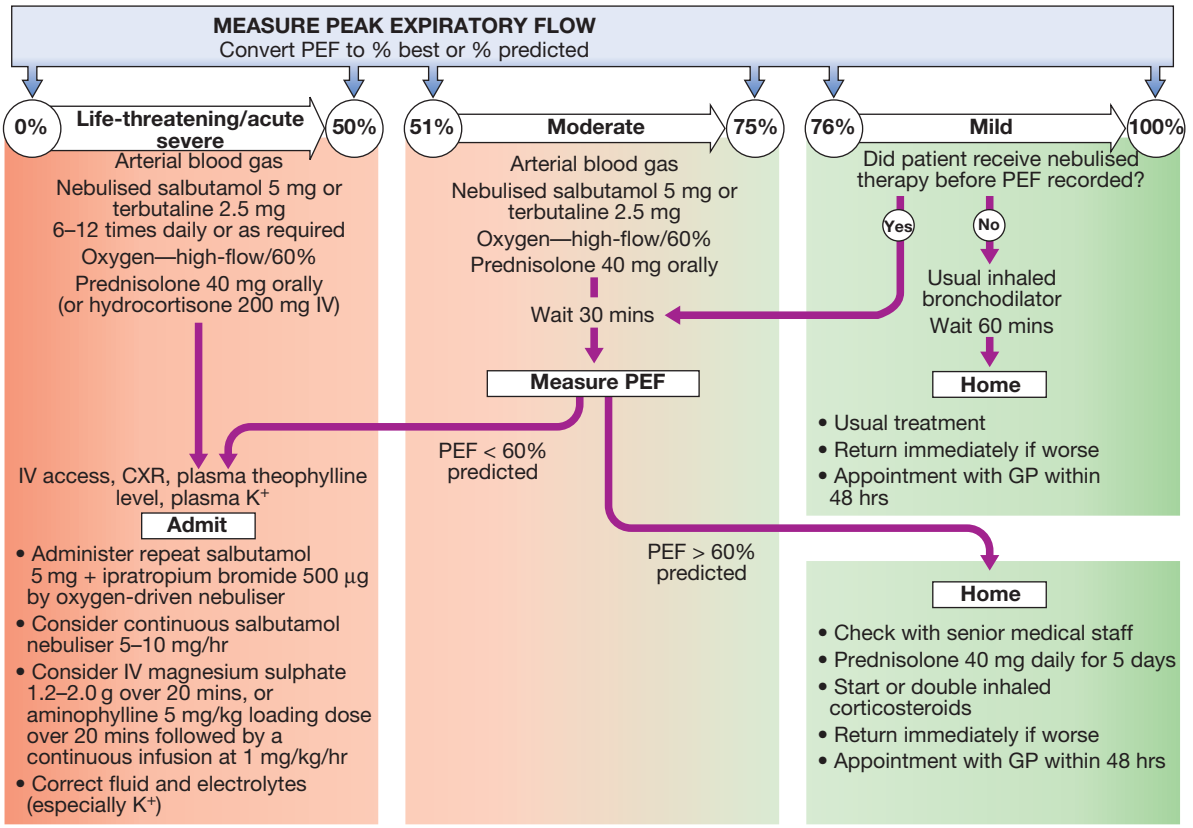

Fig. 19.24 Immediate treatment of patients with acute severe asthma.

mandatory, unless the patient is too ill to cooperate, and is most easily interpreted when expressed as a percentage of the predicted normal or of the previous best value obtained on optimal treatment (Fig. 19.24). Arterial blood gas analysis is essential to determine the $PaCO_2$, a normal or elevated level being particularly dangerous. A chest X-ray is not immediately necessary, unless pneumothorax is suspected.

Treatment includes the following measures:

- *Oxygen.* High concentrations (humidified if possible) should be administered to maintain the oxygen saturation above 92% in adults. The presence of a high $PaCO_2$ should not be taken as an indication to reduce oxygen concentration, but as a warning sign of a severe or life-threatening attack. Failure to achieve appropriate oxygenation is an indication for assisted ventilation.
- *High doses of inhaled bronchodilators.* Short-acting β_2-agonists are the agent of choice. In hospital, they are most conveniently given via a nebuliser driven by oxygen, but delivery of multiple doses of salbutamol via a metered-dose inhaler through a spacer device provides equivalent bronchodilatation and can be used in primary care. Ipratropium bromide provides further bronchodilator therapy and should be added to salbutamol in acute severe or life-threatening attacks.
- *Systemic corticosteroids.* These reduce the inflammatory response and hasten the resolution of an exacerbation. They should be administered to all patients with an acute severe attack. They can usually be administered orally as prednisolone, but intravenous hydrocortisone may be used in patients who are vomiting or unable to swallow.

There is no evidence base for the use of intravenous fluids but many patients are dehydrated due to high insensible water loss and will probably benefit. Potassium supplements may be necessary, as repeated doses of salbutamol can lower serum potassium.

If patients fail to improve, a number of further options may be considered. Intravenous magnesium may provide additional bronchodilatation in patients whose presenting PEF is below 30% predicted. Some patients appear to benefit from the use of intravenous aminophylline but cardiac monitoring is recommended.

PEF should be recorded every 15–30 minutes and then every 4–6 hours. Pulse oximetry should ensure that SaO_2 remains above 92%, but repeat arterial blood gases are necessary if the initial $PaCO_2$ measurements were normal or raised, the PaO_2 was below 8 kPa (60 mmHg), or the patient deteriorates. Box 19.26 lists the indications

19.26 Indications for assisted ventilation in acute severe asthma

- Coma
- Respiratory arrest
- Deterioration of arterial blood gas tensions despite optimal therapy
  - PaO_2 < 8 kPa (60 mmHg) and falling
  - $PaCO_2$ > 6 kPa (45 mmHg) and rising
  - pH low and falling (H^+ high and rising)
- Exhaustion, confusion, drowsiness

for endotracheal intubation and intermittent positive pressure ventilation.

Prognosis

The outcome from acute severe asthma is generally good. Death is fortunately rare but a considerable number of deaths occur in young people and many are preventable. Failure to recognise the severity of an attack, on the part of either the assessing physician or the patient, contributes to delay in delivering appropriate therapy and to under-treatment.

Prior to discharge, patients should be stable on discharge medication (nebulised therapy should have been discontinued for at least 24 hours) and the PEF should have reached 75% of predicted or personal best. The acute attack should prompt a look for and avoidance of any trigger factors, the delivery of asthma education and the provision of a written self-management plan. The patient should be offered an appointment with a GP or asthma nurse within 2 working days of discharge, and follow-up at a specialist hospital clinic within a month.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is a preventable and treatable disease characterised by persistent airflow limitation that is usually progressive, and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases. Exacerbations and comorbidities contribute to the overall severity in individual patients. Related diagnoses include chronic bronchitis (cough and sputum on most days for at least 3 months, in each of 2 consecutive years) and emphysema (abnormal permanent enlargement of the airspaces distal to the terminal bronchioles, accompanied by destruction of their walls and without obvious fibrosis). Extra-pulmonary effects include weight loss and skeletal muscle dysfunction (Fig. 19.25). Commonly associated comorbid conditions include cardiovascular disease, cerebrovascular disease, the metabolic syndrome, osteoporosis, depression and lung cancer.

Epidemiology and aetiology

The prevalence of COPD is directly related to the prevalence of tobacco smoking and, in low- and middle-income countries, the use of biomass fuels. Current estimates suggest that 80 million people worldwide suffer from moderate to severe disease. In 2005, COPD contributed to more than 3 million deaths (5% of deaths globally), but, by 2020, it is forecast to represent the third most important cause of death worldwide. The anticipated rise in morbidity and mortality from COPD will be greatest in Asian and African countries, as a result of their increasing tobacco consumption.

Other risk factors are shown in Box 19.27. Cigarette smoking represents the most significant risk factor, and the risk of developing COPD relates to both the amount and the duration of smoking. It is unusual to develop COPD with less than 10 pack years (1 pack year = 20 cigarettes/day/year) and not all smokers develop the condition, suggesting that individual susceptibility factors are important.

Pathophysiology

COPD has both pulmonary and systemic components (see Fig. 19.25). The presence of airflow limitation,

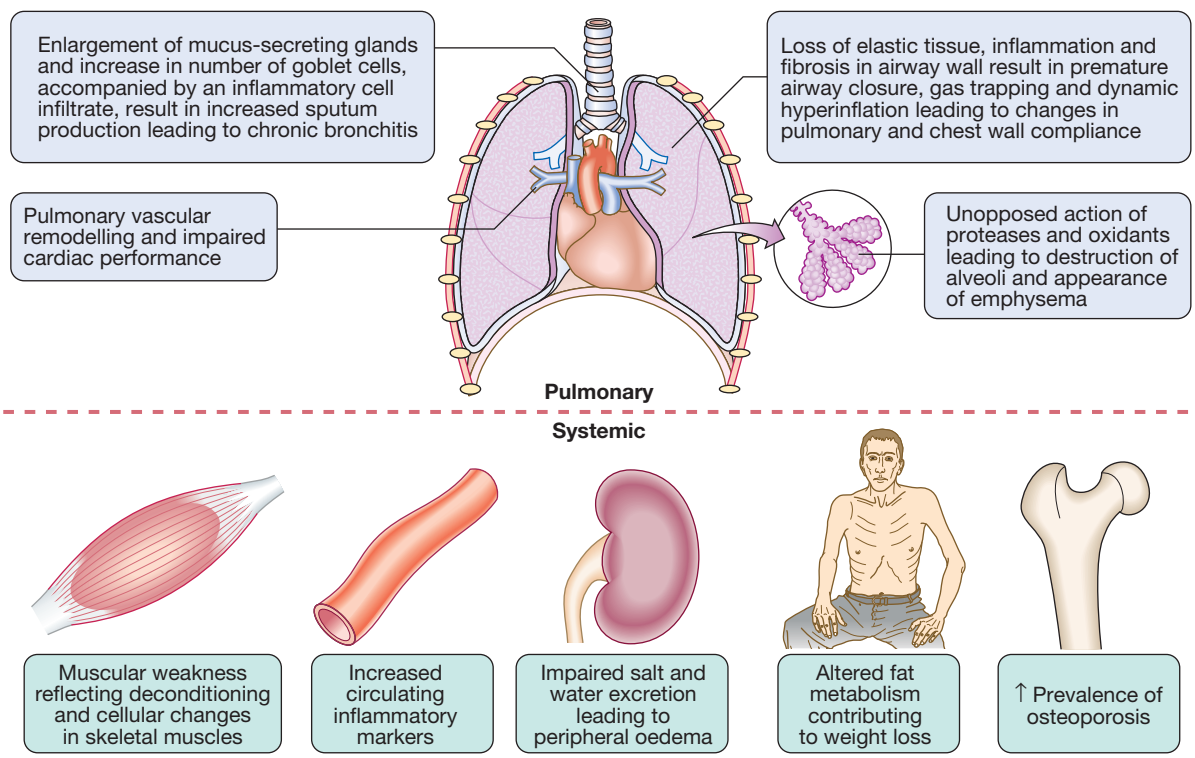

Fig. 19.25 The pulmonary and systemic features of COPD.

19.27 Risk factors for development of COPD

Environmental

- Tobacco smoke accounts for 95% of cases in UK
- Indoor air pollution; cooking with biomass fuels in confined areas in developing countries
- Occupational exposures, such as coal dust, silica and cadmium
- Low birth weight may reduce maximally attained lung function in young adult life
- Lung growth: childhood infections or maternal smoking may affect growth of lung during childhood, resulting in a lower maximally attained lung function in adult life
- Infections: recurrent infection may accelerate decline in FEV_1; persistence of adenovirus in lung tissue may alter local inflammatory response, predisposing to lung damage; HIV infection is associated with emphysema
- Low socioeconomic status
- Cannabis smoking

Host factors

- Genetic factors: α_1-antiproteinase deficiency; other COPD susceptibility genes are likely to be identified
- Airway hyper-reactivity

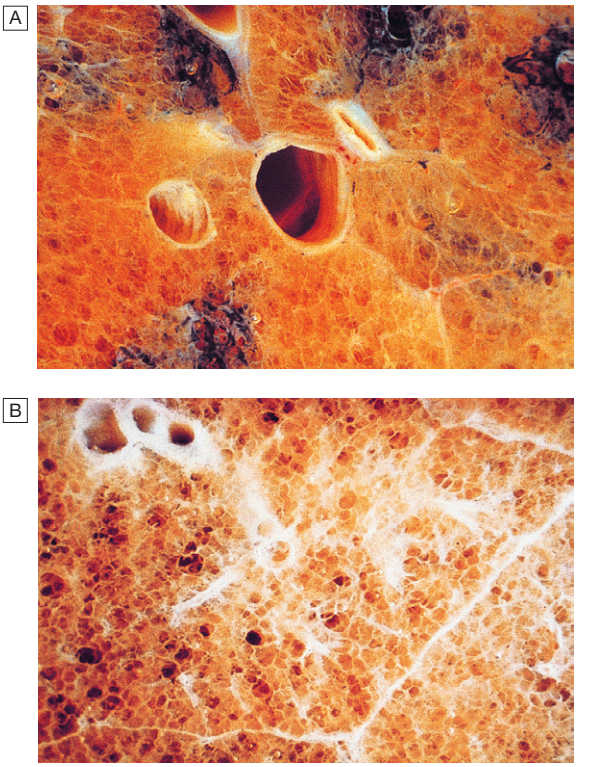

Fig. 19.26 The pathology of emphysema. A Normal lung. B Emphysematous lung showing gross loss of the normal surface area available for gas exchange.

combined with premature airway closure, leads to gas trapping and hyperinflation, reducing pulmonary and chest wall compliance. Pulmonary hyperinflation also flattens the diaphragmatic muscles and leads to an increasingly horizontal alignment of the intercostal muscles, placing the respiratory muscles at a mechanical disadvantage. The work of breathing is therefore markedly increased, first on exercise, when the time for expiration is further shortened, but then, as the disease advances, at rest.

Emphysema (Fig. 19.26) may be classified by the pattern of the enlarged airspaces as centriacinar, panacinar or paraseptal. Bullae form in some individuals. This results in impaired gas exchange and respiratory failure.

Clinical features

COPD should be suspected in any patient over the age of 40 years who presents with symptoms of chronic bronchitis and/or breathlessness. Important differential diagnoses include chronic asthma, tuberculosis, bronchiectasis and congestive cardiac failure.

Cough and associated sputum production are usually the first symptoms, often referred to as a 'smoker's cough'. Haemoptysis may complicate exacerbations of COPD but should not be attributed to COPD without thorough investigation.

Breathlessness usually precipitates the presentation to health care. The severity should be quantified by documenting what level of exertion the patient can manage before stopping; scales such as the modified MRC dyspnoea scale may be useful (Box 19.28). In advanced disease, enquiry should be made about the presence of oedema, which may be seen for the first time during an exacerbation, and morning headaches, which may suggest hypercapnia.

Physical signs (pp. 644–645) are non-specific, correlate poorly with lung function, and are seldom obvious until the disease is advanced. Breath sounds are typically quiet. Crackles may accompany infection but, if persistent, raise the possibility of bronchiectasis. Finger clubbing is not a feature of COPD and should trigger further investigation for lung cancer or fibrosis. Pitting oedema should be sought but the frequently used term 'cor pulmonale' is actually a misnomer, as the right heart seldom 'fails' in COPD and the occurrence of oedema usually relates to failure of salt and water excretion by the hypoxic hypercapnic kidney. The body mass index (BMI – p. 114) is of prognostic significance.

Two classical phenotypes have been described: 'pink puffers' and 'blue bloaters'. The former are typically thin

19.28 Modified MRC dyspnoea scale

Grade	Degree of breathlessness related to activities
0	No breathlessness, except with strenuous exercise
1	Breathlessness when hurrying on the level or walking up a slight hill
2	Walks slower than contemporaries on level ground because of breathlessness or has to stop for breath when walking at own pace
3	Stops for breath after walking about 100 m or after a few minutes on level ground
4	Too breathless to leave the house, or breathless when dressing or undressing

(MRC = Medical Research Council)

and breathless, and maintain a normal $PaCO_2$ until the late stage of disease. The latter develop (or tolerate) hypercapnia earlier and may develop oedema and secondary polycythaemia. In practice, these phenotypes often overlap.

Investigations

Although there are no reliable radiographic signs that correlate with the severity of airflow limitation, a chest X-ray is essential to identify alternative diagnoses, such as cardiac failure, other complications of smoking such as lung cancer, and the presence of bullae. A blood count is useful to exclude anaemia or polycythaemia, and in younger patients with predominantly basal emphysema, α_1-antiproteinase should be assayed.

The diagnosis requires objective demonstration of airflow obstruction by spirometry and is established when the post-bronchodilator FEV_1/FVC is less than 70%. The severity of COPD may be defined in relation to the post-bronchodilator FEV_1 (Box 19.29). A low peak flow is consistent with COPD but is non-specific, does not discriminate between obstructive and restrictive disorders, and may underestimate the severity of airflow limitation.

Measurement of lung volumes provides an assessment of hyperinflation. This is generally performed by using the helium dilution technique (p. 653); in patients with severe COPD, and with large bullae in particular, body plethysmography is preferred because the use of helium may underestimate lung volumes. Emphysema is suggested by a low gas transfer value (p. 653). Exercise tests provide an objective assessment of exercise tolerance and a baseline for judging response to bronchodilator therapy or rehabilitation programmes; they may also be valuable when assessing prognosis. Pulse oximetry of less than 93% may indicate the need for referral for a domiciliary oxygen assessment.

The assessment of health status provides valuable clinical information. The St George's Respiratory Questionnaire (SGRQ) is a commonly used research tool but is too cumbersome for routine clinical practice. The COPD Assessment Test (CAT) employs only eight questions and the scores correlate closely with the SGRQ.

HRCT is likely to play an increasing role in the assessment of COPD, as it allows the detection, characterisation and quantification of emphysema (Fig. 19.27) and is more sensitive than a chest X-ray for detecting bullae.

19.29 Spirometric classification of COPD severity based on post-bronchodilator FEV_1

Stage	Severity	FEV_1
I	Mild*	$FEV_1/FVC < 0.70$ $FEV_1 \geq 80\%$ predicted
II	Moderate	$FEV_1/FVC < 0.70$ FEV_1 50–79% predicted
III	Severe	$FEV_1/FVC < 0.70$ FEV_1 30–49% predicted
IV	Very severe	$FEV_1/FVC < 0.70$ $FEV_1 < 30\%$ predicted or $FEV_1 < 50\%$ predicted if respiratory failure present

*Mild COPD should not be diagnosed on lung function alone if the patient is asymptomatic. Based on NICE guidelines 2010.

Fig. 19.27 Gross emphysema. HRCT showing emphysema, most evident in the right lower lobe.

Management

The management of COPD (Fig. 19.28) has been the subject of unjustified pessimism. It is usually possible to help breathlessness, reduce the frequency and severity of exacerbations, enhance the health status, and improve the prognosis.

Reducing exposure to noxious particles and gases

Every attempt should be made to highlight to the patient the role of smoking in the development and progression of COPD, with advice and assistance to help them stop (p. 100). Reducing the number of cigarettes smoked each day has little impact on the course and prognosis of COPD, but complete cessation is accompanied by an improvement in lung function and deceleration in the rate of FEV_1 decline (Fig. 19.29 and Box 19.30). In regions where the indoor burning of biomass fuels is important, the introduction of non-smoking cooking devices or use of alternative fuels should be encouraged.

Bronchodilators

Bronchodilator therapy is central to the management of breathlessness. The inhaled route is preferred and a number of different agents, delivered by a variety of devices, are available. Choice should be informed by patient preference and inhaler assessment. Short-acting bronchodilators, such as the β_2-agonists salbutamol and terbutaline, or the anticholinergic ipratropium bromide, may be used for patients with mild disease, but longer-acting bronchodilators, such as the β_2-agonists salmeterol, formoterol and indacaterol, or the anticholinergic tiotropium bromide, are more appropriate for patients with moderate to severe disease. Significant improvements in breathlessness may be reported, despite minimal changes in FEV_1, probably reflecting improvements in lung emptying that reduce dynamic hyperinflation and ease the work of breathing.

EBM 19.30 Smoking cessation and COPD

'Sustained smoking cessation in mild to moderate COPD is accompanied by a reduced decline in FEV_1 compared to persistent smokers.'

- Anthonisen NR, et al. Am J Respir Crit Care Med 2002; 166:675–679.

I : Mild	II : Moderate	III : Severe	IV : Very severe
• $FEV_1/FVC < 0.70$ • $FEV_1 \geq 80\%$ predicted	• $FEV_1/FVC < 0.70$ • $50\% \leq FEV_1 < 80\%$ predicted	• $FEV_1/FVC < 0.70$ • $30\% \leq FEV_1 < 50\%$ predicted	• $FEV_1/FVC < 0.70$ • $FEV_1 < 30\%$ predicted *or* $FEV_1 < 50\%$ predicted *plus* chronic respiratory failure
Active reduction of risk factor(s); influenza vaccination **Add** short-acting bronchodilator (when needed)			
	Add regular treatment with one or more long-acting bronchodilators (when needed) **Add** rehabilitation		
		Add inhaled glucocorticosteroids if repeated exacerbations	
			Add long-term oxygen if chronic respiratory failure **Consider** surgical treatments

Fig. 19.28 Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines for treatment of COPD. Post-bronchodilator FEV_1 is recommended for the diagnosis and assessment of severity of COPD. From www.goldcopd.com – see p. 732.

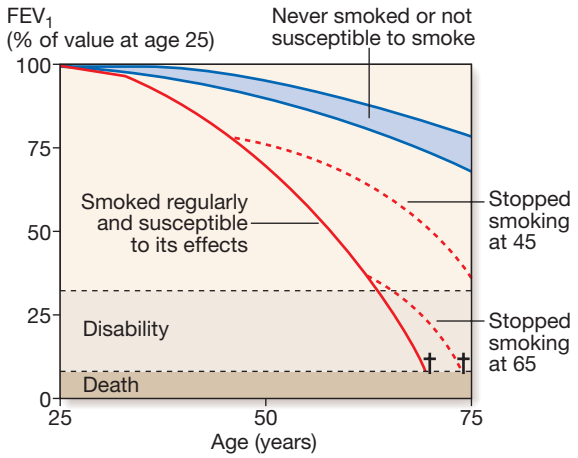

Fig. 19.29 Model of annual decline in FEV_1 with accelerated decline in susceptible smokers. When smoking is stopped, subsequent loss is similar to that in healthy non-smokers.

Oral bronchodilator therapy may be used in patients who cannot use inhaled devices efficiently. Theophylline preparations improve breathlessness and quality of life, but their use is limited by side-effects, unpredictable metabolism and drug interactions. Bambuterol, a pro-drug of terbutaline, is used on occasion. Orally active, highly selective phosphodiesterase inhibitors are currently under appraisal.

Corticosteroids

Inhaled corticosteroids (ICS) reduce the frequency and severity of exacerbations, and are currently recommended in patients with severe disease ($FEV_1 < 50\%$) who report two or more exacerbations requiring antibiotics or oral steroids per year. Regular use is associated with a small improvement in FEV_1, but ICS do not alter the natural history of the FEV_1 decline. It is more usual to prescribe a fixed combination of an ICS and a LABA.

Oral corticosteroids are useful during exacerbations but maintenance therapy contributes to osteoporosis and impaired skeletal muscle function and should be avoided. Oral corticosteroid trials assist in the diagnosis of asthma but do not predict response to inhaled steroids in COPD.

Pulmonary rehabilitation

Exercise should be encouraged at all stages and patients reassured that breathlessness, whilst distressing, is not dangerous. Multidisciplinary programmes that incorporate physical training, disease education and nutritional counselling reduce symptoms, improve health status and enhance confidence. Most programmes include 2–3 sessions per week for 6 and 12 weeks, and are accompanied by demonstrable and sustained improvements in exercise tolerance and health status.

Oxygen therapy

Long-term domiciliary oxygen therapy (LTOT) has been shown to be of significant benefit in selected patients (Boxes 19.31 and 19.32). It is most conveniently provided

EBM 19.31 Long-term domiciliary oxygen therapy

'Long-term home oxygen therapy improves survival in selected patients with COPD complicated by severe hypoxaemia (arterial PaO_2 less than 8.0 kPa (55 mmHg)).'

- Cranston JM, et al. Domiciliary oxygen for chronic obstructive pulmonary disease. Cochrane Database of Systematic Reviews, 2005, issue 4. Art no. CD001744.

For further information: www.brit-thoracic.org.uk

19.32 Prescription of long-term oxygen therapy in COPD

Arterial blood gases measured in clinically stable patients on optimal medical therapy on at least two occasions 3 weeks apart:

- $PaO_2 < 7.3$ kPa (55 mmHg) irrespective of $PaCO_2$ and $FEV_1 < 1.5$ L
- PaO_2 7.3–8 kPa (55–60 mmHg) plus pulmonary hypertension, peripheral oedema or nocturnal hypoxaemia
- the patient has stopped smoking.

Use at least 15 hrs/day at 2–4 L/min to achieve a $PaO_2 > 8$ kPa (60 mmHg) without unacceptable rise in $PaCO_2$.

by an oxygen concentrator and patients should be instructed to use oxygen for a minimum of 15 hours per day; greater benefits are seen in patients who receive more than 20 hours per day. The aim of therapy is to increase the PaO_2 to at least 8 kPa (60 mmHg) or SaO_2 to at least 90%. Ambulatory oxygen therapy should be considered in patients who desaturate on exercise and show objective improvement in exercise capacity and/or dyspnoea with oxygen. Oxygen flow rates should be adjusted to maintain SaO_2 above 90%.

Surgical intervention

Patients in whom large bullae compress surrounding normal lung tissue, who otherwise have minimal airflow limitation and a lack of generalised emphysema, may be considered for bullectomy. Patients with predominantly upper lobe emphysema, with preserved gas transfer and no evidence of pulmonary hypertension, may benefit from lung volume reduction surgery (LVRS), in which peripheral emphysematous lung tissue is resected with the aim of reducing hyperinflation and decreasing the work of breathing. Both bullectomy and LVRS can be performed thoracopically, minimising morbidity. Lung transplantation may benefit carefully selected patients with advanced disease (p. 665).

Other measures

Patients with COPD should be offered an annual influenza vaccination and, as appropriate, pneumococcal vaccination. Obesity, poor nutrition, depression and social isolation should be addressed as far as possible. Mucolytic therapy or antioxidant agents are occasionally used but with limited evidence.

Addressing end-of-life needs is an important yet often ignored aspect of care in advanced disease. Morphine may be used for palliation of breathlessness in advanced disease and benzodiazepines in low dose may reduce anxiety. Decisions regarding resuscitation should be discussed with the patient in advance of critical illness.

Prognosis

COPD has a variable natural history but is usually progressive. The prognosis is inversely related to age and directly related to the post-bronchodilator FEV_1. Other poor prognostic indicators include weight loss and pulmonary hypertension. A composite score comprising the body mass index (B), the degree of airflow obstruction (O), a measurement of dyspnoea (D) and exercise capacity (E) may assist in predicting death from respiratory and other causes (Box 19.33). Respiratory failure, cardiac disease and lung cancer represent common modes of death.

19.33 Calculation of the BODE index

	Points on BODE index			
Variable	**0**	**1**	**2**	**3**
FEV_1	≥ 65	50–64	36–49	≤ 35
Distance walked in 6 mins (m)	≥ 350	250–349	150–249	≤ 149
MRC dyspnoea scale*	0–1	2	3	4
Body mass index	> 21	≤ 21		

A patient with a BODE score of 0–2 has a mortality rate of around 10% at 52 mths, whereas a patient with a BODE score of 7–10 has a mortality rate of around 80% at 52 mths.

*See Box 19.28.

Acute exacerbations of COPD

Acute exacerbations of COPD are characterised by an increase in symptoms and deterioration in lung function and health status. They become more frequent as the disease progresses and are usually triggered by bacteria, viruses or a change in air quality. They may be accompanied by the development of respiratory failure and/or fluid retention and are an important cause of death.

Many patients can be managed at home with the use of increased bronchodilator therapy, a short course of oral corticosteroids and, if appropriate, antibiotics. The presence of cyanosis, peripheral oedema or an alteration in consciousness indicates the need for referral to hospital. In other patients, consideration of comorbidity and social circumstances may influence decisions regarding hospital admission.

Management

In patients with an exacerbation of severe COPD, high concentrations of oxygen may cause respiratory depression and worsening acidosis (p. 665). Controlled oxygen at 24% or 28% should be used with the aim of maintaining a PaO_2 above 8 kPa (60 mmHg) (or an SaO_2 between 88% and 92%) without worsening acidosis.

Nebulised short-acting β_2-agonists, combined with an anticholinergic agent (e.g. salbutamol and ipratropium), should be administered. With careful supervision, it is usually safe to drive nebulisers with oxygen, but if

19.34 Obstructive pulmonary disease in old age

- **Asthma**: may appear de novo in old age, so airflow obstruction should not always be assumed to be due to COPD.
- **PEF recordings**: older people with poor vision have difficulty reading PEF meters.
- **Perception of bronchoconstriction**: impaired by age, so an older patient's description of symptoms may not be a reliable indicator of severity.
- **Stopping smoking**: the benefits on the rate of loss of lung function decline with age but remain valuable up to the age of 80.
- **Metered-dose inhalers**: many older people cannot use these because of difficulty coordinating and triggering the device. Even mild cognitive impairment virtually precludes their use. Frequent demonstration and re-instruction in the use of all devices are required.
- **Mortality rates for acute asthma**: higher in old age, partly because patients underestimate the severity of bronchoconstriction and also develop a lower degree of tachycardia and pulsus paradoxus for the same degree of bronchoconstriction.
- **Treatment decisions**: advanced age in itself is not a barrier to intensive care or mechanical ventilation in an acute episode of asthma or COPD, but this decision may be difficult and should be shared with the patient (if possible), the relatives and the GP.

concern exists regarding oxygen sensitivity, they may be driven by compressed air and supplemental oxygen delivered by nasal cannula.

Oral prednisolone reduces symptoms and improves lung function. Currently, doses of 30 mg for 10 days are recommended but shorter courses may be acceptable. Prophylaxis against osteoporosis should be considered in patients who receive repeated courses of steroids (p. 776).

The role of bacteria in exacerbations remains controversial and there is little evidence for the routine administration of antibiotics. They are currently recommended, however, for patients reporting an increase in sputum purulence, sputum volume or breathlessness. In most cases, simple regimens are advised, such as an aminopenicillin or a macrolide. Co-amoxiclav is only required in regions where β-lactamase-producing organisms are known to be common.

If, despite the above measures, the patient remains tachypnoeic, hypercapnic and acidotic ($PaCO_2$ > 6 kPa, $H^+ \geq 45$ (pH < 7.35)), then NIV should be commenced (p. 193). Its use is associated with reduced requirements for mechanical ventilation and reduced mortality (Box 19.35). It is not useful in patients who cannot protect their airway. Mechanical ventilation may be considered in those with a reversible cause for deterioration (e.g. pneumonia), or if there is no prior history of respiratory failure.

Exacerbations may be accompanied by the development of peripheral oedema that usually responds to diuretics. There has been a vogue for using intravenous infusions of aminophylline, but evidence for benefit is limited and there is an associated risk of inducing arrhythmias and drug interactions. The use of the respiratory stimulant doxapram has been largely superseded by the development of NIV, but it may be useful for a limited period in selected patients with a low respiratory rate.

Discharge from hospital may be planned once patients are clinically stable on their usual maintenance medication. The provision of a nurse-led 'hospital at home' team providing short-term nebuliser loan improves discharge rates and additional support for the patient.

EBM 19.35 Non-invasive ventilation in COPD exacerbations

'Non-invasive ventilation is safe and effective in patients with an acute exacerbation of COPD complicated by mild to moderate respiratory acidosis, and should be considered early in the course of respiratory failure to reduce the need for endotracheal intubation, treatment failure and mortality.'

- Lim WJ, et al. Non-invasive positive pressure ventilation for treatment of respiratory failure due to exacerbations of chronic obstructive pulmonary disease. Cochrane Database of Systematic Reviews, 2004, issue 3. Art. no. CD004104.

Bronchiectasis

Bronchiectasis means abnormal dilatation of the bronchi. Chronic suppurative airway infection with sputum production, progressive scarring and lung damage occur, whatever the cause.

19.36 Causes of bronchiectasis

Congenital

- Cystic fibrosis
- Ciliary dysfunction syndromes
  - Primary ciliary dyskinesia (immotile cilia syndrome)
  - Kartagener's syndrome (sinusitis and transposition of the viscera)
- Primary hypogammaglobulinaemia (p. 881)

Acquired: children

- Pneumonia (complicating whooping cough or measles)
- Primary TB
- Inhaled foreign body

Acquired: adults

- Suppurative pneumonia
- Pulmonary TB
- Allergic bronchopulmonary aspergillosis complicating asthma (p. 697)
- Bronchial tumours

Aetiology and pathology

Bronchiectasis may result from a congenital defect affecting airway ion transport or ciliary function, such as cystic fibrosis (see below), or may be acquired secondary to damage to the airways by a destructive infection, inhaled toxin or foreign body. The result is chronic inflammation and infection in airways. Box 19.36 shows the common causes, of which tuberculosis is the most common worldwide.

Localised bronchiectasis may occur due to the accumulation of pus beyond an obstructing bronchial lesion, such as enlarged tuberculous hilar lymph nodes, a bronchial tumour or an inhaled foreign body (e.g. an aspirated peanut).

The bronchiectatic cavities may be lined by granulation tissue, squamous epithelium or normal ciliated epithelium. There may also be inflammatory changes in the deeper layers of the bronchial wall and hypertrophy of the bronchial arteries. Chronic inflammatory and fibrotic changes are usually found in the surrounding lung tissue, resulting in progressive destruction of the normal lung architecture in advanced cases.

Clinical features

The symptoms are shown in Box 19.37.

Physical signs in the chest may be unilateral or bilateral. If the bronchiectatic airways do not contain secretions and there is no associated lobar collapse, there are no abnormal physical signs. When there are large amounts of sputum in the bronchiectatic spaces, numerous coarse crackles may be heard over the affected areas. Collapse with retained secretions blocking a proximal bronchus may lead to locally diminished breath sounds, while advanced disease may cause scarring and overlying bronchial breathing. Acute haemoptysis is an important complication of bronchiectasis; management is described on page 659.

Investigations

In addition to common respiratory pathogens, sputum culture may reveal *Pseudomonas aeruginosa*, fungi such as *Aspergillus* and various mycobacteria. Frequent cultures

19.37 Symptoms of bronchiectasis

- **Cough**: chronic, daily, persistent
- **Sputum**: copious, continuously purulent
- **Pleuritic pain**: when infection spreads to involve pleura, or with segmental collapse due to retained secretions
- **Haemoptysis**:
  Streaks of blood common, larger volumes with exacerbations of infection
  Massive haemoptysis requiring bronchial artery embolisation sometimes occurs
- **Infective exacerbation**: increased sputum volume with fever, malaise, anorexia
- **Halitosis**: frequently accompanies purulent sputum
- **General debility**: difficulty maintaining weight, anorexia, exertional breathlessness

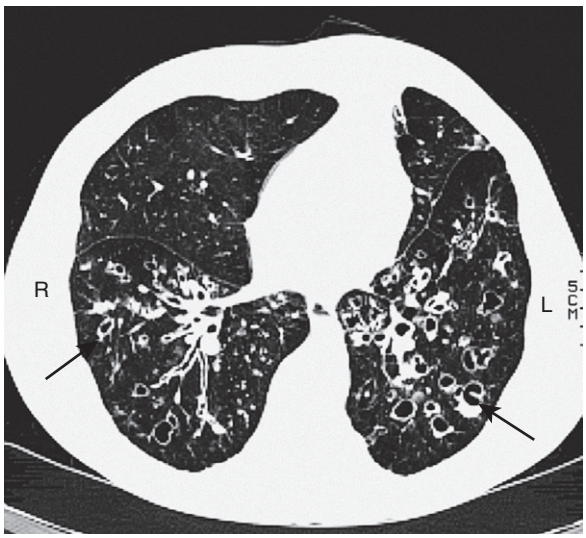

Fig. 19.30 CT of bronchiectasis. Extensive dilatation of the bronchi, with thickened walls (arrows) in both lower lobes.

are necessary to ensure appropriate treatment of resistant organisms.

Bronchiectasis, unless very gross, is not usually apparent on a chest X-ray. In advanced disease, thickened airway walls, cystic bronchiectatic spaces, and associated areas of pneumonic consolidation or collapse may be visible. CT is much more sensitive, and shows thickened, dilated airways (Fig. 19.30).

A screening test can be performed in patients suspected of having a ciliary dysfunction syndrome by measuring the time taken for a small pellet of saccharin placed in the anterior chamber of the nose to reach the pharynx, at which point the patient can taste it. This time should not exceed 20 minutes but is greatly prolonged in patients with ciliary dysfunction. Ciliary beat frequency may also be assessed from biopsies taken from the nose. Structural abnormalities of cilia can be detected by electron microscopy.

Management

In patients with airflow obstruction, inhaled bronchodilators and corticosteroids should be used to enhance airway patency.

Physiotherapy

Patients should be shown how to perform regular daily physiotherapy to assist the drainage of excess bronchial secretions. Efficiently executed, this is of great value both in reducing the amount of cough and sputum, and in preventing recurrent episodes of bronchopulmonary infection. Patients should lie in a position in which the lobe to be drained is uppermost. Deep breathing followed by forced expiratory manœuvres (the 'active cycle of breathing' technique) helps to move secretions in the dilated bronchi towards the trachea, from which they can be cleared by vigorous coughing. Devices that increase airway pressure either by a constant amount (positive expiratory pressure mask) or in an oscillatory manner (flutter valve), aid sputum clearance in some patients, and a variety of techniques should be tried to find the one that suits the individual. The optimum duration and frequency of physiotherapy depend on the amount of sputum, but 5–10 minutes twice daily is a minimum for most patients.

Antibiotic therapy

For most patients with bronchiectasis, the appropriate antibiotics are the same as those used in COPD (p. 678) but larger doses and longer courses are required, and resolution of symptoms is often incomplete. When secondary infection occurs with staphylococci and Gram-negative bacilli, in particular *Pseudomonas* species, antibiotic therapy becomes more challenging and should be guided by the microbiological sensitivities. For *Pseudomonas*, oral ciprofloxacin (500–750 mg twice daily) or ceftazidime by intravenous injection or infusion (1–2 g 3 times daily) may be required. Haemoptysis in bronchiectasis often responds to treatment of the underlying infection, although, in severe cases, percutaneous embolisation of the bronchial circulation by an interventional radiologist may be necessary.

Surgical treatment

Excision of bronchiectatic areas is only indicated in a small proportion of cases. These are usually patients in whom the bronchiectasis is confined to a single lobe or segment on CT. Unfortunately, many of the patients in whom medical treatment proves unsuccessful are also unsuitable for surgery because of either extensive bilateral bronchiectasis or coexisting severe airflow obstruction. In progressive forms of bronchiectasis, resection of destroyed areas of lung that are acting as a reservoir of infection should only be considered as a last resort.

Prognosis

The disease is progressive when associated with ciliary dysfunction and cystic fibrosis, and eventually causes respiratory failure. In other patients, the prognosis can be relatively good if physiotherapy is performed regularly and antibiotics are used aggressively.

Prevention

As bronchiectasis commonly starts in childhood following measles, whooping cough or a primary tuberculous infection, adequate prophylaxis for and treatment of these conditions are essential. The early recognition and treatment of bronchial obstruction are also important.

Cystic fibrosis

Genetics, pathogenesis and epidemiology

Cystic fibrosis (CF) is the most common fatal genetic disease in Caucasians, with autosomal recessive inheritance, a carrier rate of 1 in 25, and an incidence of about 1 in 2500 live births (pp. 48 and 53). CF is the result of mutations affecting a gene on the long arm of chromosome 7, which codes for a chloride channel known as cystic fibrosis transmembrane conductance regulator (*CFTR*); this influences salt and water movement across epithelial cell membranes. The most common *CFTR* mutation in northern European and American populations is Δ*F508*, but over a thousand mutations of this gene have now been identified. The genetic defect causes increased sodium and chloride content in sweat and increased resorption of sodium and water from respiratory epithelium (Fig. 19.31). Relative dehydration of the airway epithelium is thought to predispose to chronic bacterial infection and ciliary dysfunction, leading to bronchiectasis. The gene defect also causes disorders in the gut epithelium, pancreas, liver and reproductive tract (see below).

In the 1960s, few patients with CF survived childhood, yet with aggressive treatment of airway infection and nutritional support, life expectancy has improved dramatically, so that there are now more adults than children with CF in many developed countries. Until recently, the diagnosis was most commonly made from the clinical picture (bowel obstruction, failure to thrive, steatorrhoea and/or chest symptoms in a young child), supported by sweat electrolyte testing and genotyping. Patients with unusual phenotypes were commonly missed, however, and late diagnosis led to poorer outcomes. Neonatal screening for CF using immunoreactive trypsin and genetic testing of newborn blood samples is now routine in the UK, and should reduce delayed diagnosis and improve outcomes. Prenatal screening by amniocentesis may be offered to those known to be at high risk.

Clinical features

The lungs are macroscopically normal at birth, but bronchiolar inflammation and infections usually lead to bronchiectasis in childhood. At this stage, the lungs are most commonly infected with *Staphylococcus aureus*; however, in adulthood, many patients become colonised with *Pseudomonas aeruginosa*. Recurrent exacerbations of bronchiectasis, initially in the upper lobes but subsequently throughout both lungs, cause progressive lung damage, resulting ultimately in death from respiratory failure. Other clinical manifestations are shown in Box 19.38. Most men with CF are infertile due to failure of development of the vas deferens, but microsurgical sperm

19.38 Complications of cystic fibrosis

Respiratory	
• Infective exacerbations of bronchiectasis • Spontaneous pneumothorax • Haemoptysis • Nasal polyps	• Respiratory failure • Cor pulmonale • Lobar collapse due to secretions
Gastrointestinal	
• Malabsorption and steatorrhoea • Distal intestinal obstruction syndrome	• Biliary cirrhosis and portal hypertension • Gallstones
Others	
• Diabetes (25% of adults) • Delayed puberty • Male infertility • Stress incontinence due to repeated forced cough	• Psychosocial problems • Osteoporosis • Arthropathy • Cutaneous vasculitis

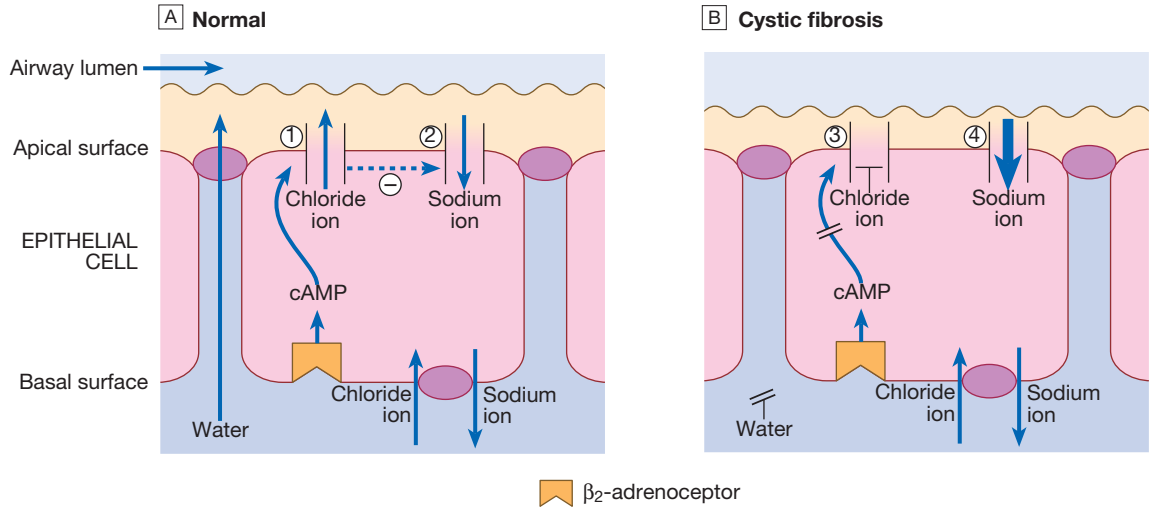

Fig. 19.31 Cystic fibrosis: basic defect in the pulmonary epithelium. A The CF gene codes for a chloride channel (1) in the apical (luminal) membrane of epithelial cells in the conducting airways. This is normally controlled by cyclic adenosine monophosphate (cAMP) and indirectly by β-adrenoceptor stimulation, and is one of several apical ion channels which control the quantity and solute content of airway-lining fluid. Normal channels appear to inhibit the adjacent epithelial sodium channels (2). B In cystic fibrosis, one of many CF gene defects causes absence or defective function of this chloride channel (3). This leads to reduced chloride secretion and loss of inhibition of sodium channels, with excessive sodium resorption (4) and dehydration of the airway lining. The resulting abnormal airway-lining fluid predisposes to infection by mechanisms still to be fully explained.

aspiration and in vitro fertilisation are possible. Genotype is a poor predictor of disease severity in individuals; even siblings with matching genotypes may have different phenotypes. This suggests that other 'modifier genes', as yet unidentified, influence clinical outcome.

Management

Treatment of CF lung disease

The management of CF lung disease is that of severe bronchiectasis. All patients with CF who produce sputum should perform chest physiotherapy regularly, and more frequently during exacerbations. While infections with *Staph. aureus* can often be managed with oral antibiotics, intravenous treatment (frequently self-administered at home through an implanted subcutaneous vascular port) is usually needed for *Pseudomonas* infections. Regular nebulised antibiotic therapy (colistin or tobramycin) is used between exacerbations in an attempt to suppress chronic *Pseudomonas* infection.

Unfortunately, the bronchi of many CF patients eventually become colonised with pathogens that are resistant to most antibiotics. Resistant strains of *P. aeruginosa*, *Stenotrophomonas maltophilia* and *Burkholderia cepacia* are the main culprits, and may require prolonged treatment with unusual combinations of antibiotics. *Aspergillus* and non-tuberculous mycobacteria are also frequently found in the sputum of CF patients but, in most cases, these behave as benign 'colonisers' of the bronchiectatic airways and do not require specific therapy. Some patients have coexistent asthma, which is treated with inhaled bronchodilators and corticosteroids; allergic bronchopulmonary aspergillosis (p. 697) also occurs occasionally in CF.

Four maintenance treatments have been shown to cause modest rises in lung function and/or to reduce the frequency of chest exacerbations in CF patients (Box 19.39). Individual responses are variable and should be carefully monitored to avoid burdening patients with treatments that prove ineffective.

For advanced CF lung disease, home oxygen and NIV may be necessary to treat respiratory failure. Ultimately, lung transplantation can produce dramatic improvements but is limited by donor organ availability.

Treatment of non-respiratory manifestations of CF

There is a clear link between good nutrition and prognosis in CF. Malabsorption due to exocrine pancreatic failure is treated with oral pancreatic enzymes and vitamin supplements. The increased caloric requirements of CF patients are met by supplemental feeding, including nasogastric or gastrostomy tube feeding if required. Diabetes eventually develops in over 25% of patients and often requires insulin therapy. Osteoporosis secondary to malabsorption and chronic ill health should be sought and treated.

Novel therapies for cystic fibrosis

Small molecules designed to correct the function of particular CFTR defects are being developed, and one (ivacaftor) gives significant clinical benefits in patients with the G551D mutation. Somatic gene therapy for CF is also under development. Manufactured normal copies of the CF gene are 'packaged' in liposomes or virus vectors and administered to the airways by aerosol inhalation. Trials are under way but more efficient gene delivery methods are needed to make this practical.

19.39 Treatments that reduce chest exacerbations and/or improve lung function in cystic fibrosis

Therapy	Patients treated
Nebulised recombinant human DNase 2.5 mg daily	Age ≥ 5, FVC > 40% predicted
Nebulised tobramycin 300 mg twice daily, given in alternate mths	Patients colonised with *Pseudomonas aeruginosa*
Regular oral azithromycin 500 mg three times/wk	Patients colonised with *Pseudomonas aeruginosa*
Nebulised hypertonic saline, 4 mL 7%, twice daily	Age ≥ 6, FEV_1 > 40% predicted

19.40 Cystic fibrosis in adolescence

- **Issues for the patient**:
  - Move to adult CF centre – loss of trusted paediatric team
  - Feelings of being different from peers due to chronic illness
  - Demanding treatments that conflict with social and school life
  - Pressure to take responsibility for self-care
  - Relationship/fertility concerns
- **Issues for the patient's parents**:
  - Loss of control over patient's treatment – feeling excluded
  - Loss of trusted paediatric team
  - Need to develop trust in adult team
  - Feelings of helplessness when adolescent rebels or will not take treatment
- **Issues for the CF team**:
  - Reluctance or refusal by patient to engage with transition
  - Management of deterioration due to non-adherence
  - Motivation of adolescents to self-care
  - Provision of adolescent-friendly health-care environment

INFECTIONS OF THE RESPIRATORY SYSTEM

Infections of the upper and lower respiratory tract are a major cause of morbidity and mortality, particularly in patients at the extremes of age, and those with pre-existing lung disease or immune suppression.

Upper respiratory tract infection

Upper respiratory tract infections (URTIs), such as coryza (the common cold), acute pharyngitis and acute tracheobronchitis, are the most common of all communicable diseases and represent the most frequent cause of short-term absenteeism from work and school. The vast majority are caused by viruses (p. 328) and, in adults, are usually short-lived and rarely serious.

Acute coryza is the most common URTI and is usually the result of rhinovirus infection. In addition to general malaise, acute coryza typically causes nasal discharge, sneezing and cough. Involvement of the pharynx results in a sore throat, that of the larynx a hoarse or lost voice.

If complicated by a tracheitis or bronchitis, chest tightness and wheeze typical of asthma occur. Specific investigation is rarely warranted and treatment with simple analgesics, antipyretics and decongestants is all that is required. Symptoms usually resolve quickly, but if repeated URTIs 'go to the chest', a more formal diagnosis of asthma ought to be considered. A variety of viruses causing URTI may also trigger exacerbations of asthma or COPD and aggravate other lung diseases.

Bordetella pertussis, the cause of whooping cough, is an important source of URTI. It is highly contagious and is notifiable in the UK. Vaccination confers protection and is usually offered in infancy, but its efficacy wanes in adult life and the infection is easily spread. Adults usually experience a mild illness similar to acute coryza, but some individuals develop paroxysms of coughing which can persist for weeks to months, earning whooping cough the designation of 'the cough of 100 days'. The diagnosis may be confirmed by bacterial culture, polymerase chain reaction (PCR) from a nasopharyngeal swab or serological testing. If the illness is recognised early in the clinical course, macrolide antibiotics may ameliorate the course.

Rhinosinusitis typically causes a combination of nasal congestion, blockage or discharge, and may be accompanied by facial pain/pressure or loss of smell. Examination usually confirms erythematous swollen nasal mucosa and pus may be evident. Nasal polyps should be sought and dental infection excluded. Treatment with topical corticosteroids, nasal decongestants and regular nasal douching are usually sufficient and, although bacterial infection is often present, antibiotics are only indicated if symptoms persist for more than 5 days. Persistent symptoms or recurrent episodes should prompt a referral to an ear, nose and throat specialist.

Influenza is discussed on page 319.

Pneumonia

Pneumonia is as an acute respiratory illness associated with recently developed radiological pulmonary shadowing, which may be segmental, lobar or multilobar. The context in which pneumonia develops is highly indicative of the likely organism(s) involved; therefore, pneumonias are usually classified as community- or hospital-acquired, or as occurring in immunocompromised hosts. 'Lobar pneumonia' is a radiological and pathological term referring to homogeneous consolidation of one or more lung lobes, often with associated pleural inflammation. 'Bronchopneumonia' refers to more patchy alveolar consolidation associated with bronchial and bronchiolar inflammation, often affecting both lower lobes.

The inflammatory response in lobar pneumonia evolves through stages of congestion, red then grey hepatisation, and finally resolution. In the first stage, the alveolar units are flooded by a proteinaceous exudate and by neutrophils and red blood cells, and numerous pneumococci may be observed. As fibrin forms on the cut surface of the affected lobe, it resembles liver and so this stage is known as 'red hepatisation'. As congestion resolves, the lung tissue becomes grey ('grey hepatisation'), and ultimately, clearance and repair mechanisms restore the normal architecture of the lung.

Community-acquired pneumonia

Figures from the UK suggest that an estimated 5–11/1000 adults suffer from community-acquired pneumonia (CAP) each year, accounting for around 5–12% of all lower respiratory tract infections. It affects all age groups but is particularly common at the extremes of age; worldwide, CAP continues to kill more children than any other illness, and its propensity to ease the passing of the frail and elderly led to pneumonia being known as the 'old man's friend'.

Most cases are spread by droplet infection and, whilst CAP may occur in previously healthy individuals, several factors may impair the effectiveness of local defences and predispose to CAP (Box 19.41). *Streptococcus pneumoniae* (Fig. 19.32) remains the most common infecting agent. The likelihood that other organisms may be involved depends on the age of the patient and the clinical context. Viral infections are important causes of CAP in children, and their contribution to adult CAP is increasingly recognised (Box 19.42).

A 'best guess' as to the likely organism may be made from the context in which pneumonia develops, but not from the clinical and radiological picture, which does not differ sufficiently from one organism to another; the term 'atypical pneumonia' has therefore been dropped. *Mycoplasma pneumoniae* is more common in young people and rare in the elderly, whereas *Haemophilus influenzae* is more common in the elderly, particularly when underlying lung disease is present. *Legionella pneumophila* occurs in local outbreaks centred on contaminated cooling towers in hotels, hospitals and other industrial buildings. *Staphylococcus aureus* is more common following an episode of influenza. Foreign travel raises the possibility of infections that might otherwise be unusual in the UK: for example, *Burkholderia pseudomallei* from South-east Asia. Travel also facilitates the spread of illnesses such as severe acute

19.41 Factors that predispose to pneumonia

- Cigarette smoking
- Upper respiratory tract infections
- Alcohol
- Corticosteroid therapy
- Old age
- Recent influenza infection
- Pre-existing lung disease
- HIV
- Indoor air pollution

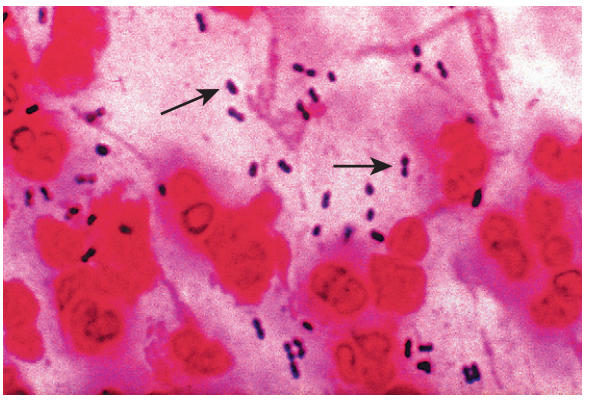

Fig. 19.32 Gram stain of sputum showing Gram-positive diplococci characteristic of *Strep. pneumoniae* (arrows).

19.42 Organisms causing community-acquired pneumonia

Bacteria

- *Streptococcus pneumoniae*
- *Mycoplasma pneumoniae*
- *Legionella pneumophila*
- *Chlamydia pneumoniae*
- *Haemophilus influenzae*
- *Staphylococcus aureus*
- *Chlamydia psittaci*
- *Coxiella burnetii* (Q fever, 'querry' fever)
- *Klebsiella pneumoniae* (Freidländer's bacillus)
- *Actinomyces israelii*

Viruses

- Influenza, parainfluenza
- Measles
- Herpes simplex
- Varicella
- Adenovirus
- Cytomegalovirus (CMV)
- Coronavirus (Urbani SARS-associated coronavirus)

(SARS = severe acute respiratory syndrome)

respiratory syndrome (SARS), caused by a form of coronavirus arising in the Guangdong province of China, but which spread rapidly through Hong Kong and Vietnam, and then throughout the world. Certain occupations may be associated with exposure to specific bacteria (p. 715).

Clinical features

Pneumonia, particularly lobar pneumonia, usually presents as an acute illness. Systemic features such as fever, rigors, shivering and malaise predominate and delirium may be present. The appetite is invariably lost and headache frequently reported.

Pulmonary symptoms include cough, which at first is characteristically short, painful and dry, but later accompanied by the expectoration of mucopurulent sputum. Rust-coloured sputum may be seen in patients with *Strep. pneumoniae*, and the occasional individual may report haemoptysis. Pleuritic chest pain may be a presenting feature and, on occasion, may be referred to the shoulder or anterior abdominal wall. Upper abdominal tenderness is sometimes apparent in patients with lower lobe pneumonia or if there is associated hepatitis. Less typical presentations may be seen in the very young and the elderly.

On examination, the respiratory and pulse rate may be raised and the blood pressure low, while an assessment of the mental state may reveal a delirium. These are important indicators of the severity of the illness (Fig. 19.33). Not all patients are pyrexial but this is a helpful diagnostic clue if present. Oxygen saturation on air may be low, and the patient cyanosed and distressed.

Chest signs (p. 645) vary, depending on the phase of the inflammatory response. When consolidated, the lung is typically dull to percussion and, as conduction of sound is enhanced, auscultation reveals bronchial breathing and whispering pectoriloquy; crackles are heard throughout. However, in many patients, signs are more subtle with reduced air entry only, but crackles are usually present.

An assessment of nutrition is important as, if poor, the response to treatment will be impaired, particularly in the elderly. On occasion, inferences as to the likely organism may be drawn from clinical examination. For example, the presence of herpes labialis may point to streptococcal infection, as may the finding of 'rusty' sputum. The presence of poor dental hygiene should prompt consideration of *Klebsiella* or *Actinomyces israelii*. The differential diagnosis of pneumonia is shown in Box 19.43.

19.43 Differential diagnosis of pneumonia

- Pulmonary infarction
- Pulmonary/pleural TB
- Pulmonary oedema (can be unilateral)
- Pulmonary eosinophilia (p. 713)
- Malignancy: bronchoalveolar cell carcinoma
- Rare disorders: cryptogenic organising pneumonia/ bronchiolitis obliterans organising pneumonia (COP/BOOP) (p. 708)

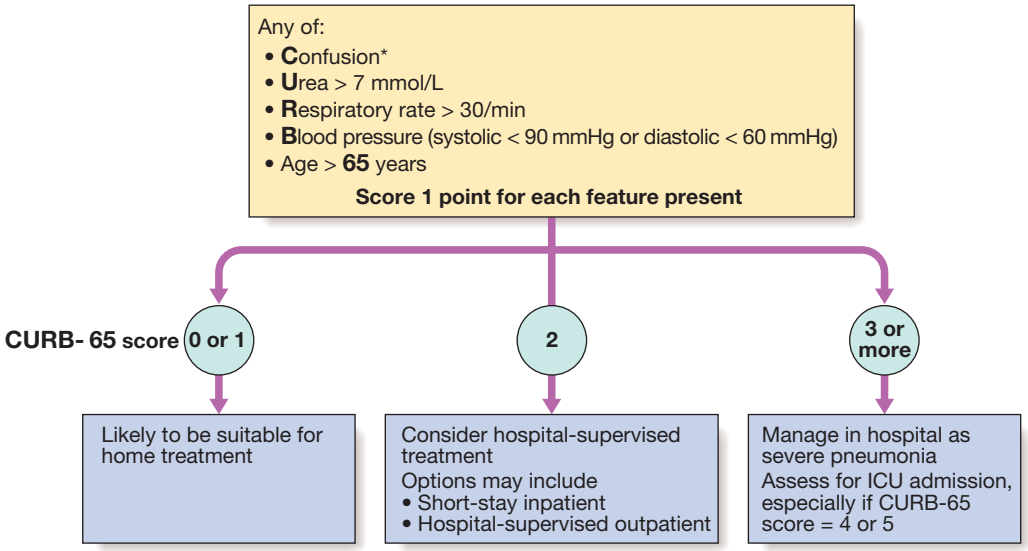

Fig. 19.33 Hospital CURB-65. *Defined as a Mental Test Score of 8 or less, or new disorientation in person, place or time. (Urea of 7 mmol/L ≅ 20 mg/dL.)

19.44 Investigations in CAP

Blood

Full blood count
- Very high (> 20 × 10^9/L) or low (< 4 × 10^9/L) white cell count: marker of severity
- Neutrophil leucocytosis > 15 × 10^9/L: suggests bacterial aetiology
- Haemolytic anaemia: occasional complication of *Mycoplasma*

Urea and electrolytes
- Urea > 7 mmol/L (~20 mg/dL): marker of severity
- Hyponatraemia: marker of severity

Liver function tests
- Abnormal if basal pneumonia inflames liver
- Hypoalbuminaemia: marker of severity

Erythrocyte sedimentation rate/C-reactive protein
- Non-specifically elevated

Blood culture
- Bacteraemia: marker of severity

Serology
- Acute and convalescent titres for *Mycoplasma*, *Chlamydia*, *Legionella* and viral infections

Cold agglutinins
- Positive in 50% of patients with *Mycoplasma*

Arterial blood gases
- Measure when SaO_2 < 93% or when severe clinical features to assess ventilatory failure or acidosis

Sputum

Sputum samples
- Gram stain (see Fig. 19.32), culture and antimicrobial sensitivity testing

Oropharynx swab
- PCR for *Mycoplasma pneumoniae* and other atypical pathogens

Urine
- Pneumococcal and/or *Legionella* antigen

Chest X-ray

Lobar pneumonia
- Patchy opacification evolves into homogeneous consolidation of affected lobe
- Air bronchogram (air-filled bronchi appear lucent against consolidated lung tissue) may be present (see Fig. 19.34)

Bronchopneumonia
- Typically patchy and segmental shadowing

Complications
- Para-pneumonic effusion, intrapulmonary abscess or empyema

Staph. aureus
- Suggested by multilobar shadowing, cavitation, pneumatocoeles and abscesses

Pleural fluid
- Always aspirate and culture when present in more than trivial amounts, preferably with ultrasound guidance

Investigations

The aims of investigation (Box 19.44) are to confirm the diagnosis and exclude other conditions, assess the severity and identify the development of complications. Typical chest X-ray findings in a lobar pneumonia are shown in Figure 19.34. Whilst many cases of mild to moderate CAP can be successfully managed without identification of the organism, a range of microbiological tests should be performed on patients with severe CAP.

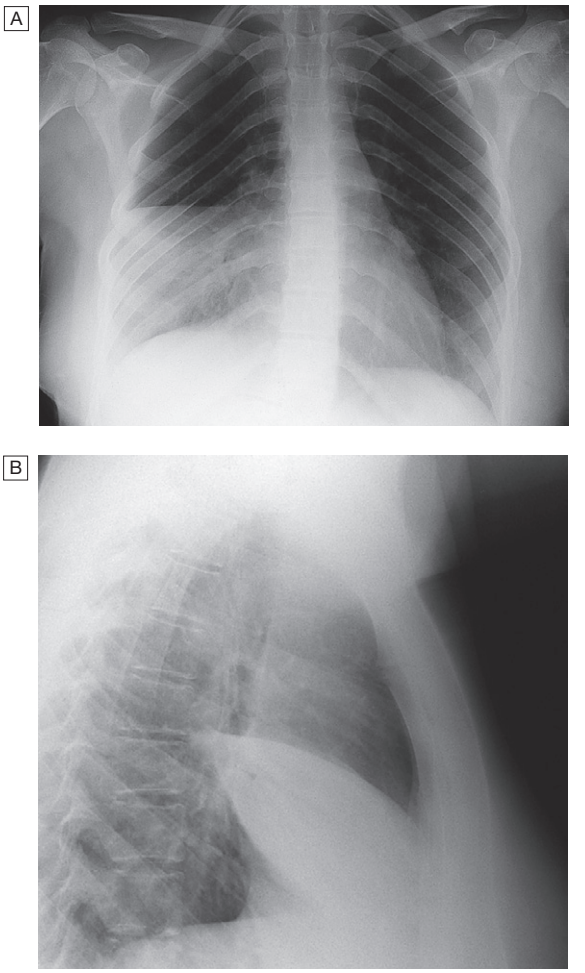

Fig. 19.34 Pneumonia of the right middle lobe. A PA view: consolidation in the right middle lobe with characteristic opacification beneath the horizontal fissure and loss of normal contrast between the right heart border and lung. B Lateral view: consolidation confined to the anteriorly situated middle lobe.

Management

The most important aspects of management are oxygenation, fluid balance and antibiotic therapy. In severe or prolonged illness, nutritional support may be required.

Oxygen

Oxygen should be administered to all patients with tachypnoea, hypoxaemia, hypotension or acidosis, with the aim of maintaining the PaO_2 at or above 8 kPa (60 mmHg) or the SaO_2 at or above 92%. High concentrations (35% or more), preferably humidified, should be used in all patients who do not have hypercapnia associated with COPD. Continuous positive airway pressure (CPAP) should be considered in those who remain hypoxic despite this, and these patients should be managed in a high-dependency or intensive care environment, where mechanical ventilation can be rapidly

19.45 Indications for referral to ITU

- CURB score of 4–5, failing to respond rapidly to initial management
- Persisting hypoxia (PaO_2 < 8 kPa (60 mmHg)), despite high concentrations of oxygen
- Progressive hypercapnia
- Severe acidosis
- Circulatory shock
- Reduced conscious level

employed. Indications for referral to the intensive therapy unit (ITU) are summarised in Box 19.45.

Intravenous fluids

These should be considered in patients with severe illness, older patients and those who are vomiting. Otherwise, an adequate oral intake of fluid should be encouraged. Inotropic support may be required in patients with shock (p. 190).

Antibiotics

Prompt administration of antibiotics improves the outcome. The initial choice of antibiotic is guided by clinical context, severity assessment, local knowledge of antibiotic resistance patterns and any available epidemiological information. Current regimens are detailed in Box 19.46. In most patients with uncomplicated pneumonia, a 7-day course is adequate, although treatment is usually required for longer in those with *Legionella*, staphylococcal or *Klebsiella* pneumonia. Oral antibiotics are usually adequate unless the patient has a severe illness, impaired consciousness, loss of swallowing reflex, or functional or anatomical reasons for malabsorption.

It is important to relieve pleural pain, as it may prevent the patient from breathing normally and coughing efficiently. For the majority, simple analgesia with paracetamol, co-codamol or NSAIDs is sufficient. In some patients, opiates may be required but these must be used with extreme caution in patients with poor respiratory function, as they may suppress ventilation. Physiotherapy is not usually indicated in patients with CAP, but may help expectoration in those who suppress cough because of pleural pain.

Most patients respond promptly to antibiotic therapy. However, fever may persist for several days and the chest X-ray often takes several weeks or even months to resolve, especially in old age. Delayed recovery suggests either that a complication has occurred (Box 19.47), that the diagnosis is incorrect (see Box 19.43) or, alternatively, that the pneumonia may be secondary to a proximal bronchial obstruction or recurrent aspiration. The mortality rate of adults with non-severe pneumonia is very low (< 1%); hospital death rates are typically between 5 and 10% but may be as high as 50% in severe illness.

19.46 Antibiotic treatment for CAP*

Uncomplicated CAP

- Amoxicillin 500 mg 3 times daily orally

If patient is allergic to penicillin

- Clarithromycin 500 mg twice daily orally ***or*** Erythromycin 500 mg 4 times daily orally

If *Staphylococcus* is cultured or suspected

- Flucloxacillin 1–2 g 4 times daily IV ***plus***
- Clarithromycin 500 mg twice daily IV

If *Mycoplasma* or *Legionella* is suspected

- Clarithromycin 500 mg twice daily orally or IV ***or*** Erythromycin 500 mg 4 times daily orally IV ***plus***
- Rifampicin 600 mg twice daily IV in severe cases

Severe CAP

- Clarithromycin 500 mg twice daily IV ***or*** Erythromycin 500 mg 4 times daily IV ***plus***
- Co-amoxiclav 1.2 g 3 times daily IV ***or*** Ceftriaxone 1–2 g daily IV ***or*** Cefuroxime 1.5 g 3 times daily IV ***or***
- Amoxicillin 1 g 4 times daily IV ***plus*** flucloxacillin 2 g 4 times daily IV

*Adapted from British Thoracic Society Guidelines.

19.47 Complications of pneumonia

- Para-pneumonic effusion – common
- Empyema (p. 662)
- Retention of sputum causing lobar collapse
- Deep vein thrombosis and pulmonary embolism
- Pneumothorax, particularly with *Staph. aureus*
- Suppurative pneumonia/lung abscess
- ARDS, renal failure, multi-organ failure (p. 192)
- Ectopic abscess formation (*Staph. aureus*)
- Hepatitis, pericarditis, myocarditis, meningoencephalitis
- Pyrexia due to drug hypersensitivity

Discharge and follow-up

The decision to discharge patients depends on their home circumstances and the likelihood of complications. A chest X-ray need not be repeated before discharge in those making a satisfactory clinical recovery. Clinical review should be arranged around 6 weeks later and a chest X-ray obtained if there are persistent symptoms, physical signs or reasons to suspect underlying malignancy.

Prevention

Current smokers should be advised to stop. Influenza and pneumococcal vaccination should be considered in selected patients (p. 148). Because of the mode of spread, *Legionella pneumophila* has important public health implications and usually requires notification to the appropriate health authority. In developing countries, tackling malnourishment and indoor air pollution, and encouraging immunisation against measles, pertussis and *Haemophilus influenzae* type b are particularly important in children.

Hospital-acquired pneumonia

Hospital-acquired or nosocomial pneumonia is a new episode of pneumonia occurring at least 2 days after admission to hospital. It is the second most common hospital-acquired infection (HAI) and the leading cause of HAI-associated death. The elderly are particularly at risk, along with patients in intensive care units, especially when mechanically ventilated; in the latter case,

19.48 Factors predisposing to hospital-acquired pneumonia

Reduced host defences against bacteria

- Reduced immune defences (e.g. corticosteroid treatment, diabetes, malignancy)
- Reduced cough reflex (e.g. post-operative)
- Disordered mucociliary clearance (e.g. anaesthetic agents)
- Bulbar or vocal cord palsy

Aspiration of nasopharyngeal or gastric secretions

- Immobility or reduced conscious level
- Vomiting, dysphagia (N.B. stroke disease), achalasia or severe reflux
- Nasogastric intubation

Bacteria introduced into lower respiratory tract

- Endotracheal intubation/tracheostomy
- Infected ventilators/nebulisers/bronchoscopes
- Dental or sinus infection

Bacteraemia

- Abdominal sepsis
- IV cannula infection
- Infected emboli

19.49 Respiratory infection in old age

- **Increased risk of and from respiratory infection**: because of reduced immune responses, increased closing volumes, reduced respiratory muscle strength and endurance, altered mucus layer, poor nutritional status and the increased prevalence of chronic lung disease.
- **Predisposing factors**: other medical conditions may predispose to infection, e.g. swallowing difficulties due to stroke increase the risk of aspiration pneumonia.
- **Atypical presentation**: older patients often present with confusion, rather than breathlessness or cough.
- **Mortality**: the vast majority of deaths from pneumonia in developed countries occur in older people.
- **Influenza**: has a much higher complication rate, morbidity and mortality. Vaccination significantly reduces morbidity and mortality in old age but uptake is poor.
- **TB**: most cases in old age represent reactivation of previous, often unrecognised disease and may be precipitated by steroid therapy, diabetes mellitus and the factors above. Cryptic miliary TB is an occasional alternative presentation. Older people more commonly suffer adverse effects from antituberculous chemotherapy and require close monitoring.

the term 'ventilator-associated pneumonia' (VAP) is used. Healthcare-associated pneumonia (HCAP) is the development of pneumonia in a person who has spent at least 2 days in hospital within the last 90 days, or has attended a haemodialysis unit, received intravenous antibiotics, or been resident in a nursing home or other long-term care facility. The factors predisposing to the development of pneumonia in a hospitalised patient are listed in Box 19.48. The organisms implicated in early-onset HAP (occurring within 4–5 days of admission) are similar to those involved in CAP. Late-onset HAP is associated with a different range of pathogens to CAP, with more Gram-negative bacteria (e.g. *Escherichia*, *Pseudomonas*, *Klebsiella* species and *Acinetobacter baumannii*), *Staph. aureus* (including the meticillin-resistant type (MRSA)) and anaerobes.

Clinical features and investigations

The diagnosis should be considered in any hospitalised or ventilated patient who develops purulent sputum (or endotracheal secretions), new radiological infiltrates, an otherwise unexplained increase in oxygen requirement, a core temperature of more than 38.3°C, and a leucocytosis or leucopenia. However, the clinical features and radiographic signs are variable and non-specific, raising a broad differential diagnosis that includes venous thromboembolism, ARDS, pulmonary oedema, pulmonary haemorrhage and drug toxicity. Therefore, in contrast to CAP, microbiological confirmation should be sought whenever possible. As in CAP, the full blood count (FBC), urea and electrolytes (U&E), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), and arterial blood gas samples should be sent for analysis and a chest X-ray performed, but other investigations and imaging may be necessary to exclude other conditions. Adequate sputum samples may be difficult to obtain in frail elderly patients and physiotherapy should be considered to aid expectoration. In patients who are mechanically ventilated, bronchoscopy-directed protected brush specimens, bronchoalveolar lavage (BAL) or endotracheal aspirates may be obtained.

Management

The principles of management are similar to those for CAP, focusing on adequate oxygenation, appropriate fluid balance and antibiotics. However, the choice of empirical antibiotic therapy is considerably more challenging, given the diversity of pathogens and the potential for drug resistance.

In early-onset HAP, patients who have received no previous antibiotics can be treated with co-amoxiclav or cefuroxime. If the patient has received a course of recent antibiotics, then piperacillin/tazobactam or a third-generation cephalosporin should be considered.

In late-onset HAP, the choice of antibiotics must cover the Gram-negative bacteria (see above), *Staph. aureus* (including MRSA) and anaerobes. Anti-pseudomonal cover may be provided by a carbapenem (meropenem) or a third-generation cephalosporin combined with an aminoglycoside. MRSA cover may be provided by glycopeptides, such as vancomycin or linezolid. *A. baumannii* is usually sensitive to carbapenems but resistant cases may require the prolonged administration of nebulised colistin. The choice of agents is most appropriately guided by knowledge of local patterns of microbiology and antibiotic resistance. It is usual to commence broad-based cover, discontinuing less appropriate antibiotics as culture results become available. In the absence of good evidence, the duration of antibiotic therapy remains a matter for clinical judgement.

Physiotherapy is important to aid expectoration in the immobile and elderly, and nutritional support is often required.

Prevention

Despite appropriate management, the mortality from HAP is approximately 30%, so prevention is very important. Good hygiene is paramount, particularly with

regard to handwashing and any equipment used. The risk of aspiration should be minimised, and the use of stress ulcer prophylaxis with proton pump inhibitors limited, as they may increase the risk of ventilator-associated pneumonia. Oral antiseptic (chlorhexidine 2%) may be used to decontaminate the upper airway, and some intensive care units employ selective decontamination of the digestive tract when the anticipated requirement for ventilation will exceed 48 hours.

Suppurative pneumonia, aspiration pneumonia and pulmonary abscess

These conditions are considered together, as their aetiology and clinical features overlap. Suppurative pneumonia is characterised by destruction of the lung parenchyma by the inflammatory process and, although microabscess formation is a characteristic histological feature, 'pulmonary abscess' is usually taken to refer to lesions in which there is a large localised collection of pus, or a cavity lined by chronic inflammatory tissue, from which pus has escaped by rupture into a bronchus.

Suppurative pneumonia and pulmonary abscess often develop after the inhalation of septic material during operations on the nose, mouth or throat under general anaesthesia, or of vomitus during anaesthesia or coma, particularly if oral hygiene is poor. Additional risk factors for aspiration pneumonia include bulbar or vocal cord palsy, stroke, achalasia or oesophageal reflux, and alcoholism. Aspiration tends to localise to dependent areas of the lung, such as the apical segment of the lower lobe in a supine patient. Suppurative pneumonia and pulmonary abscess may also complicate local bronchial obstruction from a neoplasm or foreign body.

Infections are usually due to a mixture of anaerobes and aerobes in common with the typical flora encountered in the mouth and upper respiratory tract. Isolates of *Bacteroides melaninogenicus*, *Fusobacterium necrophorum*, anaerobic or micro-aerophilic cocci, and *Bacteroides fragilis* may be identified. When suppurative pneumonia or a pulmonary abscess occurs in a previously healthy lung, the most likely infecting organism is *Staph. aureus* or *Klebsiella pneumoniae*.

Bacterial infection of a pulmonary infarct or a collapsed lobe may also produce a suppurative pneumonia or lung abscess. The organisms isolated from the sputum include *Strep. pneumoniae*, *Staph. aureus*, *Strep. pyogenes*, *H. influenzae* and, in some cases, anaerobic bacteria. In many cases, however, no pathogen can be isolated, particularly when antibiotics have been given.

Strains of community-acquired MRSA (CA-MRSA) produce the cytotoxin Panton–Valentine leukocidin. The organism is mainly responsible for suppurative skin infection but may be associated with rapidly progressive, severe, necrotising pneumonia.

Lemierre's syndrome is a rare cause of pulmonary abscesses. The usual causative agent is the anaerobe, *F. necrophorum*. The illness typically commences as a sore throat, painful swollen neck, fever, rigor, haemoptysis and dyspnoea, and spread into the jugular veins leads to thrombosis and metastatic spread of the organisms.

Injecting drug-users are at particular risk of developing haematogenous lung abscess, often in association with endocarditis affecting the pulmonary and tricuspid valves.

19.50 Clinical features of suppurative pneumonia

Symptoms

- Cough with large amounts of sputum, sometimes fetid and blood-stained
- Pleural pain common
- Sudden expectoration of copious amounts of foul sputum if abscess ruptures into a bronchus

Clinical signs

- High remittent pyrexia
- Profound systemic upset
- Digital clubbing may develop quickly (10–14 days)
- Consolidation on chest examination; signs of cavitation rarely found
- Pleural rub common
- Rapid deterioration in general health, with marked weight loss if not adequately treated

A non-infective form of aspiration pneumonia – exogenous lipid pneumonia – may follow the aspiration of animal, vegetable, or mineral oils.

The clinical features of suppurative pneumonia are summarised in Box 19.50.

Investigations and management

Radiological features of suppurative pneumonia include homogeneous lobar or segmental opacity consistent with consolidation or collapse. Abscesses are characterised by cavitation and fluid level. Occasionally, a pre-existing emphysematous bulla becomes infected and appears as a cavity containing an air–fluid level.

Aspiration pneumonia can be treated with intravenous co-amoxiclav 1.2 g 3 times daily. If an anaerobic bacterial infection is suspected (e.g. from fetor of the sputum), oral metronidazole 400 mg 3 times daily should be added. Further modification of antibiotics may be required, depending on the clinical response and the microbiological results. CA-MRSA is usually susceptible to a variety of oral non-β-lactam antibiotics, such as trimethoprim/sulfamethoxazole, clindamycin, tetracyclines and linezolid. Parenteral therapy with vancomycin or daptomycin can also be considered. *F. necrophorum* is highly susceptible to β-lactam antibiotics, and to metronidazole, clindamycin and third-generation cephalosporins. Prolonged treatment for 4–6 weeks may be required in some patients with lung abscess. Physiotherapy is of great value, especially when suppuration is present in the lower lobes or when a large abscess cavity has formed.

In most patients, there is a good response to treatment and, although residual fibrosis and bronchiectasis are common sequelae, these seldom give rise to serious morbidity. Surgery should be contemplated if no improvement occurs, despite optimal medical therapy. Removal or treatment of any obstructing endobronchial lesion is essential.

Pneumonia in the immunocompromised patient

Patients immunocompromised by drugs or disease (particularly HIV, p. 400) are at high risk of pulmonary infection. The majority of cases are caused by the same pathogens that cause pneumonia in

19.51 Causes of immune suppression-associated lung infection

	Causes	Infecting organisms
Defective phagocytic function	Acute leukaemia Cytotoxic drugs Agranulocytosis	Gram-positive bacteria, including *Staph. aureus* Gram-negative bacteria Fungi, e.g. *Candida albicans* and *Aspergillus fumigatus*
Defects in cell-mediated immunity	Immunosuppressive drugs Cytotoxic chemotherapy Lymphoma Thymic aplasia	Viruses *Cytomegalovirus* *Herpesvirus* *Adenovirus* *Influenza* Fungi *Pneumocystis jirovecii* (formerly *carinii*) *Candida albicans* *Aspergillus fumigatus*
Defects in antibody production	Multiple myeloma Chronic lymphocytic leukaemia	*Haemophilus influenzae* *Mycoplasma pneumoniae*

non-immunocompromised individuals, but in patients with more profound immunosuppression, unusual organisms or those normally considered to be of low virulence or non-pathogenic may become 'opportunistic' pathogens (Box 19.51). Therefore, the possibility of Gram-negative bacteria, especially *Pseudomonas aeruginosa*, viral agents, fungi, mycobacteria, and less common organisms such as *Nocardia asteroides* has to be considered. Infection is often due to more than one organism.

Clinical features

These typically include fever, cough and breathlessness, but are influenced by the degree of immunosuppression; symptoms are less specific in the more profoundly immunosuppressed. The speed of onset tends to be less rapid in patients with opportunistic organisms such as *Pneumocystis jirovecii* and mycobacterial infections than with bacterial infections (p. 400). In *P. jirovecii* pneumonia, symptoms of cough and breathlessness can be present for several days or weeks before the onset of systemic symptoms or the appearance of X-ray abnormalities. The clinical features of invasive pulmonary aspergillosis are described on page 698.

Diagnosis

The approach is informed by the clinical context and severity of the illness. Invasive investigations, such as bronchoscopy, BAL, transbronchial biopsy or surgical lung biopsy, are often impractical, as many patients are too ill to undergo these safely. However, 'induced sputum' (p. 652) offers a relatively safe method of obtaining microbiological samples. HRCT is useful in differentiating the likely cause:

- Focal unilateral airspace opacification favours bacterial infection, mycobacteria or *Nocardia*.
- Bilateral opacification favours *P. jirovecii* pneumonia, fungi, viruses and unusual bacteria, e.g. *Nocardia*.
- Cavitation may be seen with *N. asteroides*, mycobacteria and fungi.
- The presence of a 'halo sign' may suggest *Aspergillus* (see Fig. 19.45, p. 698).
- Pleural effusions suggest a pyogenic bacterial infection and are uncommon in *P. jirovecii* pneumonia.

Management

In theory, treatment should be based on the identified causative organism but, in practice, this is frequently unknown and broad-spectrum antibiotic therapy is required, such as a third-generation cephalosporin or a quinolone, plus an antistaphylococcal antibiotic, or an antipseudomonal penicillin plus an aminoglycoside.

Thereafter, treatment may be tailored according to the results of investigations and the clinical response. These may dictate the addition of antifungal or antiviral therapies. The management of *P. jirovecii* infection is detailed on page 400, and that of invasive aspergillosis on page 698.

Tuberculosis

Epidemiology

Tuberculosis (TB) is caused by infection with *Mycobacterium tuberculosis* (MTB), which is part of a complex of organisms including *M. bovis* (reservoir cattle) and *M. africanum* (reservoir human). Recent figures suggest a decline in the incidence of TB, but its impact on world health remains significant. In 2010, an estimated 8.8 million incident cases occurred and TB was estimated to account for nearly 1.5 million deaths, making it the second most common cause of death due to an infective disease. Furthermore, it is estimated that around one-third of the world's population has latent TB. The majority of cases occur in the world's poorest nations, who struggle to cover the costs associated with management and control programmes (Fig. 19.35). In Africa, the resurgence of TB has been largely driven by HIV disease and, in the former Soviet Union and Baltic states, by a lack of appropriate health care associated with social and political upheaval.

Pathology and pathogenesis

M. bovis infection arises from drinking non-sterilised milk from infected cows. *M. tuberculosis* is spread by the inhalation of aerosolised droplet nuclei from other infected patients. Once inhaled, the organisms lodge in the alveoli and initiate the recruitment of macrophages and lymphocytes. Macrophages undergo transformation into epithelioid and Langhans cells, which aggregate with the lymphocytes to form the classical tuberculous granuloma (Fig. 19.36). Numerous granulomas aggregate to form a primary lesion or 'Ghon focus' (a pale yellow, caseous nodule, usually a few millimetres to 1–2 cm in diameter), which is characteristically situated in the periphery of the lung. Spread of organisms to the hilar lymph nodes is followed by a similar pathological reaction, and the combination of the primary lesion and regional lymph nodes is referred to as the 'primary complex of Ranke'. Reparative processes encase the primary complex in a fibrous capsule, limiting the spread of bacilli: so-called latent TB (p. 695). If no further complications ensue, this lesion eventually

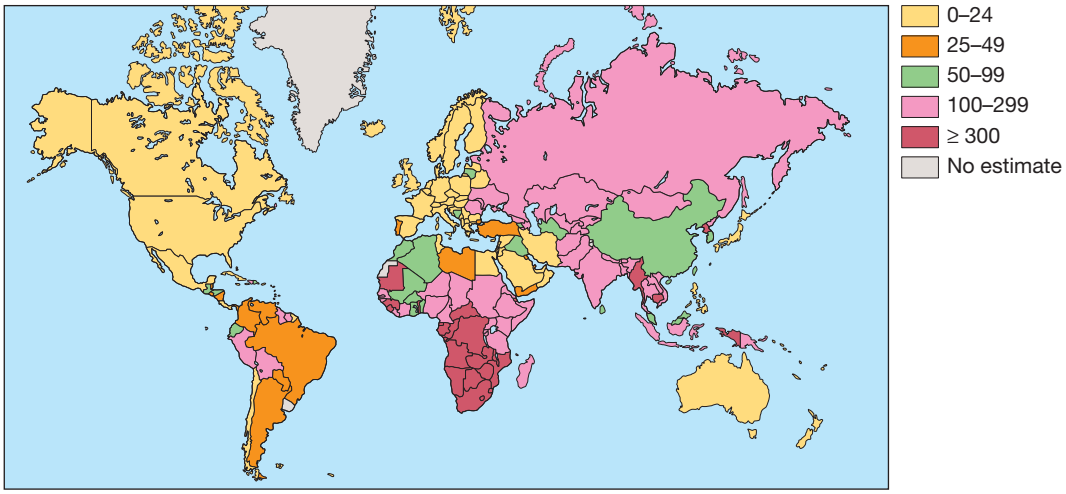

Fig. 19.35 Worldwide incidence of tuberculosis. Estimated new cases (all forms) per 100 000 population (WHO). From Maartens and Wilkinson 2007 – see p. 732.

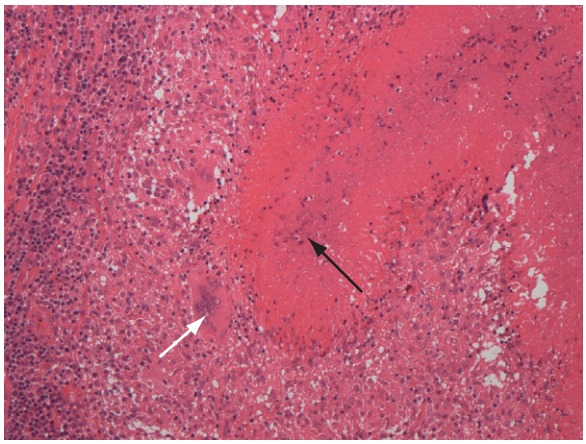

Fig. 19.36 Tuberculous granuloma. Normal lung tissue is lost and replaced by a mass of fibrous tissue with granulomatous inflammation characterised by large numbers of macrophages and multinucleate giant cells (white arrow). The central area of this focus shows caseous degeneration (black arrow).

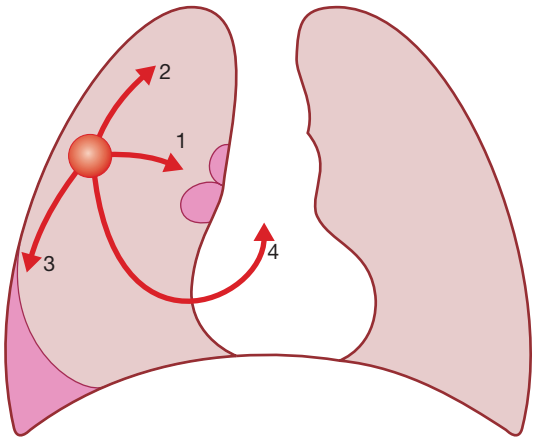

Fig. 19.37 Primary pulmonary TB. (1) Spread from the primary focus to hilar and mediastinal lymph glands to form the 'primary complex', which in most cases heals spontaneously. (2) Direct extension of the primary focus – progressive pulmonary TB. (3) Spread to the pleura – tuberculous pleurisy and pleural effusion. (4) Blood-borne spread: *few bacilli* – pulmonary, skeletal, renal, genitourinary infection, often months or years later; *massive spread* – miliary TB and meningitis.

calcifies and is clearly seen on a chest X-ray. However, lymphatic or haematogenous spread may occur before immunity is established, seeding secondary foci in other organs, including lymph nodes, serous membranes, meninges, bones, liver, kidneys and lungs, which may lie dormant for years. The only clue that infection has occurred may be the appearance of a cell-mediated, delayed-type hypersensitivity reaction to tuberculin, demonstrated by tuberculin skin testing. If these reparative processes fail, primary progressive disease ensues (Fig. 19.37). The estimated lifetime risk of developing disease after primary infection is 10%, with roughly half of this risk occurring in the first 2 years after infection. Factors predisposing to TB are summarised in Box 19.52 and the natural history of infection with TB is summarised in Box 19.53.

Clinical features: pulmonary disease

Primary pulmonary TB

Primary TB refers to the infection of a previously uninfected (tuberculin-negative) individual. A few patients develop a self-limiting febrile illness but clinical disease only occurs if there is a hypersensitivity reaction or progressive infection (Box 19.54). Progressive primary disease may appear during the course of the initial illness or after a latent period of weeks or months.

Miliary TB

Blood-borne dissemination gives rise to miliary TB, which may present acutely but more frequently is characterised by 2–3 weeks of fever, night sweats, anorexia, weight loss and a dry cough. Hepatosplenomegaly may develop and the presence of a headache may indicate coexistent tuberculous meningitis. Auscultation of the chest is frequently normal, but in more advanced disease, widespread crackles are evident. Fundoscopy may show choroidal tubercles. The classical appearances on chest X-ray are of fine 1–2 mm lesions ('millet seed') distributed throughout the lung fields, although occasionally the appearances are coarser. Anaemia and

19.52 Factors increasing the risk of TB

Patient-related

- Age (children > young adults < elderly)
- First-generation immigrants from high-prevalence countries
- Close contacts of patients with smear-positive pulmonary TB
- Overcrowding (prisons, collective dormitories); homelessness (doss houses and hostels)
- Chest X-ray evidence of self-healed TB
- Primary infection < 1 yr previously
- Smoking: cigarettes and bidis (Indian cigarettes made of tobacco wrapped in temburini leaves)

Associated diseases

- Immunosuppression: HIV, anti-tumour necrosis factor (TNF) therapy, high-dose corticosteroids, cytotoxic agents
- Malignancy (especially lymphoma and leukaemia)
- Diabetes mellitus
- Chronic kidney disease
- Silicosis
- Gastrointestinal disease associated with malnutrition (gastrectomy, jejuno-ileal bypass, cancer of the pancreas, malabsorption)
- Deficiency of vitamin D or A
- Recent measles in children

19.53 Natural history of untreated primary TB

Time from infection	Manifestations
3–8 wks	Primary complex, positive tuberculin skin test
3–6 mths	Meningeal, miliary and pleural disease
Up to 3 yrs	Gastrointestinal, bone and joint, and lymph node disease
Around 8 yrs	Renal tract disease
From 3 yrs onwards	Post-primary disease due to reactivation or re-infection

Adapted from Grange JM. In: Davies PDO, ed. Clinical tuberculosis. London: Hodder Arnold; 1998.

19.54 Features of primary TB

Infection (4–8 wks)

- Influenza-like illness
- Skin test conversion
- Primary complex

Disease

- Lymphadenopathy: hilar (often unilateral), paratracheal or mediastinal
- Collapse (especially right middle lobe)
- Consolidation (especially right middle lobe)
- Obstructive emphysema
- Cavitation (rare)
- Pleural effusion
- Miliary
- Meningitis
- Pericarditis

Hypersensitivity

- Erythema nodosum
- Phlyctenular conjunctivitis
- Dactylitis

19.55 Cryptic TB

- Age over 60 yrs
- Intermittent low-grade pyrexia of unknown origin
- Unexplained weight loss, general debility (hepatosplenomegaly in 25–50%)
- Normal chest X-ray
- Blood dyscrasias; leukaemoid reaction, pancytopenia
- Negative tuberculin skin test
- Confirmation by biopsy with granulomas and/or acid-fast bacilli in liver or bone marrow

leucopenia reflect bone marrow involvement. 'Cryptic' miliary TB is an unusual presentation sometimes seen in old age (Box 19.55).

Post-primary pulmonary TB

Post-primary disease refers to exogenous ('new' infection) or endogenous (reactivation of a dormant primary lesion) infection in a person who has been sensitised by earlier exposure. It is most frequently pulmonary and characteristically occurs in the apex of an upper lobe, where the oxygen tension favours survival of the strictly aerobic organism. The onset is usually insidious, developing slowly over several weeks. Systemic symptoms include fever, night sweats, malaise, and loss of appetite and weight, and are accompanied by progressive pulmonary symptoms (Box 19.56). Very occasionally, this form of TB may present with one of the complications listed in Box 19.57. Radiological changes include ill-defined opacification in one or both of the upper lobes, and as progression occurs, consolidation, collapse and cavitation develop to varying degrees (Fig. 19.38). It is often difficult to distinguish active from quiescent disease on radiological criteria alone, but the presence of a miliary pattern or cavitation favours active disease. In extensive disease, collapse may be marked and results in significant displacement of the trachea and mediastinum. Occasionally, a caseous lymph node may drain into an adjoining bronchus, leading to tuberculous pneumonia.

Clinical features: extrapulmonary disease

Extrapulmonary tuberculosis accounts for about 20% of cases in those who are HIV-negative but is more common in HIV-positive individuals.

Lymphadenitis

Lymph nodes are the most common extrapulmonary site of disease. Cervical and mediastinal glands are affected most frequently, followed by axillary and inguinal, and more than one region may be involved. Disease may represent primary infection, spread from contiguous sites, or reactivation. Supraclavicular lymphadenopathy is often the result of spread from mediastinal disease. The nodes are usually painless and initially mobile but become matted together with time. When caseation and liquefaction occur, the swelling becomes fluctuant and may discharge through the skin with the formation of a 'collar-stud' abscess and sinus formation. Approximately half of cases fail to show any constitutional features, such as fevers or night sweats. The tuberculin test is usually strongly positive. During or after treatment, paradoxical enlargement,

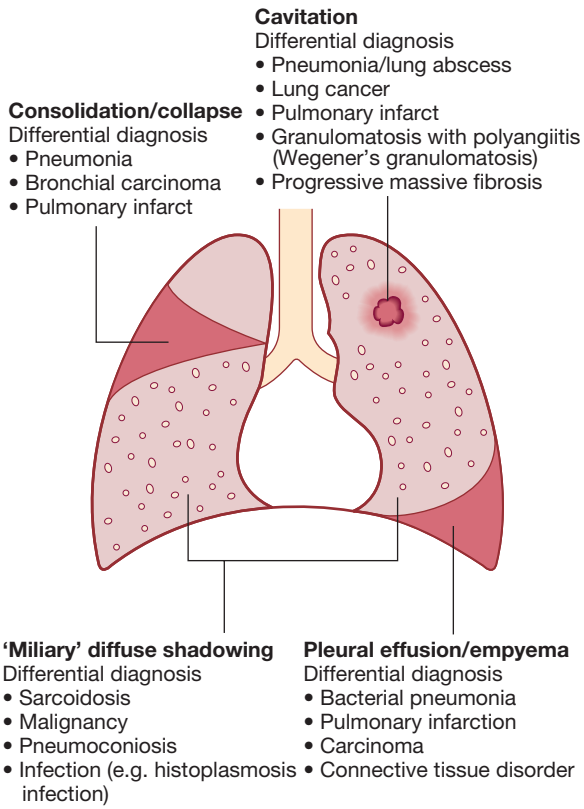

Fig. 19.38 Chest X-ray: major manifestations and differential diagnosis of pulmonary TB. Less common manifestations include pneumothorax, ARDS (p. 192), cor pulmonale and localised emphysema.

development of new nodes and suppuration may all occur but without evidence of continued infection; surgical excision is rarely necessary. In non-immigrant children in the UK, most mycobacterial lymphadenitis is caused by opportunistic mycobacteria, especially of the *M. avium* complex.

Gastrointestinal tuberculosis

TB can affect any part of the bowel and patients may present with a wide range of symptoms and signs (Fig. 19.39). Upper gastrointestinal tract involvement is rare and is usually an unexpected histological finding in an endoscopic or laparotomy specimen. Ileocaecal disease accounts for approximately half of abdominal TB cases. Fever, night sweats, anorexia and weight loss are usually prominent and a right iliac fossa mass may be palpable. Up to 30% of cases present with an acute abdomen. Ultrasound or CT may reveal thickened bowel wall, abdominal lymphadenopathy, mesenteric thickening or ascites. Barium enema and small bowel enema reveal narrowing, shortening and distortion of the bowel, with caecal involvement predominating. Diagnosis rests on obtaining histology by either colonoscopy or mini-laparotomy. The main differential diagnosis is Crohn's disease (p. 897). Tuberculous peritonitis is characterised by abdominal distension, pain and constitutional symptoms. The ascitic fluid is exudative and cellular, with a predominance of lymphocytes. Laparoscopy reveals multiple white 'tubercles' over the peritoneal and omental surfaces. Low-grade hepatic dysfunction is common in miliary disease, in which biopsy reveals granulomas. Occasionally, patients may be frankly icteric, with a mixed hepatic/cholestatic picture.

19.56 Clinical presentations of pulmonary TB

- Chronic cough, often with haemoptysis
- Pyrexia of unknown origin
- Unresolved pneumonia
- Exudative pleural effusion
- Asymptomatic (diagnosis on chest X-ray)
- Weight loss, general debility
- Spontaneous pneumothorax

19.57 Chronic complications of pulmonary TB

Pulmonary

- Massive haemoptysis
- Cor pulmonale
- Fibrosis/emphysema
- Atypical mycobacterial infection
- Aspergilloma
- Lung/pleural calcification
- Obstructive airways disease
- Bronchiectasis
- Bronchopleural fistula

Non-pulmonary

- Empyema necessitans
- Laryngitis
- Enteritis*
- Anorectal disease*
- Amyloidosis
- Poncet's polyarthritis

*From swallowed sputum.

Pericardial disease

Disease occurs in two forms (see Fig. 19.39 and p. 639): pericardial effusion and constrictive pericarditis. Fever and night sweats are rarely prominent and the presentation is usually insidious, with breathlessness and abdominal swelling. Coexistent pulmonary disease is very rare, with the exception of pleural effusion. Pulsus paradoxus, a raised JVP, hepatomegaly, prominent ascites and peripheral oedema are common to both types. Pericardial effusion is associated with increased pericardial dullness and a globular enlarged heart on chest X-ray, and pericardial calcification occurs in around 25% of cases. Constriction is associated with an early third heart sound and, occasionally, atrial fibrillation. Diagnosis is based on the clinical, radiological and echocardiographic findings (p. 640). The effusion is frequently blood-stained. Open pericardial biopsy can be performed where there is diagnostic uncertainty. The addition of corticosteroids to anti-tuberculosis treatment has been shown to help both forms of pericardial disease.

Central nervous system disease

Meningeal disease represents the most important form of central nervous system TB. Unrecognised and untreated, it is rapidly fatal. Even when appropriate treatment is prescribed, mortality rates of 30% have been reported, whilst survivors may be left with neurological sequelae. Clinical features, investigations and management are described on page 1204.

Bone and joint disease

The spine is the most common site for bony TB (Pott's disease), which usually presents with chronic back pain and typically involves the lower thoracic and lumbar

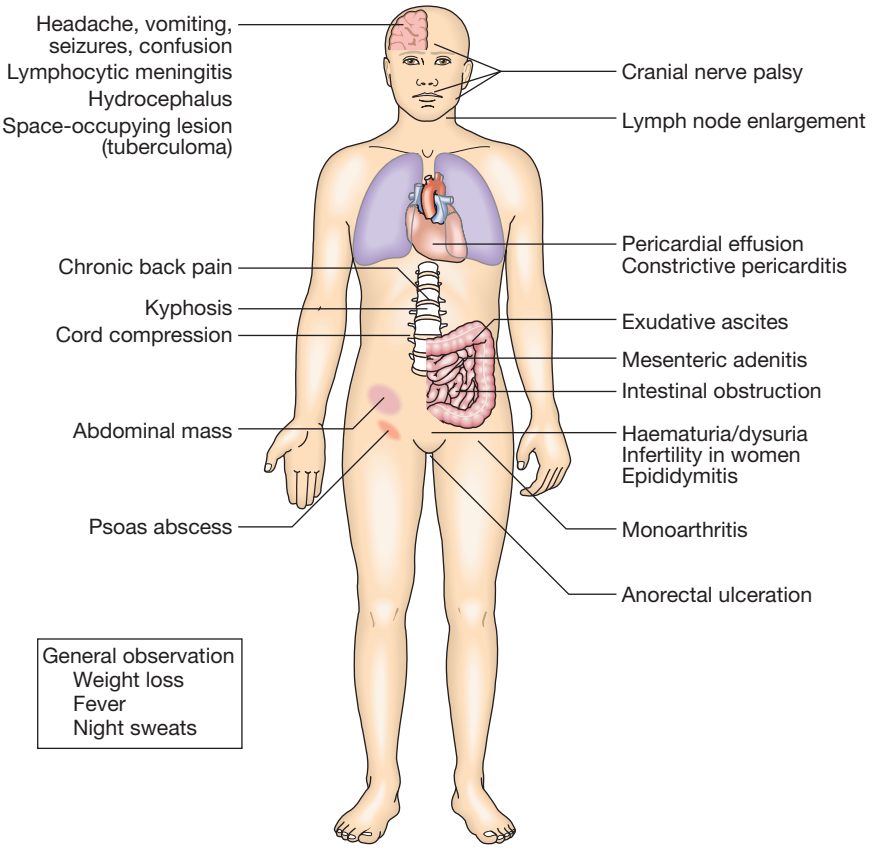

Fig. 19.39 Systemic presentations of extrapulmonary TB.

spine (see Fig. 19.39). The infection starts as a discitis and then spreads along the spinal ligaments to involve the adjacent anterior vertebral bodies, causing angulation of the vertebrae with subsequent kyphosis. Paravertebral and psoas abscess formation is common and the disease may present with a large (cold) abscess in the inguinal region. CT or MRI is valuable in gauging the extent of disease, the amount of cord compression, and the site for needle biopsy or open exploration, if required. The major differential diagnosis is malignancy, which tends to affect the vertebral body and leave the disc intact. Important complications include spinal instability or cord compression.

TB can affect any joint but most frequently involves the hip or knee. Presentation is usually insidious, with pain and swelling; fever and night sweats are uncommon. Radiological changes are often non-specific but, as disease progresses, reduction in joint space and erosions appear. Poncet's arthropathy is an immunologically mediated polyarthritis that usually resolves within 2 months of starting treatment.

Genitourinary disease

Fever and night sweats are rare with renal tract TB and patients are often only mildly symptomatic for many years. Haematuria, frequency and dysuria are often present, with sterile pyuria found on urine microscopy and culture. In women, infertility from endometritis, or pelvic pain and swelling from salpingitis or a tubo-ovarian abscess occurs occasionally. In men, genitourinary TB may present as epididymitis or prostatitis.

Fig. 19.40 Typical changes of tuberculosis. The chest X-ray shows bilateral upper lobe airspace shadowing with cavitation.

Diagnosis

The presence of an otherwise unexplained cough for more than 2–3 weeks, particularly in regions where TB is prevalent, or typical chest X-ray changes (Fig. 19.40), should prompt further investigation (Box 19.58). Direct microscopy of sputum remains the most important first step. The probability of detecting acid-fast bacilli is proportional to the bacillary burden in the sputum (typically positive when 5000–10 000 organisms are present). By virtue of their substantial, lipid-rich wall, tuberculous bacilli are difficult to stain. The most effective

19.58 Diagnosis of TB

Specimens required

Pulmonary
- Sputum* (induced with nebulised hypertonic saline if not expectorating)
- Bronchoscopy with washings or BAL
- Gastric washing* (mainly used for children)

Extrapulmonary
- Fluid examination (cerebrospinal, ascitic, pleural, pericardial, joint): yield classically very low
- Tissue biopsy (from affected site): bone marrow/liver may be diagnostic in disseminated disease

Diagnostic tests
- Tuberculin skin test: low sensitivity/specificity; useful only in primary or deep-seated infection
- Stain
  - Ziehl–Neelsen
  - Auramine fluorescence
- Nucleic acid amplification
- Culture
  - Solid media (Löwenstein–Jensen, Middlebrook)
  - Liquid media (e.g. BACTEC or MGIT)
- Pleural fluid: adenosine deaminase
- Response to empirical antituberculous drugs (usually seen after 5–10 days)

Baseline blood tests
- FBC, CRP, ESR, U&E and LFTs

*At least 2 but preferably 3, including an early morning sample.
(BAL = bronchoalveolar lavage; MGIT = mycobacteria growth indicator tube)

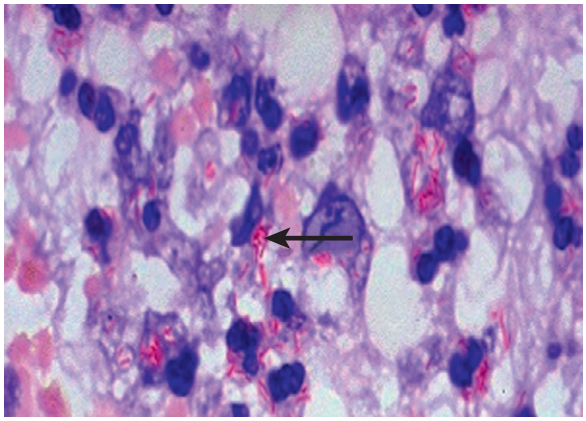

Fig. 19.41 Positive Ziehl–Neelsen stain. Mycobacteria retain the red carbol fuchsin stain, despite washing with acid and alcohol.

techniques are the Ziehl–Neelsen (Fig. 19.41) and rhodamine–auramine. The latter causes the tuberculous bacilli to fluoresce against a dark background and is easier to use when numerous specimens need to be examined; however, it is more complex and expensive, limiting use in resource-poor regions.

A positive smear is sufficient for the presumptive diagnosis of TB but definitive diagnosis requires culture. Smear-negative sputum should also be cultured, as only 10–100 viable organisms are required for sputum to be culture-positive. A diagnosis of smear-negative TB may be made in advance of culture if the chest X-ray appearances are typical of TB and there is no response to a broad-spectrum antibiotic.

MTB grows slowly and may take between 4 and 6 weeks to appear on solid medium, such as Löwenstein–Jensen or Middlebrook. Faster growth (1–3 weeks) occurs in liquid media, such as the radioactive BACTEC system or the non-radiometric mycobacteria growth indicator tube (MGIT). The BACTEC method is the most widely accepted as the reference standard in developed nations and detects mycobacterial growth by measuring the liberation of $^{14}CO_2$, following metabolism of ^{14}C-labelled substrate present in the medium.

Drug sensitivity testing is particularly important in those with a previous history of TB, treatment failure or chronic disease, and in those who are resident in or have visited an area of high prevalence of resistance, or who are HIV-positive. The detection of rifampicin resistance, using molecular tools to test for the presence of the *rpo* gene currently associated with around 95% of rifampicin-resistant cases, is important, as rifampicin forms the cornerstone of 6-month chemotherapy.

Nucleic acid amplification tests, such as the Xpert/RIF test, combine the potential to diagnose TB and detect the presence of rifampicin resistance, and may become the test of first choice in individuals with HIV or those suspected to have multi-drug-resistant tuberculosis (MDR-TB). If a cluster of cases suggests a common source, confirmation may be sought by fingerprinting of isolates with restriction-fragment length polymorphism (RFLP).

The diagnosis of extrapulmonary TB can be more challenging. There are generally fewer organisms (particularly in meningeal or pleural fluid), so culture or histopathological examination of tissue is more important. Adenosine deaminase in pleural fluid, and to a lesser extent in CSF, may assist in confirming suspected TB. In the presence of HIV, examination of sputum may still be useful, as subclinical pulmonary disease is common.

Management

Chemotherapy

The treatment of TB is based on the principle of an initial intensive phase to reduce the bacterial population rapidly, followed by a continuation phase to destroy any remaining bacteria (Box 19.59). Standard treatment involves 6 months' treatment with isoniazid and rifampicin, supplemented in the first 2 months with pyrazinamide and ethambutol. Fixed-dose tablets combining two or three drugs are preferred. Treatment should be commenced immediately in any patient who is smear-positive, or smear-negative but with typical chest X-ray changes and no response to standard antibiotics.

Six months of therapy is appropriate for all patients with new-onset pulmonary TB and most cases of extrapulmonary TB. However, 12 months of therapy is recommended for meningeal TB, including involvement of the spinal cord in cases of spinal TB; in these cases, ethambutol may be replaced by streptomycin. Pyridoxine should be prescribed in pregnant women and malnourished patients to reduce the risk of peripheral neuropathy with isoniazid. Where drug resistance is not anticipated, patients can be assumed to be non-infectious after 2 weeks of appropriate therapy.

19.59 Treatment of new TB patients (World Health Organization recommendations)

Intensive phase	Continuation phase	Comments
Standard regimen		
2 mths of HRZE	4 mths of HR	
2 mths of HRZE	4 mths of HRE	Applies only in countries with high levels of isoniazid resistance in new TB patients, and where isoniazid drug susceptibility testing in new patients is not done (or results are unavailable) before the continuation phase begins
Dosing frequency		
Daily*	Daily	Optimal
Daily*	3 times/wk	Acceptable alternative for any new patient receiving directly observed therapy
3 times/wk	3 times/wk	Acceptable alternative, provided that the patient is receiving directly observed therapy and is NOT living with HIV or living in an HIV-prevalent setting

*Daily (rather than 3 times weekly) intensive-phase dosing may help to prevent acquired drug resistance in TB patients starting treatment with isoniazid resistance. (H = isoniazid; R = rifampicin; Z = pyrazinamide; E = ethambutol) Adapted from WHO Treatment of Tuberculosis Guidelines, 4th edn.

19.60 Main adverse reactions of first-line antituberculous drugs

	Isoniazid	Rifampicin	Pyrazinamide	Streptomycin	Ethambutol
Mode of action	Cell wall synthesis	DNA transcription	Unknown	Protein synthesis	Cell wall synthesis
Major adverse reactions	Peripheral neuropathy[1] Hepatitis[2] Rash	Febrile reactions Hepatitis Rash Gastrointestinal disturbance	Hepatitis Gastrointestinal disturbance Hyperuricaemia	8th nerve damage Rash	Retrobulbar neuritis[3] Arthralgia
Less common adverse reactions	Lupoid reactions Seizures Psychoses	Interstitial nephritis Thrombocytopenia Haemolytic anaemia	Rash Photosensitisation Gout	Nephrotoxicity Agranulocytosis	Peripheral neuropathy Rash

[1]The risk may be reduced by prescribing pyridoxine. [2]More common in patients with a slow acetylator status and in alcoholics. [3]Reduced visual acuity and colour vision may be reported with higher doses and are usually reversible.

Most patients can be treated at home. Admission to a hospital unit with appropriate isolation facilities should be considered where there is uncertainty about the diagnosis, intolerance of medication, questionable treatment adherence, adverse social conditions or a significant risk of MDR-TB (culture-positive after 2 months on treatment, or contact with known MDR-TB).

Patients treated with rifampicin should be advised that their urine, tears and other secretions will develop a bright orange/red coloration, and women taking the oral contraceptive pill must be warned that its efficacy will be reduced and alternative contraception may be necessary. Ethambutol and streptomycin should be used with caution in renal failure, with appropriate dose reduction and monitoring of drug levels. Adverse drug reactions occur in about 10% of patients, but are significantly more common with HIV co-infection (Box 19.60).

Baseline liver function and regular monitoring are important for patients treated with standard therapy. Rifampicin may cause asymptomatic hyperbilirubinaemia but, along with isoniazid and pyrazinamide, may also cause hepatitis. Mild asymptomatic increases in transaminases are common but significant hepatotoxicity only occurs in 2–5%. It is appropriate to stop treatment and allow any symptoms to subside and the liver function tests (LFTs) to recover before commencing a stepwise re-introduction of the individual drugs. Less hepatotoxic regimens may be considered, including streptomycin, ethambutol and fluoroquinolone.

Corticosteroids reduce inflammation and limit tissue damage, and are currently recommended when treating pericardial or meningeal disease, and in children with endobronchial disease. They may confer benefit in TB of the ureter, pleural effusions and extensive pulmonary disease, and can suppress hypersensitivity drug reactions. Surgery should be considered in cases complicated by massive haemoptysis, loculated empyema, constrictive pericarditis, lymph node suppuration, and spinal disease with cord compression, but usually only after a full course of antituberculosis treatment.

The effectiveness of therapy for pulmonary TB is assessed by further sputum smear at 2 months and at 5 months. Treatment failure is defined as a positive sputum smear or culture at 5 months or any patient with a multidrug resistant strain, regardless of whether they are smear-positive or negative. Extrapulmonary TB must be assessed clinically or radiographically, as appropriate.

Control and prevention

The World Health Organization (WHO) is committed to reducing the incidence of TB by 2015. Supporting the development of laboratory and health-care services to improve detection and treatment of active and latent TB is an important component of this goal.

Detection of latent TB

Contact tracing is a legal requirement in many countries. It has the potential to identify the probable index case, other cases infected by the same index patient (with or without evidence of disease), and close contacts who should receive BCG vaccination (see below) or chemotherapy. Approximately 10–20% of close contacts of patients with smear-positive pulmonary TB and 2–5% of those with smear-negative, culture-positive disease have evidence of TB infection.

Cases are commonly identified using the tuberculin skin test (Box 19.61 and Fig 19.42). An otherwise asymptomatic contact with a positive tuberculin skin test but a normal chest X-ray may be treated with chemoprophylaxis to prevent infection from progressing to clinical disease. Chemoprophylaxis is also recommended for children aged less than 16 years identified during contact tracing as having a strongly positive tuberculin test, children aged less than 2 years in close contact with smear-positive pulmonary disease, those in whom recent tuberculin conversion has been confirmed, and babies of mothers with pulmonary TB. It should also be considered for HIV-infected close contacts of a patient with smear-positive disease. A course of rifampicin and isoniazid for 3 months or isoniazid for 6 months is effective.

19.61 Skin testing in TB: tests using purified protein derivative (PPD)

Heaf test

- Read at 3–7 days
- Multipuncture method
  - Grade 1: 4–6 papules
  - Grade 2: Confluent papules forming ring
  - Grade 3: Central induration
  - Grade 4: > 10 mm induration

Mantoux test

- Read at 2–4 days
- 10 tuberculin units used
  - Positive when induration 5–14 mm (equivalent to Heaf grade 2) and > 15 mm (Heaf grade 3–4)

False negatives

- Severe TB (25% of cases negative)
- Newborn and elderly
- HIV (if CD4 count < 200 cells/mL)
- Malnutrition
- Recent infection (e.g. measles) or immunisation
- Immunosuppressive drugs
- Malignancy
- Sarcoidosis

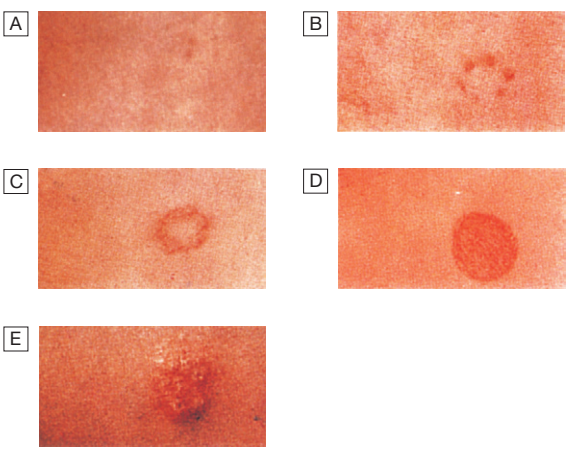

Fig. 19.42 Gradings of the Heaf test response. A Negative. B Grade 1. C Grade 2. D Grade 3. E Grade 4.

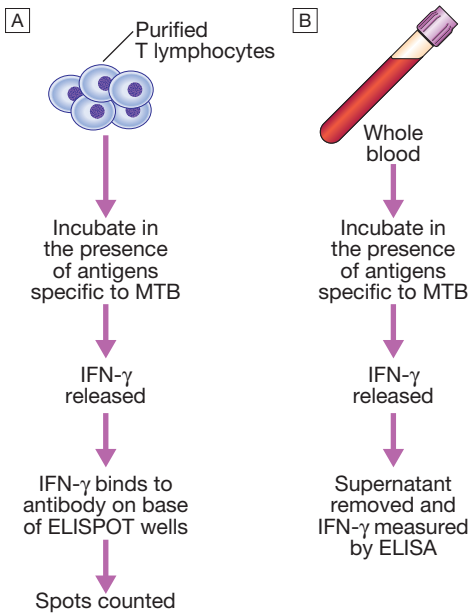

Fig. 19.43 The principles of interferon-gamma release assays. A sample of either purified T cells (T-SPOT.TB® test) or whole blood (QuantiFERON®–TB Gold test) is incubated in the presence of antigens specific to *Mycobacterium tuberculosis* (MTB). The release of interferon-gamma (IFN-γ) by the cells is measured by enzyme-lined immunosorbent assay (ELISA). (ELISPOT = enzyme-linked immunosorbent spot assay)

Tuberculin skin testing may be associated with false-positive reactions in those who have had a BCG vaccination and in areas where exposure to non-tuberculous mycobacteria is high. The skin tests may also be falsely negative in the setting of immunosuppression or overwhelming infection. These limitations may be overcome by employing interferon-gamma release assays (IGRAs) (Fig. 19.43). These tests measure the release of IFN-γ from sensitised T cells in response to antigens, such as early secretory antigenic target (ESAT)-6 or culture filtrate protein (CFP)-10, that are encoded by genes specific to the MTB and are not shared with BCG or opportunistic mycobacteria. The greater specificity of these tests, combined with the logistical convenience of one blood test, as opposed to two visits for skin testing, suggests that IGRAs will replace the tuberculin skin test in low-incidence, high-income countries.

Directly observed therapy

Poor adherence to therapy is a major factor in prolonged illness, risk of relapse, and the emergence of drug resistance. Directly observed therapy (DOT) involves the supervised administration of therapy 3 times weekly to improve adherence. DOT has become an important control strategy in resource-poor nations. In the UK, it is currently recommended for patients thought unlikely to be adherent to therapy: homeless people and drifters, alcohol or drug users, patients with serious mental illness and those with a history of non-compliance.

TB and HIV/AIDS

The close links between HIV and TB, particularly in sub-Saharan Africa, and the potential for both diseases to overwhelm health-care funding in resource-poor nations have been recognised, with the promotion of programmes that link detection and treatment of TB with detection and treatment of HIV. It is recommended that all patients with TB should be tested for HIV disease. Mortality is high and TB is a leading cause of death in HIV patients. Full discussion of its presentation and management is given on page 400.

Drug-resistant TB

Drug-resistant TB is defined by the presence of resistance to any first-line agent. Multidrug-resistant TB (MDR-TB) is defined by resistance to at least rifampicin and isoniazid, with or without other drug resistance. Extensively drug-resistant TB (XDR-TB) is defined as resistance to at least rifampicin and isoniazid, in addition to any quinolone and at least one injectable second-line agent. The prevalence of MDR-TB is rising, particularly in the former Soviet Union, Central Asia and Africa. It is more common in those with a prior history of TB, particularly if treatment has been inadequate, and those with HIV infection. Box 19.62 lists the factors contributing to the emergence of drug-resistant TB. Diagnosis is challenging, especially in developing countries, and although cure may be possible, it requires prolonged treatment with less effective, more toxic and more expensive therapies. The mortality rate from MDR-TB is high and that from XDR-TB higher still.

Vaccines

BCG (the Calmette–Guérin bacillus), a live attenuated vaccine derived from *M. bovis*, is the most established TB vaccine. It is administered by intradermal injection and is highly immunogenic. BCG appears to be effective in preventing disseminated disease, including tuberculous meningitis, in children, but its efficacy in adults is inconsistent and new vaccines are urgently needed. Current vaccination policies vary worldwide according to incidence and health-care resources, but usually target children and other high-risk individuals. BCG is very safe, with the occasional complication of local abscess formation. It should not be administered to those who are immunocompromised (e.g. by HIV) or pregnant.

Prognosis

Following successful completion of chemotherapy, cure should be anticipated in the majority of patients. There is a small (< 5%) and unavoidable risk of relapse. Most relapses occur within 5 months and usually have the same drug susceptibility. In the absence of treatment, a patient with smear-positive TB will remain infectious for an average of 2 years; in 1 year, 25% of untreated cases will die. Death is more likely in those who are smear-positive and those who smoke. A few patients die unexpectedly soon after commencing therapy and it is possible that some have subclinical hypoadrenalism that is unmasked by a rifampicin-induced increase in steroid metabolism. HIV-positive patients have higher mortality rates and a modestly increased risk of relapse.

19.62 Factors contributing to the emergence of drug-resistant TB

- Drug shortages
- Poor-quality drugs
- Lack of appropriate supervision
- Transmission of drug-resistant strains
- Prior anti-tuberculosis treatment
- Treatment failure (smear-positive at 5 mths)

Opportunistic mycobacterial infection

Other species of environmental mycobacteria (often termed 'atypical') may cause human disease (Box 19.63). The sites commonly involved are the lungs, lymph nodes, skin and soft tissues. The most widely recognised of these mycobacteria, *M. avium* complex (MAC), is well described in severe HIV disease (CD4 count < 50 cells/mL – p. 407). However, several others (including MAC) colonise and/or infect apparently immunocompetent patients with chronic lung diseases such as COPD, bronchiectasis, pneumoconiosis, old TB, or cystic fibrosis. The clinical presentation varies from a relatively indolent course in some to an aggressive course characterised by cavitatory or nodular disease in others. Radiological appearances may be similar to classical TB, but in patients with bronchiectasis, opportunistic infection may present with lower-zone nodules. The most commonly reported organisms include *M. kansasii*, *M. malmoense*, *M. xenopi* and *M. abscessus*, but geographical variation is marked. *M. abscessus* and *M. fortuitum* grow rapidly but the majority grow slowly. More rapid diagnostic systems are under development, including DNA probes, high-performance liquid chromatography (HPLC), PCR restriction enzyme analysis (PRA) and 16S rRNA gene sequence analysis. With the exception of *M. kansasii*, drug sensitivity testing is usually unhelpful in predicting treatment response. There is usually no requirement for notification, as the organisms are not normally communicable.

19.63 Site-specific opportunistic mycobacterial disease

Pulmonary

Respiratory diseases caused by fungi

The majority of fungi encountered by humans are harmless saprophytes but in certain circumstances (Box 19.64) some species may cause disease by infecting human tissue, promoting damaging allergic reactions or producing toxins. 'Mycosis' is the term applied to disease caused by fungal infection.

Aspergillus species

Most cases of bronchopulmonary aspergillosis are caused by *Aspergillus fumigatus*, but other members of the genus (*A. clavatus*, *A. flavus*, *A. niger* and *A. terreus*) occasionally cause disease. The conditions associated with *Aspergillus* species are listed in Box 19.65.

Allergic bronchopulmonary aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) occurs as a result of a hypersensitivity reaction to germinating fungal spores in the airway wall. The condition may complicate the course of asthma and cystic fibrosis, and is a recognised cause of pulmonary eosinophilia (p. 713). The prevalence of ABPA is approximately 1–2% in asthma and 5–10% in cystic fibrosis. A variety of human leucocyte antigens (HLA) convey both an increased and a decreased risk of developing the condition, suggesting that genetic susceptibility is important.

Clinical features and investigations

Clinical features depend on the stage of the disease. Common manifestations in the early phase include fever, breathlessness, cough productive of bronchial casts, and worsening of asthmatic symptoms. The appearance of radiographic infiltrates may cause ABPA to be mistaken for pneumonia, but the diagnosis may also be suggested by segmental or lobar collapse on chest X-rays of patients whose asthma symptoms are stable. Diagnostic features are shown in Box 19.66 and the typical *Aspergillus* hyphae in Figure 19.44. If bronchiectasis develops, its symptoms and complications often overshadow those of asthma.

19.64 Factors predisposing to fungal disease

Systemic factors

- Diabetes mellitus
- Chronic alcoholism
- HIV
- Radiotherapy
- Corticosteroids and other immunosuppressant medication

Local factors

- Tissue damage by suppuration or necrosis
- Alteration of normal bacterial flora by antibiotic therapy

19.65 Classification of bronchopulmonary aspergillosis

- Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)
- Extrinsic allergic alveolitis (*Aspergillus clavatus*)
- Intracavitary aspergilloma
- Invasive pulmonary aspergillosis
- Chronic and subacute pulmonary aspergillosis

19.66 Features of allergic bronchopulmonary aspergillosis

- Asthma (in the majority of cases)
- Proximal bronchiectasis (inner two-thirds of chest CT field)
- Positive skin test to an extract of *A. fumigatus*
- Elevated total serum IgE > 417 KU/L or 1000 ng/mL
- Elevated serum IgE (*A. fumigatus*) or IgG (*A. fumigatus*)
- Peripheral blood eosinophilia > 0.5×10^9/L
- Presence or history of chest X-ray abnormalities
- Fungal hyphae of *A. fumigatus* on microscopic examination of sputum

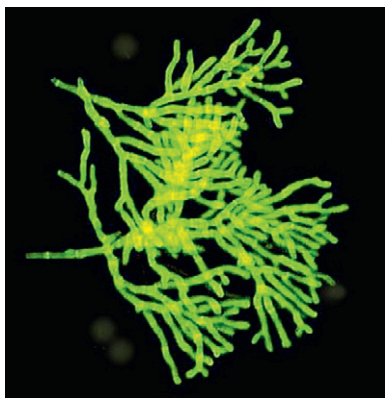

Fig. 19.44 Branching *Aspergillus* hyphae seen in ABPA. The figure shows the use of calcofluor white, a non-specific fluorochrome stain that binds to fungi and fluoresces when exposed to light of the appropriate wavelength. *Aspergillus fumigatus* was subsequently grown on culture.

Management

ABPA is generally considered an indication for regular therapy with low-dose oral corticosteroids (prednisolone 7.5–10 mg daily), with the aim of suppressing the immunopathological responses and preventing progressive tissue damage. In some patients, itraconazole (400 mg/day) facilitates a reduction in oral steroids, and a 4-month trial is usually recommended to assess its efficacy. The use of specific anti-IgE monoclonal antibodies is under consideration. Exacerbations, particularly when associated with new chest X-ray changes, should be treated promptly with prednisolone 40–60 mg daily and physiotherapy. If persistent lobar collapse occurs, bronchoscopy (usually under general anaesthetic) should be performed to remove impacted mucus and ensure prompt re-inflation.

Aspergilloma

Inhaled *Aspergillus* may lodge and germinate in areas of damaged lung tissue, forming a fungal ball or 'aspergilloma'. The upper lobes are most frequently involved and fungal balls readily form in tuberculous cavities (Fig. 19.45). Less common causes include damage from a lung abscess cavity, a bronchiectatic space, pulmonary infarct, sarcoid, ankylosing spondylitis or even a cavitated tumour. The presence of multiple aspergilloma cavities in a diseased area of lung has been termed a 'complex aspergilloma' (see below).

Clinical features and investigations

Simple aspergillomas are often asymptomatic and are identified incidentally on chest X-ray. However, they

Fig. 19.45 CT of aspergilloma in the left upper lobe. The rounded fungal ball is separated from the wall of the cavity by a 'halo' of air.

may cause recurrent haemoptysis, which may be severe and life-threatening. Non-specific systemic features, such as lethargy and weight loss, may also be reported.

The fungal ball produces a tumour-like opacity on X-ray, but can be distinguished from a carcinoma by the presence of a crescent of air between the fungal ball and the upper wall of the cavity. HRCT is more sensitive (see Fig. 19.45). Elevated serum precipitins to *A. fumigatus* are found in virtually all patients. Sputum microscopy typically demonstrates scanty hyphal fragments and is usually positive on culture. Less than half exhibit skin hypersensitivity to extracts of *A. fumigatus*. Rarely, other filamentous fungi can cause intracavitary mycetoma and are identified by culture.

Management

Asymptomatic cases do not require treatment. Specific antifungal therapy is of no value and steroids may predispose to invasion. Aspergillomas complicated by haemoptysis should be excised surgically. In those unfit for surgery, palliative procedures range from local instillation of amphotericin B to bronchial artery embolisation. The latter may be used to control haemoptysis prior to definitive surgery.

Invasive pulmonary aspergillosis

Invasive pulmonary aspergillosis (IPA) is most commonly a complication of profound neutropenia caused by drugs (especially immunosuppressants) and/or disease (Box 19.67).

Clinical features and investigations

Acute IPA causes a severe necrotising pneumonia and must be considered in any immunocompromised patient who develops fever, new respiratory symptoms (particularly pleural pain or haemoptysis) or a pleural rub. Invasion of pulmonary vessels causes thrombosis and infarction, and systemic spread may occur to the brain, heart, kidneys and others organs. Tracheobronchial aspergillosis involvement is characterised by the formation of fungal plaques and ulceration.

HRCT characteristically shows macronodules (usually ≥ 1 cm), which may be surrounded by a 'halo' of low attenuation if captured early (< 5 days). Culture or histopathological evidence of *Aspergillus* in diseased tissues provides a definitive diagnosis, but the majority of patients are too ill for invasive tests such as bronchoscopy or lung biopsy. Other investigations include detection of *Aspergillus* cell wall components (galactomannan and β-1,3-glucan) in blood or BAL fluid and *Aspergillus* DNA by PCR. Diagnosis is often inferred from a combination of features (Box 19.68).

Management and prevention

IPA carries a high mortality rate, especially if treatment is delayed. The treatment of choice is voriconazole. Second-line agents include liposomal amphotericin,

19.67 Risk factors for invasive aspergillosis

- Neutropenia: risk related to duration and degree
- Solid organ or allogeneic stem cell transplantation
- Prolonged high-dose corticosteroid therapy
- Leukaemia and other haematological malignancies
- Cytotoxic chemotherapy
- Advanced HIV disease
- Severe COPD
- Critically ill patients on intensive care units
- Chronic granulomatous disease

19.68 Criteria for the diagnosis of probable invasive pulmonary aspergillosis[1]

Host factors

- Recent history of neutropenia (< 0.5×10^9/L for ≥ 10 days) temporally related to the onset of fungal disease
- Recipient of allogeneic stem cell transplant
- Prolonged use of corticosteroids (average minimum 0.3 mg/kg/day prednisolone or equivalent) for > 3 wks (excludes ABPA)
- Treatment with other recognised T-cell immune suppressants, such as ciclosporin, TNF-α blockers, specific monoclonal antibodies (e.g. alemtuzumab) or nucleoside analogues during the last 90 days
- Inherited severe immune deficiency, e.g. chronic granulomatous disease or severe combined immune deficiency (p. 80)

Clinical criteria[2]

- The presence of one of the following on CT:
  1. Dense, well-circumscribed lesion(s) with or without a halo sign
  2. Air crescent sign
  3. Cavity

Tracheobronchitis

- Tracheobronchial ulceration, nodule, pseudomembrane, plaque or eschar seen on bronchoscopy

Mycological criteria

- Mould in sputum, BAL fluid or bronchial brush, indicated by one of the following:
  1. Recovery of fungal elements indicating a mould of *Aspergillus*
  2. Recovery by culture of a mould of *Aspergillus*
- Indirect tests (detection of antigen or cell wall constituents)
  1. Galactomannan antigen in plasma, serum or BAL fluid
  2. β-1,3-glucan detected in serum (detects other species of fungi, as well as *Aspergillus*)[3]

[1]Adapted from European Organisation for Research and Treatment of Cancer/Mycoses Study Group. [2]Must be consistent with the mycological findings and temporally related to current episode. [3]May be useful as a preliminary screening tool for invasive aspergillosis.

caspofungin or posaconazole. Response may be assessed clinically, radiologically and serologically (by estimation of the circulating galactomannan level). Recovery is dependent on immune reconstitution, which may be accompanied by enlargement and/or cavitation of pulmonary nodules.

Patients at risk of *Aspergillus* (and other fungal infections) should be nursed in rooms with high-efficiency particulate air (HEPA) filters and laminar airflow. In areas with high spore counts, patients are advised to wear a mask if venturing outside their hospital room. Posaconazole (200 mg 3 times daily) or itraconazole (200 mg/day) may be prescribed for primary prophylaxis, and patients with a history of definite or probable IPA should be considered for secondary prophylaxis before further immunosuppression.

Chronic and subacute pulmonary aspergillosis

Chronic pulmonary aspergillosis (CPA) is an indolent non-invasive complication of chronic lung disease, such as COPD, tuberculosis, opportunistic mycobacterial disease or fibrotic lung disease. It may be associated with malnutrition, diabetes or liver disease and co-infection with opportunistic mycobacteria. CPA may mimic tuberculosis, resulting in its delayed diagnosis. Features include cough (with or without haemoptysis), weight loss, anorexia and fatigue over months or years, with associated fever, night sweats and elevated inflammatory markers. Radiological features include thick-walled cavities (predominantly apical), pulmonary infiltrates, pleural thickening and, later, fibrosis. The terms chronic necrotising (CNPA), cavitary ('complex aspergilloma') and fibrosing pulmonary aspergillosis have been applied, depending on the predominant features. There is overlap between CNPA and 'subacute' and 'semi-invasive' aspergillosis. Subacute aspergillosis is increasingly recognised in intensive care patients, especially those with COPD. The diagnosis is made by a combination of radiological examination, histopathology, isolation of fungus from the respiratory tract and detection of *Aspergillus* IgG in serum. Treatment usually involves prolonged indefinite courses of itraconazole or voriconazole, but cure is unusual. The most frequent pattern is chronic relapse/remission with gradual deterioration. Surgical intervention is fraught with complications and should be avoided.

Other fungal infections

Mucormycosis (p. 384) may present with a pulmonary syndrome indistinguishable clinically from acute IPA. Diagnosis relies on histopathology (where available) and/or culture of the organism from diseased tissue. The principles of treatment are as for other forms of mucormycosis: correction of predisposing factors, antifungal therapy with high-dose lipid amphotericin B or posaconazole, and surgical débridement.

Histoplasmosis, coccidioidomycosis, blastomycosis and cryptococcosis are discussed on pages 384–386.

TUMOURS OF THE BRONCHUS AND LUNG

Lung cancer is the most common cause of death from cancer worldwide, causing 1.4 million deaths per year (Box 19.69). Tobacco use is the major preventable cause. Just as tobacco use and cancer rates are falling in some developed countries, both smoking and lung cancer are rising in Eastern Europe and in many developing countries. The great majority of tumours in the lung are primary bronchial carcinomas and, in contrast to many other tumours, the prognosis remains poor, with fewer than 30% of patients surviving at 1 year and 6–8% at 5 years. Carcinomas of many other organs, as well as osteogenic and other sarcomas, may cause metastatic pulmonary deposits.

19.69 The burden of lung cancer

- Strikes 900 000 men and 330 000 women each year
- Accounts for 18% of all cancer deaths
- More than a threefold increase in deaths since 1950
- Rates rising in women: female lung cancer deaths outnumber male in some Nordic countries
- Has overtaken breast cancer in several countries, making it the most common cause of cancer death in men and women

Primary tumours of the lung

Aetiology

Cigarette smoking is by far the most important cause of lung cancer. It is thought to be directly responsible for at least 90% of lung carcinomas, the risk being proportional to the amount smoked and to the tar content of cigarettes. The death rate from the disease in heavy smokers is 40 times that in non-smokers. Risk falls slowly after smoking cessation, but remains above that in non-smokers for many years. It is estimated that 1 in 2 smokers dies from a smoking-related disease, about half in middle age. The effect of 'passive' smoking is more difficult to quantify but is currently thought to be a factor in 5% of all lung cancer deaths. Exposure to naturally occurring radon is another risk. The incidence of lung cancer is slightly higher in urban than in rural dwellers, which may reflect differences in atmospheric pollution (including tobacco smoke) or occupation, since a number of industrial materials are associated with lung cancer (p. 266). In recent years, the strong link between smoking and ill health has led many Western governments to legislate against smoking in public places, and smoking prevalence and some smoking-related diseases are already declining in these countries (p. 100).

Bronchial carcinoma

The incidence of bronchial carcinoma increased dramatically during the 20th century as a direct result of the tobacco epidemic (Fig. 19.46). In women, smoking prevalence and deaths from lung cancer continue to increase, and more women now die of lung cancer than breast cancer in the USA and the UK.

Pathology

Bronchial carcinomas arise from the bronchial epithelium or mucous glands. The common cell types are listed in Box 19.70. When the tumour occurs in a large bronchus, symptoms arise early, but tumours originating in a peripheral bronchus can grow very large without

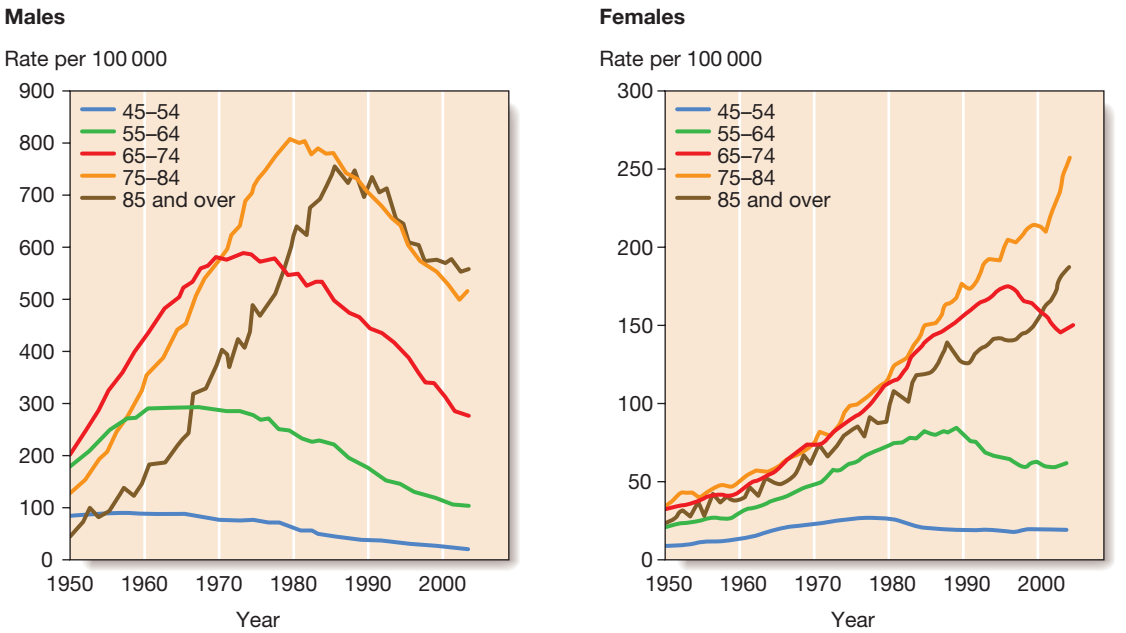

Fig. 19.46 **Mortality trends from lung cancer in England and Wales, 1950–2004, by age and year of death.** A Males. B Females. Note the decline in mortality from lung cancer in men towards the end of this period, reflecting a change in smoking habit.

19.70 Common cell types in bronchial carcinoma

Cell type	%
Squamous	35
Adenocarcinoma	30
Small-cell	20
Large-cell	15

producing symptoms, resulting in delayed diagnosis. Peripheral squamous tumours may undergo central necrosis and cavitation, and may resemble a lung abscess on X-ray (Fig. 19.47). Bronchial carcinoma may involve the pleura directly or by lymphatic spread, and may extend into the chest wall, invading the intercostal nerves or the brachial plexus and causing pain. Lymphatic spread to mediastinal and supraclavicular lymph nodes often occurs before diagnosis. Blood-borne metastases occur most commonly in liver, bone, brain, adrenals and skin. Even a small primary tumour may cause widespread metastatic deposits and this is a particular characteristic of small-cell lung cancers.

Clinical features

Lung cancer presents in many different ways, reflecting local, metastatic or paraneoplastic tumour effects.

- *Cough*. This is the most common early symptom. It is often dry but secondary infection may cause purulent sputum. A change in the character of a smoker's cough, particularly if associated with other new symptoms, should always raise suspicion of bronchial carcinoma.
- *Haemoptysis*. Haemoptysis is common, especially with central bronchial tumours. Although it may be caused by bronchitic infection, haemoptysis in a smoker should always be investigated to exclude a bronchial carcinoma. Occasionally, central tumours invade large vessels, causing sudden massive haemoptysis that may be fatal.
- *Bronchial obstruction*. This is another common presentation, and the clinical and radiological manifestations (Figs 19.48 and 19.5, p. 650; Box 19.71) depend on the site and extent of the obstruction, any secondary infection, and the extent of coexisting lung disease. Complete obstruction causes collapse of a lobe or lung, with breathlessness, mediastinal displacement and dullness to percussion with reduced breath sounds. Partial bronchial obstruction may cause a monophonic, unilateral wheeze that fails to clear

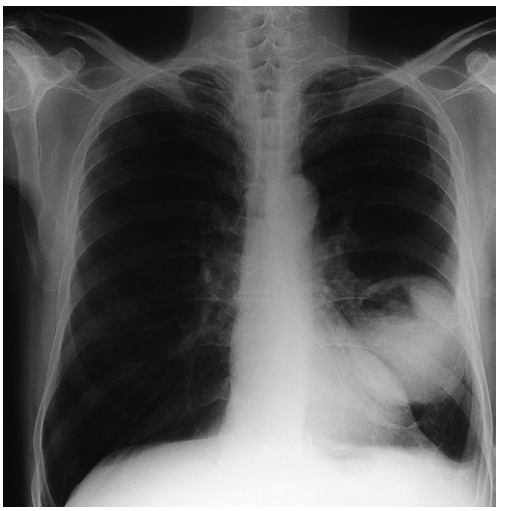

Fig. 19.47 **Large cavitated bronchial carcinoma in left lower lobe.**

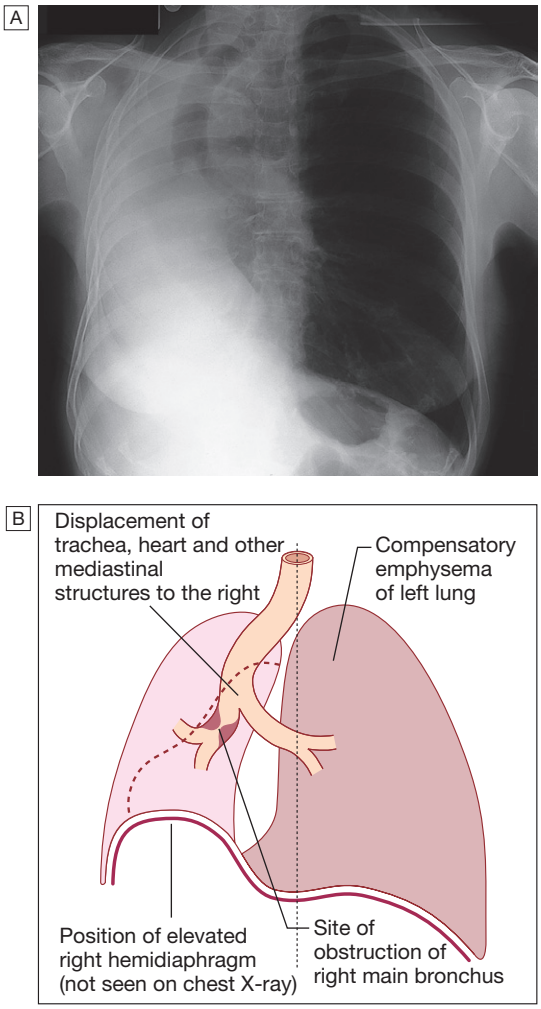

Fig. 19.48 Collapse of the right lung: effects on neighbouring structures. A Chest X-ray. B The typical abnormalities are highlighted.

19.71 Causes of large bronchus obstruction

Common

- Bronchial carcinoma or adenoma
- Enlarged tracheobronchial lymph nodes (malignant or tuberculous)
- Inhaled foreign bodies (especially right lung)
- Bronchial casts or plugs consisting of inspissated mucus or blood clot (especially asthma, cystic fibrosis, haemoptysis, debility)
- Collections of mucus or mucopus retained in the bronchi as a result of ineffective expectoration (especially postoperative following abdominal surgery)

Rare

- Aortic aneurysm
- Giant left atrium
- Pericardial effusion
- Congenital bronchial atresia
- Fibrous bronchial stricture (e.g. following tuberculosis or bronchial surgery/lung transplant)

with coughing, and may also impair the drainage of secretions to cause pneumonia or lung abscess as a presenting problem. Pneumonia that recurs at the same site or responds slowly to treatment, particularly in a smoker, should always suggest an underlying bronchial carcinoma. Stridor (a harsh inspiratory noise) occurs when the larynx, trachea or a main bronchus is narrowed by the primary tumour or by compression from malignant enlargement of the subcarinal and paratracheal lymph nodes.

- *Breathlessness*. Breathlessness may be caused by collapse or pneumonia, or by tumour causing a large pleural effusion or compressing a phrenic nerve and leading to diaphragmatic paralysis.
- *Pain and nerve entrapment*. Pleural pain usually indicates malignant pleural invasion, although it can occur with distal infection. Intercostal nerve involvement causes pain in the distribution of a thoracic dermatome. Carcinoma in the lung apex may cause Horner's syndrome (ipsilateral partial ptosis, enophthalmos, miosis and hypohidrosis of the face – p. 1172) due to involvement of the sympathetic chain at or above the stellate ganglion. Pancoast's syndrome (pain in the inner aspect of the arm, sometimes with small muscle wasting in the hand) indicates malignant destruction of the T1 and C8 roots in the lower part of the brachial plexus by an apical lung tumour.
- *Mediastinal spread*. Involvement of the oesophagus may cause dysphagia. If the pericardium is invaded, arrhythmia or pericardial effusion may occur. Superior vena cava obstruction by malignant nodes causes suffusion and swelling of the neck and face, conjunctival oedema, headache and dilated veins on the chest wall, and is most commonly due to bronchial carcinoma. Involvement of the left recurrent laryngeal nerve by tumours at the left hilum causes vocal cord paralysis, voice alteration and a 'bovine' cough (lacking the normal explosive character). Supraclavicular lymph nodes may be palpably enlarged or identified using ultrasound; if so, a needle aspirate may provide a simple means of cytological diagnosis.
- *Metastatic spread*. This may lead to focal neurological defects, epileptic seizures, personality change, jaundice, bone pain or skin nodules. Lassitude, anorexia and weight loss usually indicate metastatic spread.
- *Finger clubbing*. Overgrowth of the soft tissue of the terminal phalanx, leading to increased nail curvature and nail bed fluctuation, is often seen (p. 644).
- *Hypertrophic pulmonary osteoarthropathy* (*HPOA*). This is a painful periostitis of the distal tibia, fibula, radius and ulna, with local tenderness and sometimes pitting oedema over the anterior shin. X-rays reveal subperiosteal new bone formation. While most frequently associated with bronchial carcinoma, HPOA can occur with other tumours.
- *Non-metastatic extrapulmonary effects* (Box 19.72). The syndrome of inappropriate antidiuretic hormone secretion (SIADH, p. 438) and ectopic adrenocorticotrophic hormone secretion (p. 774) are usually associated with small-cell lung cancer. Hypercalcaemia may indicate malignant bone

19.72 Non-metastatic extrapulmonary manifestations of bronchial carcinoma

Endocrine (Ch. 20)

- Inappropriate antidiuretic hormone secretion causing hyponatraemia
- Ectopic adrenocorticotrophic hormone secretion
- Hypercalcaemia due to secretion of parathyroid hormone-related peptides
- Carcinoid syndrome (p. 889)
- Gynaecomastia

Neurological (Ch. 26)

- Polyneuropathy
- Myelopathy
- Cerebellar degeneration
- Myasthenia (Lambert–Eaton syndrome, p. 1227)

Other

- Digital clubbing
- Hypertrophic pulmonary osteoarthropathy
- Nephrotic syndrome
- Polymyositis and dermatomyositis
- Eosinophilia

destruction or production of hormone-like peptides by a tumour. Associated neurological syndromes may occur with any type of bronchial carcinoma.

Investigations

The main aims of investigation are to confirm the diagnosis, establish the histological cell type and define the extent of the disease.

Imaging

Bronchial carcinoma produces a range of appearances on chest X-ray, from lobar collapse (see Fig. 19.5, p. 650) to mass lesions, effusion or malignant rib destruction (Fig. 19.49 and Box 19.73). CT should be performed early as it may reveal mediastinal or metastatic spread and is helpful for planning biopsy procedures: for example, in establishing whether a tumour is accessible by bronchoscopy or percutaneous CT-guided biopsy.

Biopsy and histopathology

Around three-quarters of primary lung tumours can be visualised and sampled directly by biopsy and brushing using a flexible bronchoscope. Bronchoscopy also allows an assessment of operability, from the proximity of central tumours to the main carina (Fig. 19.50).

For tumours which are too peripheral to be accessible by bronchoscope, the yield of 'blind' bronchoscopic washings and brushings from the radiologically affected area is low, and percutaneous needle biopsy under CT or ultrasound guidance is a more reliable way to obtain a histological diagnosis. There is a small risk of iatrogenic pneumothorax, which may preclude the procedure if there is extensive coexisting COPD. In patients who are unfit for invasive investigation, sputum cytology can reveal malignant cells (Fig. 19.51), although the yield is low.

In patients with pleural effusions, pleural aspiration and biopsy is the preferred investigation. Where facilities exist, thoracoscopy increases yield by allowing targeted biopsies under direct vision. In patients with metastatic disease, the diagnosis can often be confirmed by needle aspiration or biopsy of affected lymph nodes, skin lesions, liver or bone marrow.

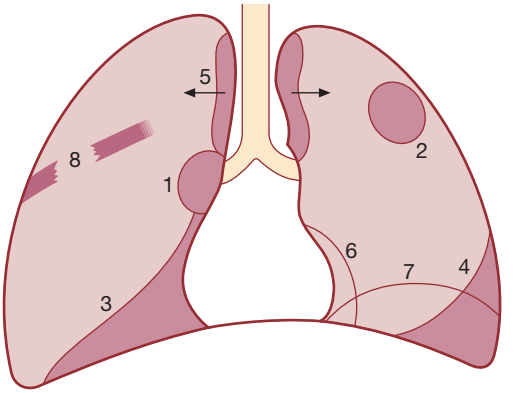

Fig. 19.49 Common radiological presentations of bronchial carcinoma. See Box 19.73 for details.

19.73 Common radiological presentations of bronchial carcinoma

1 Unilateral hilar enlargement

- Central tumour. Hilar glandular involvement. However, a peripheral tumour in the apical segment of a lower lobe can look like an enlarged hilar shadow on the PA X-ray

2 Peripheral pulmonary opacity (p. 660)

- Usually irregular but well circumscribed, and may contain irregular cavitation. Can be very large

3 Lung, lobe or segmental collapse

- Usually caused by tumour within the bronchus, leading to occlusion. Lung collapse may be due to compression of the main bronchus by enlarged lymph glands

4 Pleural effusion

- Usually indicates tumour invasion of pleural space; very rarely, a manifestation of infection in collapsed lung tissue distal to a bronchial carcinoma

5–7 Broadening of mediastinum, enlarged cardiac shadow, elevation of a hemidiaphragm

- Paratracheal lymphadenopathy may cause widening of the upper mediastinum. A malignant pericardial effusion will cause enlargement of the cardiac shadow. If a raised hemidiaphragm is caused by phrenic nerve palsy, screening will show it to move paradoxically upwards when patient sniffs

8 Rib destruction

- Direct invasion of the chest wall or blood-borne metastatic spread can cause osteolytic lesions of the ribs

Staging to guide treatment

The propensity of small-cell lung cancer to metastasise early dictates that patients with this are usually not suitable for surgical intervention. In patients with non-small-cell cancer, appropriate treatment and prognosis are determined by disease extent, so careful staging is required. CT scanning is used early to detect obvious local or distant spread. Enlarged upper mediastinal nodes may be sampled using a bronchoscope equipped with endobronchial ultrasound (EBUS) or by mediastinoscopy. Nodes in the lower mediastinum can be

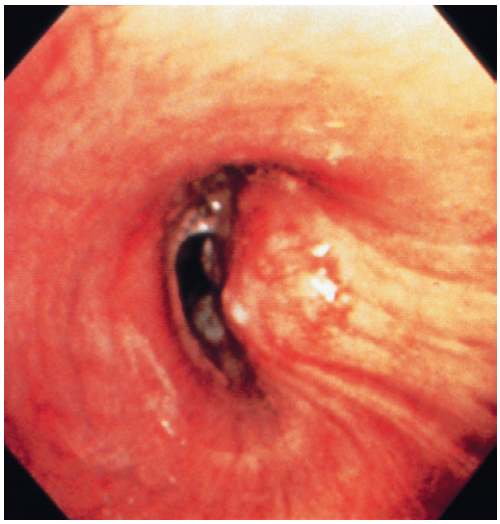

Fig. 19.50 Bronchoscopic view of a bronchogenic carcinoma. There is distortion of mucosal folds, partial occlusion of the airway lumen and abnormal tumour tissue.

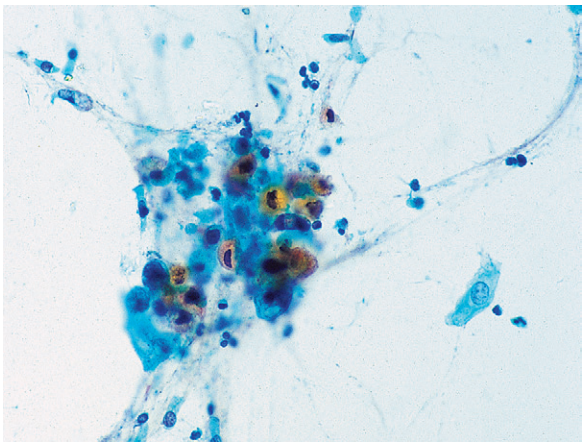

Fig. 19.51 Sputum sample showing a cluster of carcinoma cells. There is keratinisation, with orangeophilia of the cytoplasm. Non-keratinised forms are also seen. The nuclei are large and 'coal-black' in density. These features suggest squamous cell bronchogenic carcinoma.

sampled through the oesophageal wall using endoscopic ultrasound. Combined CT and PET imaging (see Fig. 19.6, p. 651) is used increasingly to detect metabolically active tumour metastases. Head CT, radionuclide bone scanning, liver ultrasound and bone marrow biopsy are generally reserved for patients with clinical, haematological or biochemical evidence of tumour spread to these sites. Information on tumour size and nodal and metastatic spread is then collated to assign the patient to one of seven staging groups that determine optimal management and prognosis (Fig. 19.52). Detailed physiological testing is required to assess whether the patient's respiratory and cardiac function is sufficient to allow aggressive treatment.

Management

Surgical resection carries the best hope of long-term survival, but some patients treated with radical radiotherapy and chemotherapy also achieve prolonged remission or cure. Unfortunately, in over 75% of cases, treatment with the aim of cure is not possible, or is inappropriate due to extensive spread or comorbidity. Such patients are offered palliative therapy and best supportive care. Radiotherapy and in some cases chemotherapy can relieve distressing symptoms.

Surgical treatment

Accurate pre-operative staging, coupled with improvements in surgical and post-operative care, now offers 5-year survival rates of over 75% in stage I disease (N0, tumour confined within visceral pleura) and 55% in stage II disease, which includes resection in patients with ipsilateral peribronchial or hilar node involvement.

Radiotherapy

While much less effective than surgery, radical radiotherapy can offer long-term survival in selected patients with localised disease in whom comorbidity precludes surgery. Radical radiotherapy is usually combined with chemotherapy when lymph nodes are involved (stage III). Highly targeted (stereotactic) radiotherapy may be given in 3–5 treatments for small lesions.

The greatest value of radiotherapy, however, is in the palliation of distressing complications, such as superior

Tumour stage	Lymph node spread			
	N0 (None)	N1 (Ipsilateral hilar)	N2 (Ipsilateral mediastinal or subcarinal)	N3 (Contralateral or supraclavicular)
T1 (<3 cm)	Ia (50%)	IIa (36%)	IIIa (19%)	IIIb (7%)
T2a (3–5 cm)	Ib (43%)			
T2b (5–7 cm)	IIa (36%)	IIb (25%)		
T3 (>7 cm)	IIb (25%)	IIIa (19%)		
T4 (Invading heart, vessels, oesophagus, carina etc.)	IIIa (19%)		IIIb (7%)	
M1 Metastases present	IV (2%)			

Fig. 19.52 Tumour stage and 5-year survival in non-small cell lung cancer. The figure shows the relationship between tumour extent (size, lymph node status and metastases) and average prognosis (% survival at 5 years for each clinical stage). Adapted from Detterbeck 2009 - see p. 732.

vena cava obstruction, recurrent haemoptysis, and pain caused by chest wall invasion or by skeletal metastatic deposits. Obstruction of the trachea and main bronchi can also be relieved temporarily. Radiotherapy can be used in conjunction with chemotherapy in the treatment of small-cell carcinoma, and is particularly efficient at preventing the development of brain metastases in patients who have had a complete response to chemotherapy (p. 277).

Chemotherapy

The treatment of small-cell carcinoma with combinations of cytotoxic drugs, sometimes in combination with radiotherapy, can increase the median survival from 3 months to well over a year. The use of combinations of chemotherapeutic drugs requires considerable skill and should be overseen by teams of clinical oncologists and specialist nurses. Combination chemotherapy leads to better outcomes than single-agent treatment. Regular cycles of therapy, including combinations of intravenous cyclophosphamide, doxorubicin and vincristine or intravenous cisplatin and etoposide, are commonly used. In general, chemotherapy is less effective in non-small-cell bronchial cancers. However, studies in such patients using platinum-based chemotherapy regimens have shown a 30% response rate associated with a small increase in survival. Some non-small-cell lung tumours, particularly adenocarcinomas, carry detectable mutations in the epidermal growth factor receptor (*EGFR*) gene. Patients with these mutations are particularly responsive to the tyrosine kinase inhibitors gefitinib and erlotinib.

In non-small-cell carcinoma, there is some evidence that chemotherapy given before surgery may increase survival and can effectively 'down-stage' disease with limited nodal spread. Post-operative chemotherapy is now proven to enhance survival rates when operative samples show nodal involvement by tumour.

Nausea and vomiting are common side-effects of chemotherapy and are best treated with 5-HT_3 receptor antagonists (p. 289).

Laser therapy and stenting

Palliation of symptoms caused by major airway obstruction can be achieved in selected patients using bronchoscopic laser treatment to clear tumour tissue and allow re-aeration of collapsed lung. The best results are achieved in tumours of the main bronchi. Endobronchial stents can be used to maintain airway patency in the face of extrinsic compression by malignant nodes.

General aspects of management

The best outcomes are obtained when lung cancer is managed in specialist centres by multidisciplinary teams, including oncologists, thoracic surgeons, respiratory physicians and specialist nurses. Effective communication, pain relief and attention to diet are important. Lung tumours can cause clinically significant depression and anxiety, and these may need specific therapy. The management of non-metastatic endocrine manifestations is described in Chapter 20. When a malignant pleural effusion is present, an attempt should be made to drain the pleural cavity using an intercostal drain; provided the lung fully re-expands, pleurodesis with a sclerosing agent such as talc should be performed to prevent recurrent effusion.

Prognosis

The overall prognosis in bronchial carcinoma is very poor, with around 70% of patients dying within a year of diagnosis and only 6–8% of patients surviving 5 years after diagnosis. The best prognosis is with well-differentiated squamous cell tumours that have not metastasised and are amenable to surgical resection. The clinical features and prognosis of some less common benign and malignant lung tumours are given in Box 19.74.

Secondary tumours of the lung

Blood-borne metastatic deposits in the lungs may be derived from many primary tumours, in particular those of the breast, kidney, uterus, ovary, testes and thyroid. The secondary deposits are usually multiple and bilateral. Often there are no respiratory symptoms and the diagnosis is made on radiological examination. Breathlessness may occur if a considerable amount of lung tissue has been replaced by metastatic tumour.

19.74 Rare types of lung tumour

Tumour	Status	Histology	Typical presentation	Prognosis
Adenosquamous carcinoma	Malignant	Tumours with areas of unequivocal squamous and adeno-differentiation	Peripheral or central lung mass	Stage-dependent
Neuro-endocrine (carcinoid) tumour (p. 784)	Low-grade malignant	Neuroendocrine differentiation	Bronchial obstruction, cough	95% 5-yr survival with resection
Bronchial gland adenoma	Benign	Salivary gland differentiation	Tracheobronchial irritation/obstruction	Local resection curative
Bronchial gland carcinoma	Low-grade malignant	Salivary gland differentiation	Tracheobronchial irritation/obstruction	Local recurrence occurs
Hamartoma	Benign	Mesenchymal cells, cartilage	Peripheral lung nodule	Local resection curative
Bronchoalveolar carcinoma	Malignant	Tumour cells line alveolar spaces	Alveolar shadowing, productive cough	Variable, worse if multifocal

Endobronchial deposits are uncommon but can cause haemoptysis and lobar collapse.

Lymphatic infiltration may develop in patients with carcinoma of the breast, stomach, bowel, pancreas or bronchus. 'Lymphangitic carcinomatosis' causes severe and rapidly progressive breathlessness associated with marked hypoxaemia. The chest X-ray shows diffuse pulmonary shadowing radiating from the hilar regions, often associated with septal lines, and CT demonstrates characteristic polygonal thickened interlobular septa. Palliation of breathlessness with opiates may help (p. 289).

Tumours of the mediastinum

Figure 19.53 shows the four major compartments of the mediastinum, and Box 19.75 lists likely causes of a mediastinal mass in each location.

Benign tumours and cysts in the mediastinum are often diagnosed when a chest X-ray is undertaken for some other reason. In general, they do not invade vital structures but may cause symptoms by compressing the trachea or the superior vena cava. A dermoid cyst may very occasionally rupture into a bronchus.

Malignant mediastinal tumours are distinguished by their power to invade as well as compress surrounding structures. As a result, even a small malignant tumour can produce symptoms, although more commonly the tumour has attained a considerable size before this happens (Box 19.76). The most common cause is mediastinal lymph node metastases from bronchogenic carcinoma, but lymphomas, leukaemia, malignant thymic tumours and germ-cell tumours can cause similar features. Aortic and innominate aneurysms have destructive features resembling those of malignant mediastinal tumours.

19.75 Causes of a mediastinal mass

Superior mediastinum	
• Retrosternal goitre • Persistent left superior vena cava • Prominent left subclavian artery	• Thymic tumour • Dermoid cyst • Lymphoma • Aortic aneurysm
Anterior mediastinum	
• Retrosternal goitre • Dermoid cyst • Thymic tumour • Lymphoma • Aortic aneurysm	• Germ cell tumour • Pericardial cyst • Hiatus hernia through the diaphragmatic foramen of Morgagni
Posterior mediastinum	
• Neurogenic tumour • Paravertebral abscess • Oesophageal lesion	• Aortic aneurysm • Foregut duplication
Middle mediastinum	
• Bronchial carcinoma • Lymphoma • Sarcoidosis	• Bronchogenic cyst • Hiatus hernia

19.76 Clinical features of malignant mediastinal invasion

Trachea and main bronchi
• Stridor, breathlessness, cough, pulmonary collapse
Oesophagus
• Dysphagia, oesophageal displacement or obstruction on barium swallow examination
Phrenic nerve
• Diaphragmatic paralysis
Left recurrent laryngeal nerve
• Paralysis of left vocal cord with hoarseness and 'bovine' cough
Sympathetic trunk
• Horner's syndrome
Superior vena cava
• SVC obstruction: non-pulsatile distension of neck veins, subconjunctival oedema, and oedema and cyanosis of head, neck, hands and arms. Dilated anastomotic veins on chest wall
Pericardium
• Pericarditis and/or pericardial effusion

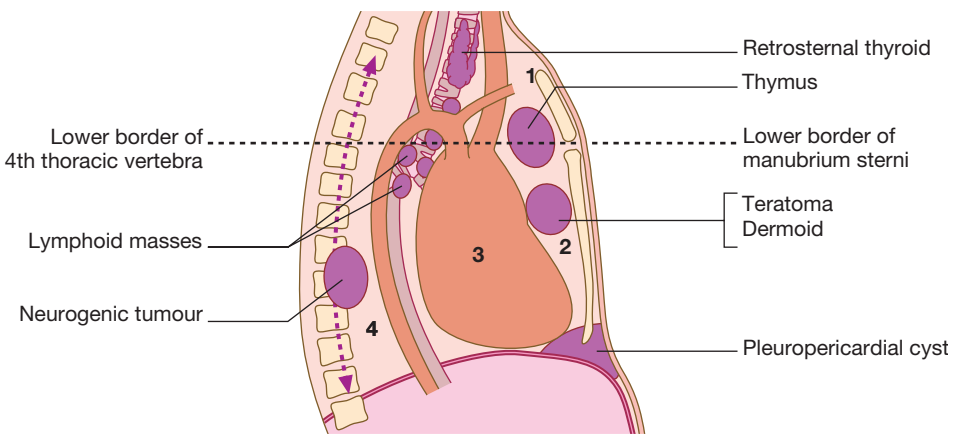

Fig. 19.53 The divisions of the mediastinum. (1) Superior mediastinum. (2) Anterior mediastinum. (3) Middle mediastinum. (4) Posterior mediastinum. Sites of the more common mediastinal tumours are also illustrated. From Johnson 1986 – see p. 732.

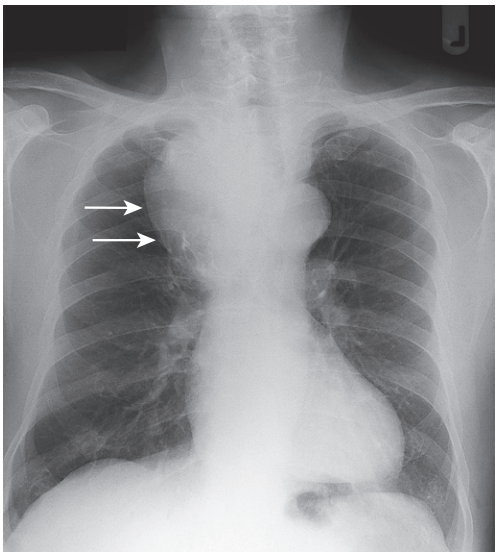

Fig. 19.54 Intrathoracic goitre (arrows) extending from right upper mediastinum.

Investigations

A benign mediastinal tumour generally appears on chest X-ray as a sharply circumscribed mediastinal opacity encroaching on one or both lung fields (Fig. 19.54). CT (or MRI) is the investigation of choice for mediastinal tumours (e.g. see Fig. 20.11B, p. 753). A malignant mediastinal tumour seldom has a clearly defined margin and often presents as a general broadening of the mediastinum.

Bronchoscopy may reveal a primary bronchial carcinoma causing mediastinal lymphadenopathy. Endobronchial ultrasound may be used to guide sampling of peribronchial masses. The posterior mediastinum can be imaged and biopsied via the oesophagus using endoscopic ultrasound (p. 651).

Mediastinoscopy under general anaesthetic can be used to visualise and biopsy masses in the superior and anterior mediastinum, but surgical exploration of the chest, with removal of part or all of the tumour, is often required to obtain a histological diagnosis.

Management

Benign mediastinal tumours should be removed surgically because most produce symptoms sooner or later. Cysts may become infected, while neural tumours have the potential to undergo malignant transformation. The operative mortality is low in the absence of coexisting cardiovascular disease, COPD or extreme age.

INTERSTITIAL AND INFILTRATIVE PULMONARY DISEASES

Diffuse parenchymal lung disease

The diffuse parenchymal lung diseases (DPLDs) are a heterogeneous group of conditions affecting the pulmonary parenchyma (interstitium) and/or alveolar lumen, which are frequently considered collectively as they share a sufficient number of clinical physiological and radiographic similarities (Box 19.77). The current classification is shown in Figure 19.55 and the potential differential diagnoses in Box 19.78. They often present with a cough that is typically dry and distressing, and breathlessness that is frequently insidious in onset but thereafter relentlessly progressive. Physical examination reveals the presence of inspiratory crackles and in many cases digital clubbing develops. Pulmonary function tests typically show a restrictive ventilatory defect in the presence of small lung volumes and reduced gas transfer. The typical radiographic findings include ground glass and reticulonodular shadowing in the earliest stages, with progression to honeycomb cysts and traction bronchiectasis. Whilst these appearances may be seen on a 'plain' chest X-ray, they are most easily appreciated on HRCT, which has assumed a central role in the evaluation of DPLD (Fig. 19.56).

19.77 Features common to the diffuse parenchymal lung diseases

Clinical presentation

- Cough: usually dry, persistent and distressing
- Breathlessness: usually slowly progressive; insidious onset; acute in some cases

Examination findings

- Crackles: typically bilateral and basal
- Clubbing: common in idiopathic pulmonary fibrosis but also seen in other types, e.g. asbestosis
- Central cyanosis and signs of right heart failure in advanced disease

Radiology

- Chest X-ray: typically small lung volumes with reticulonodular shadowing but may be normal in early or limited disease
- HRCT: combinations of ground glass changes, reticulonodular shadowing, honeycomb cysts and traction bronchiectasis, depending on stage of disease

Pulmonary function

- Typically restrictive ventilatory defect with reduced lung volumes and impaired gas transfer; exercise tests assess exercise tolerance and exercise-related fall in SaO_2

19.78 Conditions that mimic diffuse parenchymal lung disease

Infection

- Viral pneumonia
- *Pneumocystis jirovecii*
- *Mycoplasma pneumoniae*
- Tuberculosis
- Parasite, e.g. filariasis
- Fungal infection

Malignancy

- Leukaemia and lymphoma
- Lymphatic carcinomatosis
- Multiple metastases
- Bronchoalveolar carcinoma

Pulmonary oedema

Aspiration pneumonitis

Idiopathic interstitial pneumonias

The idiopathic interstitial pneumonias represent a major subgroup of DPLDs that are grouped together because

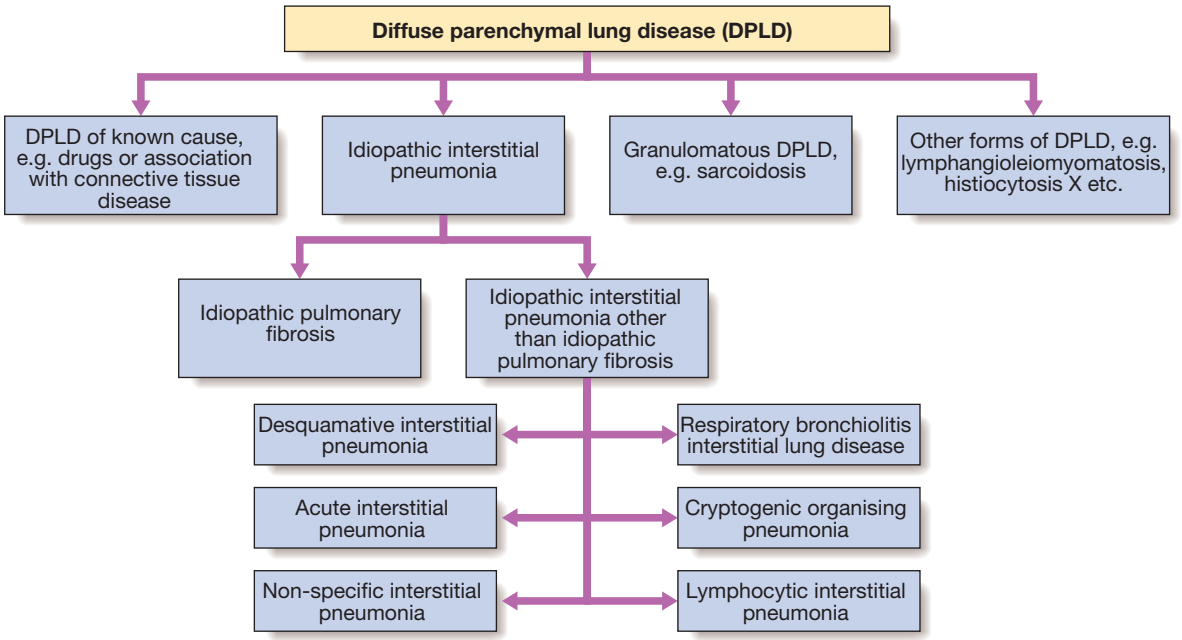

Fig. 19.55 Classification of diffuse parenchymal lung disease.

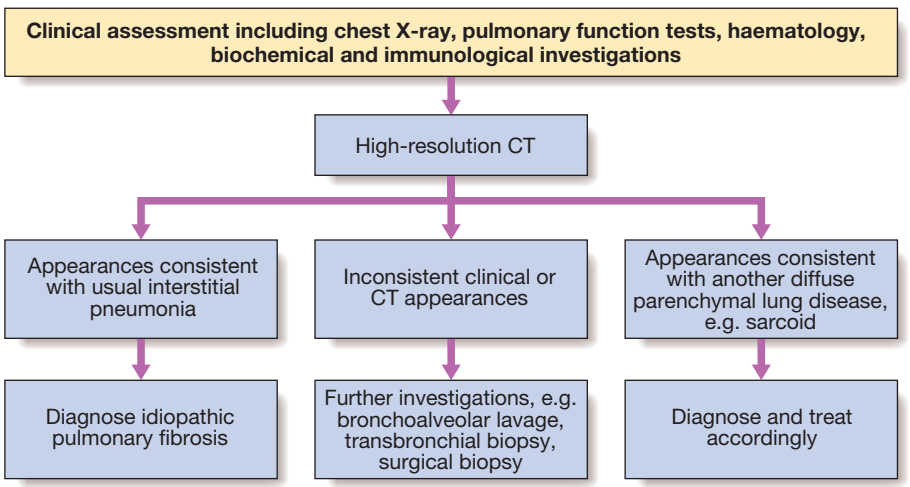

Fig. 19.56 Algorithm for the investigation of patients with interstitial lung disease following initial clinical and chest X-ray examination.

of their unknown aetiology (Box 19.79). They are often distinguished by the predominant histological pattern on tissue biopsy; hence they are frequently referred to by their pathological description – for example, usual interstitial pneumonia or non-specific interstitial pneumonia. The most important of these is idiopathic pulmonary fibrosis.

Idiopathic pulmonary fibrosis

Idiopathic pulmonary fibrosis (IPF) is defined as a progressive fibrosing interstitial pneumonia of unknown cause, occurring in adults and associated with the histological or radiological pattern of usual interstitial pneumonia (UIP). Important differentials include fibrosing diseases caused by occupational exposure, medication or connective tissue diseases, which must be excluded by careful history, examination and investigation.

The histological features of the condition are suggestive of repeated episodes of focal damage to the alveolar epithelium consistent with an autoimmune process but the aetiology remains elusive; speculation has included exposure to viruses (e.g. Epstein–Barr virus), occupational dusts (metal or wood), drugs (antidepressants) or chronic gastro-oesophageal reflux. Familial cases are rare but genetic factors that control the inflammatory and fibrotic response are likely to be important. There is a strong association with cigarette smoking.

Clinical features

IPF usually presents in the older adult and is uncommon before the age of 50 years. With the advent of

19.79 Idiopathic interstitial pneumonias

Clinical diagnosis	Notes
Usual interstitial pneumonia (UIP)	Idiopathic pulmonary fibrosis – see text
Non-specific interstitial pneumonia (NSIP)	See page 709
Respiratory bronchiolitis–interstitial lung disease	More common in men and smokers. Usually presents at age 40–60 yrs. Smoking cessation may lead to improvement. Natural history unclear
Acute interstitial pneumonia	Often preceded by viral upper respiratory tract infection. Severe exertional dyspnoea, widespread pneumonic consolidation and diffuse alveolar damage on biopsy. Prognosis often poor
Desquamative interstitial pneumonia (DIP)	More common in men and smokers. Presents at age 40–60 yrs. Insidious onset of dyspnoea. Clubbing in 50%. Biopsy shows increased macrophages in alveolar space, septal thickening and type II pneumocyte hyperplasia. Prognosis generally good
Cryptogenic organising pneumonia ('bronchiolitis obliterans organising pneumonia' – BOOP)	Presents as clinical and radiological pneumonia. Systemic features and markedly raised ESR common. Finger clubbing absent. Biopsy shows florid proliferation of immature collagen (Masson bodies) and fibrous tissue. Response to corticosteroids classically excellent
Lymphocytic interstitial pneumonia (LIP)	More common in women, slow onset over years. Investigate for associations with connective tissue disease or HIV. Unclear whether corticosteroids helpful

widespread CT scanning, it may present as an incidental finding in an otherwise asymptomatic individual but more typically presents with progressive breathlessness (which may have been insidious) and a non-productive cough. Constitutional symptoms are unusual. Clinical findings include finger clubbing and the presence of bi-basal fine late inspiratory crackles likened to the unfastening of Velcro.

Investigations

These are summarised in Box 19.80. Established IPF will be apparent on chest X-ray as bilateral lower lobe and subpleural reticular shadowing. However, the chest X-ray may be normal in individuals with early or limited disease. HRCT typically demonstrates a patchy, predominantly peripheral, subpleural and basal reticular pattern and, in more advanced disease, the presence of honeycombing cysts and traction bronchiectasis (Fig. 19.57). When these features are present, HRCT has a high positive predictive value for the diagnosis of IPF and recourse to biopsy is seldom necessary. HRCT appearances may also be sufficiently characteristic to suggest an alternative diagnosis such as hypersensitivity pneumonitis (p. 719) or sarcoidosis (p. 709). The presence of pleural plaques may suggest asbestosis (p. 718).

Pulmonary function tests classically show a restrictive defect with reduced lung volumes and gas transfer. However, lung volumes may be preserved in patients with concomitant emphysema. Dynamic tests are useful to document exercise tolerance and demonstrate exercise-induced arterial hypoxaemia, but as IPF advances, arterial hypoxaemia and hypocapnia are present at rest.

Bronchoscopy is seldom necessary unless there is a significant possibility of infection or a malignant process; lymphocytosis may suggest chronic hypersensitivity pneumonitis. The tissue samples obtained by transbronchial lung biopsy are invariably insufficient to be of value and, if tissue is required, a surgical lung biopsy should be performed. Lung biopsy should be considered in cases of diagnostic uncertainty or with atypical features. UIP is the histological pattern predominantly encountered in IPF (Fig. 19.58). However, it is also found in asbestosis, hypersensitivity pneumonitis, connective tissue diseases and drug reactions.

It is not uncommon to identify mildly positive antinuclear antibodies or anti-cyclic citrullinated peptide (anti-CCP), in which case repeat serological testing should be performed, as lung disease may precede the appearance of connective tissue disease.

19.80 Investigations in diffuse parenchymal lung disease

Laboratory investigations

- Full blood count: lymphopenia in sarcoid; eosinophilia in pulmonary eosinophilias and drug reactions; neutrophilia in hypersensitivity pneumonitis
- Ca^{2+}: may be elevated in sarcoid
- Lactate dehydrogenase: may be elevated in active alveolitis
- Serum angiotensin-converting enzyme: non-specific indicator of disease activity in sarcoid
- ESR and CRP: non-specifically raised
- Autoimmune screen: anti-cyclic citrullinated peptide (anti-CCP) and other autoantibodies may suggest connective tissue disease

Radiology (see Box 19.77)

Pulmonary function (see Box 19.77)

Bronchoscopy

- Bronchoalveolar lavage: differential cell counts may point to sarcoid and drug-induced pneumonitis, pulmonary eosinophilias, hypersensitivity pneumonitis or cryptogenic organising pneumonia; useful to exclude infection
- Transbronchial biopsy: useful in sarcoid and differential of malignancy or infection
- Bronchial biopsy: occasionally useful in sarcoid

Video-assisted thorascopic lung biopsy (in selected cases)

- Allows pathological classification: presence of asbestos bodies may suggest asbestosis, silica in occupational fibrosing lung disease

Others

- Liver biopsy: may be useful in sarcoidosis
- Urinary calcium excretion: may be useful in sarcoidosis

Management and prognosis

Treatment is difficult. Although the combination of prednisolone, azathioprine and N-acetylcysteine had shown some promise, large studies suggest that it is mostly ineffective. Disappointing results have also been reported for trials of colchicine, interferon-γ1b, bosentan and etanercept. Subject to further investigation, pirfenidone may slow the rate of decline of lung function and, by inference, improve mortality. It remains sensible to treat gastro-oesophageal reflux and to look for and treat pulmonary hypertension but, where possible, treatment with experimental agents outside clinical trials should not be tried. Where appropriate, lung transplantation should be considered. Oxygen may help breathlessness but opiates may be required to relieve severe dyspnoea. The optimum treatment for acute exacerbations is unknown but corticosteroids should probably be used.

The natural history is usually one of steady decline but some patients are prone to exacerbations, which are accompanied by an acute deterioration in breathlessness, disturbed gas exchange, and new ground glass changes or consolidation on HRCT. In advanced disease, central cyanosis is detectable and patients may develop features of right heart failure. A median survival of 3 years is widely quoted; however, the rate of disease progression varies considerably, from death within a few months to survival with minimal symptoms for many years. Serial lung function testing may provide useful prognostic information, with relative preservation of lung function suggesting longer survival, and significantly impaired gas transfer and/or desaturation on exercise heralding a poorer prognosis. The finding of high numbers of fibroblastic foci on biopsy suggests a more rapid deterioration. IPF is associated with an increased risk of carcinoma of the lung.

Fig. 19.57 Idiopathic pulmonary fibrosis. A Chest X-ray showing bilateral, predominantly lower-zone and peripheral coarse reticulonodular shadowing and small lungs. B The CT scan shows honeycombing and scarring which is most marked peripherally.

Non-specific interstitial pneumonia

The clinical picture of fibrotic non-specific interstitial pneumonia (NSIP) is similar to that of IPF, although patients tend to be women and younger in age. As with UIP, the condition may present as an isolated idiopathic pulmonary condition, but an NSIP pattern is often associated with connective tissue disease, certain drugs, chronic hypersensitivity pneumonitis and HIV infection; care must be taken to identify these possibilities, as the pulmonary condition may precede the appearance of connective tissue disease. HRCT findings are less specific than with IPF and lung biopsy may be required. The prognosis is significantly better than that of IPF, particularly in the cellular form of the condition, and the 5-year mortality rate is typically less than 15%.

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder of unknown aetiology characterised by the presence of non-caseating granulomas (Fig. 19.59). It is more often described in colder parts of northern Europe. It also appears to be more common and more severe in those

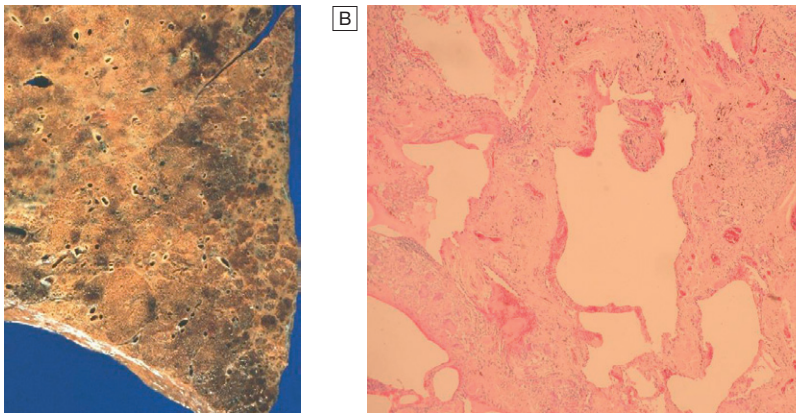

Fig. 19.58 Pathology of usual interstitial pneumonia. A Lung tissue showing subpleural scarring, most prominently down the posterior edge of the lower lobe. This distribution of fibrosis is typical of usual interstitial pneumonitis. The fibrosis may be associated with prominent cystic change known as 'honeycomb lung'. B Histology showing severe interstitial fibrosis with loss of the normal alveolar architecture and the development of 'honeycomb' cysts.

from a West Indian or Asian background, while Eskimos, Arabs and Chinese are rarely affected. The tendency for sarcoid to present in spring and summer has led to speculation about the role of infective agents, including mycobacteria, propionibacteria and viruses, but the cause remains elusive. Genetic susceptibility is supported by familial clustering; a range of class II HLA alleles confer protection from or susceptibility to the condition. Sarcoidosis occurs less frequently in smokers.

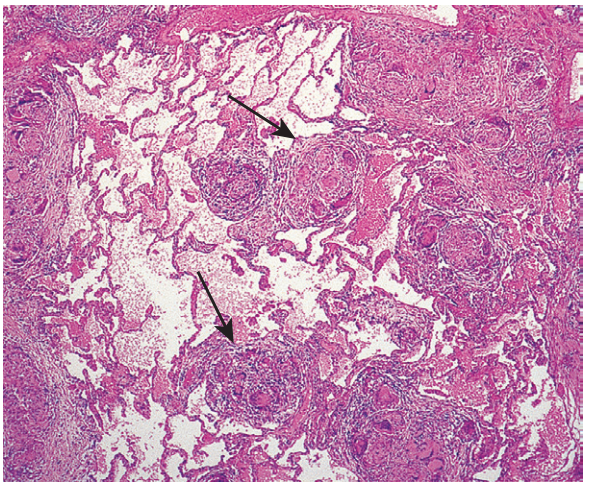

Fig. 19.59 Sarcoidosis of the lung. Histology showing non-caseating granulomas (arrows).

Clinical features

Sarcoidosis is considered with other DPLDs, as over 90% of cases affect the lungs, but the condition can involve almost any organ (Fig. 19.60 and Box 19.81). Löfgren's syndrome – an acute illness characterised by erythema nodosum, peripheral arthropathy, uveitis, bilateral hilar lymphadenopathy (BHL), lethargy and occasionally fever – is often seen in young women. Alternatively, BHL may be detected in an otherwise asymptomatic individual undergoing a chest X-ray for other purposes.

19.81 Presentation of sarcoidosis

- Asymptomatic: abnormal routine chest X-ray (~30%) or abnormal liver function tests
- Respiratory and constitutional symptoms (20–30%)
- Erythema nodosum and arthralgia (20–30%)
- Ocular symptoms (5–10%)
- Skin sarcoid (including lupus pernio) (5%)
- Superficial lymphadenopathy (5%)
- Other (1%), e.g. hypercalcaemia, diabetes insipidus, cranial nerve palsies, cardiac arrhythmias, nephrocalcinosis

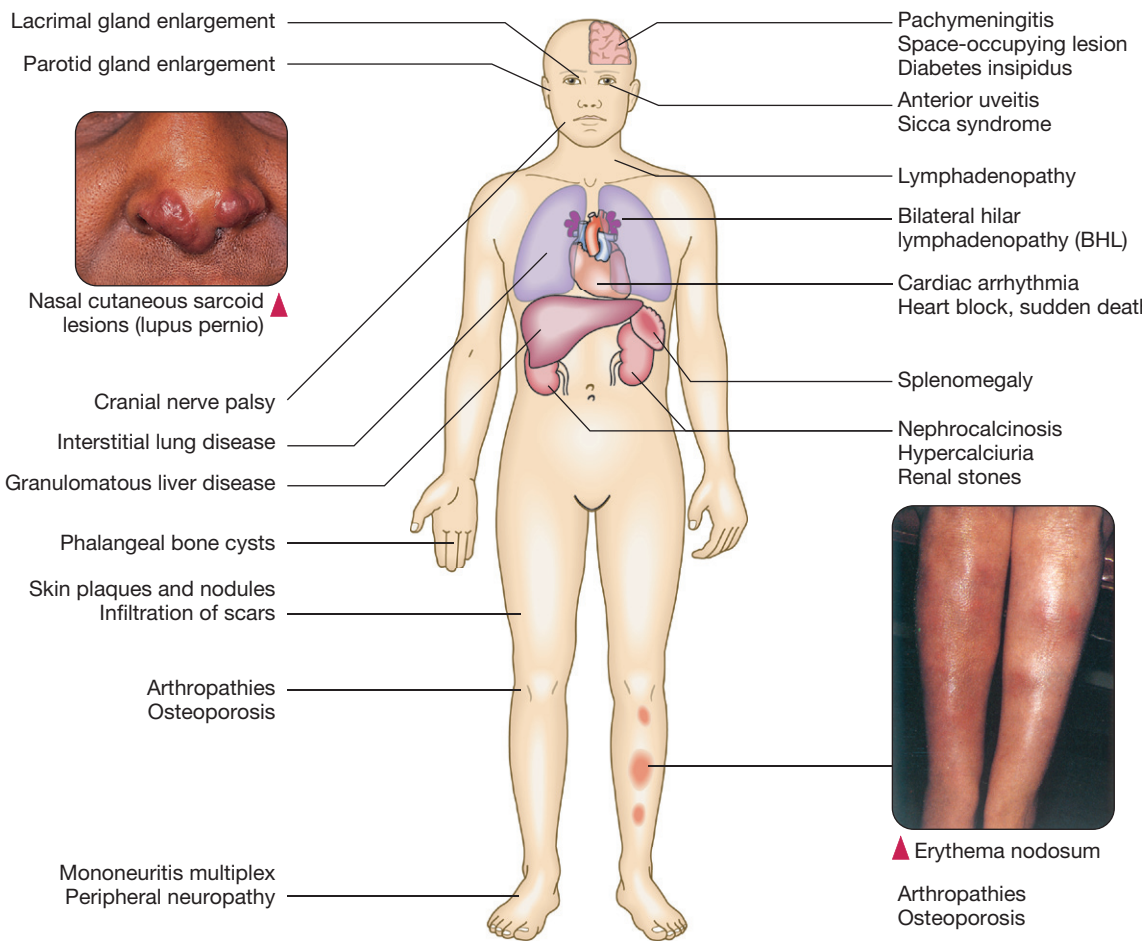

Fig. 19.60 Possible systemic involvement in sarcoidosis. *Inset (Erythema nodosum)* From Savin et al. 1997 – see p. 732.

Pulmonary disease may also present in a more insidious manner with cough, exertional breathlessness and radiographic infiltrates; chest auscultation is often unremarkable. Fibrosis occurs in 20% of cases of pulmonary sarcoidosis and may cause a silent loss of lung function. Pleural disease is uncommon and finger clubbing not a feature. Complications such as bronchiectasis, aspergilloma, pneumothorax, pulmonary hypertension and cor pulmonale have been reported but are rare.

Investigations

Lymphopenia is characteristic and liver function tests may be mildly deranged. Hypercalcaemia may be present (reflecting increased formation of calcitrol – 1,25-dihydroxyvitamin D_3 – by alveolar macrophages), particularly if the patient has been exposed to strong sunlight. Hypercalciuria may also be seen and may lead to nephrocalcinosis. Serum ACE may provide a non-specific marker of disease activity and can assist in monitoring the clinical course. Chest radiography has been used to stage sarcoid (Box 19.82). In patients with pulmonary infiltrates, pulmonary function testing may show a restrictive defect accompanied by impaired gas exchange. Exercise tests may reveal oxygen desaturation. Bronchoscopy may demonstrate a 'cobblestone' appearance of the mucosa, and bronchial and transbronchial biopsy usually shows non-caseating granulomas. The BAL fluid typically contains an increased CD4:CD8 T-cell ratio. Characteristic HRCT appearances include reticulonodular opacities that follow a perilymphatic distribution, centred on bronchovascular bundles and the subpleural areas.

The occurrence of erythema nodosum with BHL on chest X-ray is often sufficient for a confident diagnosis, without recourse to a tissue biopsy. Similarly, a typical presentation with classical HRCT features may also be accepted. Otherwise, the diagnosis should be confirmed by histological examination of the involved organ. The presence of anergy (e.g. to tuberculin skin tests) may support the diagnosis.

Management

Patients who present with acute illness and erythema nodosum are treated with NSAIDs and, if disease is severe, a short course of corticosteroids. The majority of patients enjoy spontaneous remission and so, if there is no evidence of organ damage, systemic corticosteroid therapy can be withheld for 6 months. However, prednisolone (at a starting dose of 20–40 mg/day) should be commenced immediately in the presence of hypercalcaemia, pulmonary impairment, renal impairment and uveitis (Box 19.83). Topical steroids may be useful in cases of mild uveitis, and inhaled corticosteroids have been used to shorten the duration of systemic corticosteroid use in asymptomatic parenchymal sarcoid. Patients should be warned that strong sunlight might precipitate hypercalcaemia and endanger renal function.

Features suggesting a less favourable outlook include age over 40 years, Afro-Caribbean ethnicity, persistent symptoms for more than 6 months, the involvement of more than three organs, lupus pernio and a stage III/IV chest X-ray. In patients with severe disease, methotrexate (10–20 mg/week), azathioprine (50–150 mg/day) and the use of specific tumour necrosis factor (TNF)-α inhibitors (p. 1102) have been effective. Chloroquine, hydroxychloroquine and low-dose thalidomide may be useful in cutaneous sarcoid with limited pulmonary involvement. Selected patients may be referred for consideration of single lung transplantation. The overall mortality is low (1–5%) and usually reflects cardiac involvement or pulmonary fibrosis.

19.82 Chest X-ray changes in sarcoidosis

Stage I: BHL (usually symmetrical); paratracheal nodes often enlarged
• Often asymptomatic, but may be associated with erythema nodosum and arthralgia. The majority of cases resolve spontaneously within 1 yr
Stage II: BHL and parenchymal infiltrates
• Patients may present with breathlessness or cough. The majority of cases resolve spontaneously
Stage III: parenchymal infiltrates without BHL
• Disease less likely to resolve spontaneously
Stage IV: pulmonary fibrosis
• Can cause progression to ventilatory failure, pulmonary hypertension and cor pulmonale
(BHL = bilateral hilar lymphadenopathy)

EBM 19.83 Systemic corticosteroids in pulmonary sarcoidosis

'Oral glucocorticoids administered for 6–24 months improve chest X-ray appearances and symptoms, but there is little evidence of an improvement in lung function and there are no data from follow-up beyond 2 years.'

- Paramothayan NS, et al. Corticosteroids for pulmonary sarcoidosis. Cochrane Database of Systematic Reviews, 2005, issue 2. Art. no.: CD001114.

Lung diseases due to systemic inflammatory disease

Acute respiratory distress syndrome

See page 192.

Respiratory involvement in connective tissue disorders

Pulmonary complications of connective tissue disease are common, and affect the airways, alveoli, pulmonary vasculature, diaphragm and chest wall muscles, and chest wall itself (Box 19.84). In some instances, pulmonary disease may precede the appearance of the connective tissue disorder. Indirect associations between connective tissue disorders and respiratory complications include those due to disease in other organs, e.g. thrombocytopenia causing haemoptysis; pulmonary toxic effects of drugs used to treat the connective tissue disorder, e.g. gold and methotrexate; and secondary infection due to the disease itself, neutropenia or immunosuppressive drug regimens.

19.84 Respiratory complications of connective tissue disorders

Disorder	Airways	Parenchyma	Pleura	Diaphragm and chest wall
Rheumatoid arthritis	Bronchitis, obliterative bronchiolitis, bronchiectasis, crico-arytenoid arthritis, stridor	Pulmonary fibrosis, nodules, upper lobe fibrosis, infections	Pleurisy, effusion, pneumothorax	Poor healing of intercostal drain sites
Systemic lupus erythematosus	–	Pulmonary fibrosis, 'vasculitic' infarcts	Pleurisy, effusion	Diaphragmatic weakness (shrinking lungs)
Systemic sclerosis	Bronchiectasis	Pulmonary fibrosis, aspiration pneumonia	–	Cutaneous thoracic restriction (hidebound chest)
Dermatomyositis/ polymyositis	Bronchial carcinoma	Pulmonary fibrosis	–	Intercostal and diaphragmatic myopathy
Rheumatic fever	–	Pneumonia	Pleurisy, effusion	–

Rheumatoid disease

Pulmonary involvement in rheumatoid arthritis is important, accounting for around 10–20% of the mortality associated with the condition (p. 1096). The majority of cases occur within 5 years of the rheumatological diagnosis but pulmonary manifestations may precede joint involvement in 10–20%. Pulmonary fibrosis is the most common pulmonary manifestation. All forms of interstitial disease have been described but NSIP is probably the most frequent. A rare variant of localised upper lobe fibrosis and cavitation is occasionally seen.

Pleural effusion is common, especially in men with seropositive disease. Effusions are usually small and unilateral but can be large and bilateral. Most resolve spontaneously. Biochemical testing shows an exudate with markedly reduced glucose levels and raised LDH. Effusions that fail to resolve spontaneously may respond to a short course of oral prednisolone (30–40 mg daily) but some become chronic.

Rheumatoid pulmonary nodules are usually asymptomatic and detected incidentally on imaging. They are usually multiple and subpleural in site (Fig. 19.61). Solitary nodules can mimic primary bronchial carcinoma and, when they are multiple, the differential diagnoses include pulmonary metastatic disease. Cavitation raises the possibility of tuberculosis and predisposes to pneumothorax. The combination of rheumatoid nodules and pneumoconiosis is known as Caplan's syndrome (p. 717).

Bronchitis and bronchiectasis are both more common in rheumatoid patients. Rarely, the potentially fatal condition called obliterative bronchiolitis may develop. Bacterial lower respiratory tract infections are frequent. Treatments given for rheumatoid arthritis may also be relevant: corticosteroid therapy predisposes to infections, methotrexate may cause pulmonary fibrosis, and anti-TNF therapy has been associated with the reactivation of tuberculosis.

Systemic lupus erythematosus

Pleuropulmonary involvement is more common in lupus than in any other connective tissue disorder and may be a presenting problem, in which case it is sometimes attributed incorrectly to infection or pulmonary embolism. Up to two-thirds of patients have repeated episodes of pleurisy, with or without effusions. Effusions may be bilateral and may also involve the pericardium.

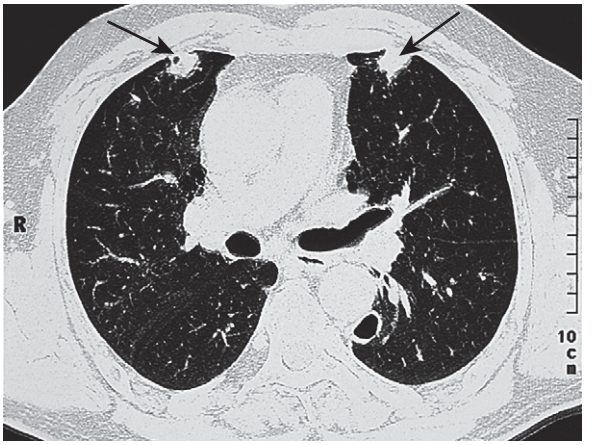

Fig. 19.61 Rheumatoid (necrobiotic) nodules. Thoracic CT just below the level of the main carina showing the typical appearance of peripheral pleural-based nodules. The nodule in the left lower lobe shows characteristic cavitation.

The most serious manifestation of lupus is an acute alveolitis, which may be associated with diffuse alveolar haemorrhage. This condition is life-threatening and requires immunosuppression.

Pulmonary fibrosis is a relatively uncommon manifestation of systemic lupus erythematosus (SLE). Some patients with SLE present with exertional dyspnoea and orthopnoea but without overt signs of pulmonary fibrosis. The chest X-ray reveals elevated diaphragms, and pulmonary function testing shows reduced lung volumes. This condition has been described as 'shrinking lungs' and has been attributed to diaphragmatic myopathy.

SLE patients with antiphospholipid antibodies are at increased risk of venous and pulmonary thromboembolism and require life-long anticoagulation.

Systemic sclerosis

Most patients with systemic sclerosis (p. 1112) eventually develop diffuse pulmonary fibrosis; at necropsy, more than 90% have evidence of lung fibrosis. In some patients, it is indolent but when progressive, as in IPF, the median survival time is around 4 years. Pulmonary fibrosis is rare in the CREST variant of progressive systemic sclerosis but isolated pulmonary hypertension may develop.

Other pulmonary complications include recurrent aspiration pneumonias secondary to oesophageal disease. Rarely, sclerosis of the skin of the chest wall may be so extensive and cicatrising as to restrict chest wall movement – this constitutes the so-called 'hidebound chest'.

Pulmonary eosinophilia and vasculitides

Pulmonary eosinophilia refers to the association of radiographic (usually pneumonic) abnormalities and peripheral blood eosinophilia. The term encompasses a group of disorders of different aetiology (Box 19.85). Eosinophils are the predominant cell recovered in sputum or BAL, and eosinophil products are likely to be the prime mediators of tissue damage.

Acute eosinophilic pneumonia

Acute eosinophilic pneumonia is an acute febrile illness (of less than 5 days' duration) characterised by diffuse pulmonary infiltrates and hypoxic respiratory failure. The pathology is usually that of diffuse alveolar damage. Diagnosis is confirmed by BAL, which characteristically demonstrates more than 25% eosinophils. The condition is usually idiopathic but drug reactions should be considered. Corticosteroids invariably induce prompt and complete resolution.

19.85 Pulmonary eosinophilia

Extrinsic (cause known)

- Helminths: e.g. *Ascaris*, *Toxocara*, *Filaria*
- Drugs: nitrofurantoin, para-aminosalicylic acid (PAS), sulfasalazine, imipramine, chlorpropamide, phenylbutazone
- Fungi: e.g. *Aspergillus fumigatus* causing allergic bronchopulmonary aspergillosis (p. 697)

Intrinsic (cause unknown)

- Cryptogenic eosinophilic pneumonia
- Churg–Strauss syndrome, diagnosed on the basis of ≥ 4 of the following features:
  - Asthma
  - Peripheral blood eosinophilia > 1.5×10^9/L (or > 10% of a total white cell count)
  - Mononeuropathy or polyneuropathy
  - Pulmonary infiltrates
  - Paranasal sinus disease
  - Eosinophilic vasculitis on biopsy of an affected site
- Hypereosinophilic syndrome
- Polyarteritis nodosa (p. 1117; rare)

Chronic eosinophilic pneumonia

Chronic eosinophilic pneumonia typically presents in an insidious manner with malaise, fever, weight loss, breathlessness and unproductive cough. The condition is more common in middle-aged females. The classical chest X-ray appearance has been likened to the photographic negative of pulmonary oedema with bilateral, peripheral and predominantly upper lobe parenchymal shadowing. The peripheral blood eosinophil count is almost always very high, and the ESR and total serum IgE are elevated. BAL reveals a high proportion of eosinophils in the lavage fluid. Response to prednisolone (20–40 mg daily) is usually dramatic. Prednisolone can usually be withdrawn after a few weeks without relapse, but long-term, low-dose therapy is occasionally necessary.

Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia occurs as a result of a mosquito-borne filarial infection caused by the tissue-dwelling human nematode *Wuchereria bancrofti* or *Brugia malayi*. The condition presents with fever, weight loss, dyspnoea and asthma-like symptoms. There is marked peripheral blood eosinophilia and elevation of total IgE. High antifilarial antibody titres are seen. The diagnosis may be confirmed by a response to treatment with diethylcarbamazine (6 mg/kg/day for 3 weeks). Tropical pulmonary eosinophilia must be distinguished from infection with *Strongyloides stercoralis* (p. 370), as corticosteroids may cause life-threatening dissemination in the latter. Ascariasis ('larva migrans') and other hookworm infestations are described in detail in Chapter 13.

Granulomatosis with polyangiitis

Granulomatosis with polyangiitis (also known as Wegener's granulomatosis) is a rare vasculitic and granulomatous condition (p. 1118). The lung is commonly involved in systemic forms of the condition but a limited pulmonary form may also occur. Respiratory symptoms include cough, haemoptysis and chest pain. Associated upper respiratory tract manifestations include nasal discharge and crusting, and otitis media. Fever, weight loss and anaemia are common. Radiological features include multiple nodules and cavitation that may resemble primary or metastatic carcinoma, or a pulmonary abscess. Tissue biopsy confirms the distinctive pattern of necrotising granulomas and necrotising vasculitis. Other respiratory complications of granulomatosis with polyangiitis include tracheal subglottic stenosis and saddle nose deformity. The differential diagnoses include mycobacterial and fungal infection and other forms of pulmonary vasculitis, including polyarteritis nodosa (pulmonary infarction), microscopic polyangiitis, Churg–Strauss syndrome (in which there is marked tissue eosinophilia and association with asthma), necrotising sarcoid, bronchocentric granulomatosis and lymphomatoid granulomatosis.

Goodpasture's syndrome

This describes the association of pulmonary haemorrhage and glomerulonephritis, in which IgG antibodies

bind to the glomerular or alveolar basement membranes (see Box 17.39, p. 499). Pulmonary disease usually precedes renal involvement and includes radiographic infiltrates and hypoxia with or without haemoptysis. It occurs more commonly in men and almost exclusively in smokers.

Lung diseases due to irradiation and drugs

Radiotherapy

Targeting radiotherapy to certain tumours is inevitably accompanied by irradiation of normal lung tissue. Although delivered in divided doses, the effects are cumulative. Acute radiation pneumonitis is typically seen within 6–12 weeks and presents with cough and dyspnoea. This may resolve spontaneously but responds to corticosteroid treatment. Chronic interstitial fibrosis may present several months later with symptoms of exertional dyspnoea and cough. Changes are often confined to the area irradiated but may be bilateral. Established post-irradiation fibrosis does not usually respond to corticosteroid treatment. The pulmonary effects of radiation (p. 277) are exacerbated by treatment with cytotoxic drugs and the phenomenon of 'recall pneumonitis' describes the appearance of radiation injury in a previously irradiated area, when chemotherapy follows radiotherapy. If the patient survives, there are long-term risks of lung cancer.

Drugs

Drugs may cause a range of pulmonary conditions (Box 19.86). Pulmonary fibrosis may occur in response to a variety of drugs, but is seen most frequently with bleomycin, methotrexate, amiodarone and nitrofurantoin. Eosinophilic pulmonary reactions can also be caused by drugs. The pathogenesis may be an immune reaction similar to that in hypersensitivity pneumonitis, which specifically attracts large numbers of eosinophils into the lungs. This type of reaction is well described as a rare reaction to a variety of antineoplastic agents (e.g. bleomycin), antibiotics (e.g. sulphonamides), sulfasalazine and the anticonvulsants phenytoin and carbamazepine. Patients usually present with breathlessness, cough and fever. The chest X-ray characteristically shows patchy shadowing. Most cases resolve completely on withdrawal of the drug, but if the reaction is severe, rapid resolution can be obtained with corticosteroids.

Drugs may also cause other lung diseases, such as asthma, pulmonary haemorrhage and pleural disease. An ARDS-like syndrome of acute non-cardiogenic pulmonary oedema may present with dramatic onset of breathlessness, severe hypoxaemia and signs of alveolar oedema on the chest X-ray. This syndrome has been reported most frequently in cases of opiate overdose in drug addicts (p. 219) but also after salicylate overdose, and occasionally after therapeutic doses of drugs, including hydrochlorothiazides and some cytotoxic agents.

Rare interstitial lung diseases

See Box 19.88.

19.86 Drug-induced respiratory disease

Non-cardiogenic pulmonary oedema (ARDS)

- Hydrochlorothiazide
- Thrombolytics (streptokinase)
- IV β-adrenoceptor agonists (e.g. for premature labour)
- Aspirin and opiates (in overdose)

Non-eosinophilic alveolitis

- Amiodarone, flecainide, gold, nitrofurantoin, cytotoxic agents – especially bleomycin, busulfan, mitomycin C, methotrexate, sulfasalazine

Pulmonary eosinophilia

- Antimicrobials (nitrofurantoin, penicillin, tetracyclines, sulphonamides, nalidixic acid)
- Drugs used in joint disease (gold, aspirin, penicillamine, naproxen)
- Cytotoxic drugs (bleomycin, methotrexate, procarbazine)
- Psychotropic drugs (chlorpromazine, dosulepin, imipramine)
- Anticonvulsants (carbamazepine, phenytoin)
- Others (sulfasalazine, nadolol)

Pleural disease

- Bromocriptine, amiodarone, methotrexate, methysergide
- Induction of SLE – phenytoin, hydralazine, isoniazid

Asthma

- Pharmacological mechanisms (β-blockers, cholinergic agonists, aspirin and NSAIDs)
- Idiosyncratic reactions (tamoxifen, dipyridamole)

19.87 Interstitial lung disease in old age

- **Idiopathic pulmonary fibrosis**: the most common interstitial lung disease, with a worse prognosis.
- **Chronic aspiration pneumonitis**: must always be considered in elderly patients presenting with bilateral basal shadowing on a chest X-ray.
- **Granulomatosis with polyangiitis (Wegener's granulomatosis)**: a rare condition but more common in old age. Renal involvement is more common at presentation and upper respiratory problems are fewer.
- **Asbestosis**: symptoms may only appear in old age because of the prolonged latent period between exposure and disease.
- **Drug-induced interstitial lung disease**: more common, presumably because of the increased chance of exposure to multiple drugs.
- **Rarer interstitial disease**: sarcoidosis, idiopathic pulmonary haemosiderosis, alveolar proteinosis and eosinophilic pneumonia rarely present.
- **Increased dyspnoea**: coexistent muscle weakness, chest wall deformity (e.g. thoracic kyphosis) and deconditioning may all exacerbate dyspnoea associated with interstitial lung disease.
- **Surgical lung biopsy**: often inappropriate in the very frail. A diagnosis therefore frequently depends on clinical and HRCT findings alone.

19.88 Rare interstitial lung diseases

Disease	Presentation	Chest X-ray	Course
Idiopathic pulmonary haemosiderosis	Haemoptysis, breathlessness, anaemia	Bilateral infiltrates, often perihilar Diffuse pulmonary fibrosis	Rapidly progressive in children Slow progression or remission in adults Death from massive pulmonary haemorrhage or cor pulmonale and respiratory failure
Alveolar proteinosis	Breathlessness and cough Occasionally fever, chest pain and haemoptysis	Diffuse bilateral shadowing, often more pronounced in the hilar regions Air bronchogram	Spontaneous remission in one-third Whole-lung lavage or granulocyte macrophage–colony stimulating factor (GM–CSF) therapy may be effective
Langerhans cell histiocytosis (histiocytosis X)	Breathlessness, cough, pneumothorax	Diffuse interstitial shadowing progressing to honeycombing	Course unpredictable but may progress to respiratory failure Smoking cessation may be followed by significant improvement Poor response to immunosuppressive treatment
Neurofibromatosis	Breathlessness and cough in a patient with multiple organ involvement with neurofibromas including skin	Bilateral reticulonodular shadowing of diffuse interstitial fibrosis	Slow progression to death from respiratory failure Poor response to corticosteroid therapy
Alveolar microlithiasis	May be asymptomatic Breathlessness and cough	Diffuse calcified micronodular shadowing more pronounced in the lower zones	Slowly progressive to cor pulmonale and respiratory failure May stabilise in some
Lymphangioleiomyomatosis	Haemoptysis, breathlessness, pneumothorax and chylous effusion in females	Diffuse bilateral shadowing CT shows characteristic thin-walled cysts with well-defined walls throughout both lungs	Progressive to death within 10 yrs Oestrogen ablation and progesterone therapy of doubtful value Consider lung transplantation
Pulmonary tuberous sclerosis	Very similar to lymphangioleiomyomatosis, except occasionally occurs in men		

OCCUPATIONAL AND ENVIRONMENTAL LUNG DISEASE

The role of occupation and environmental exposure in lung disease is a particularly important area of respiratory medicine. Occupational lung disease is common and, in addition to the challenges of its diagnosis and management, often involves discussions about the workplace and, in some circumstances, lawyers. Many countries encourage the registration of cases of occupational lung disease.

Occupational airway disease

Occupational asthma

Occupational asthma (OA) should be considered in any individual of working age who develops new-onset asthma, particularly if the patient reports an improvement in asthma symptoms during periods away from work, e.g. at weekends and on holiday. Workers in certain occupations appear to be at particularly high risk (Box 19.89) and the condition is more common in smokers and atopic individuals. Depending on the intensity of exposure, asthmatic symptoms usually develop within the first year of employment but are classically preceded by a latent period. Symptoms of rhinoconjunctivitis often precede the development of asthma. When OA follows exposure to high molecular weight proteins, sensitisation to the agent may be demonstrated by skin testing or measurement of specific IgE. Confirmation of OA should be sought from lung function tests, which usually involves serial recording of peak flow at work, at least 4 times per day for at least 3 weeks and, if possible, including a period away from work (Fig. 19.62). In certain circumstances, specific challenge tests are required to confirm the diagnosis.

It may be possible to remove the worker from the implicated agent but when this is not feasible,

19.89 Occupational asthma

Most frequently reported causative agents

- Isocyanates
- Flour and grain dust
- Colophony and fluxes
- Latex
- Animals
- Aldehydes
- Wood dust

Workers most commonly reported to occupational asthma schemes

- Paint sprayers
- Bakers and pastry-makers
- Nurses
- Chemical workers

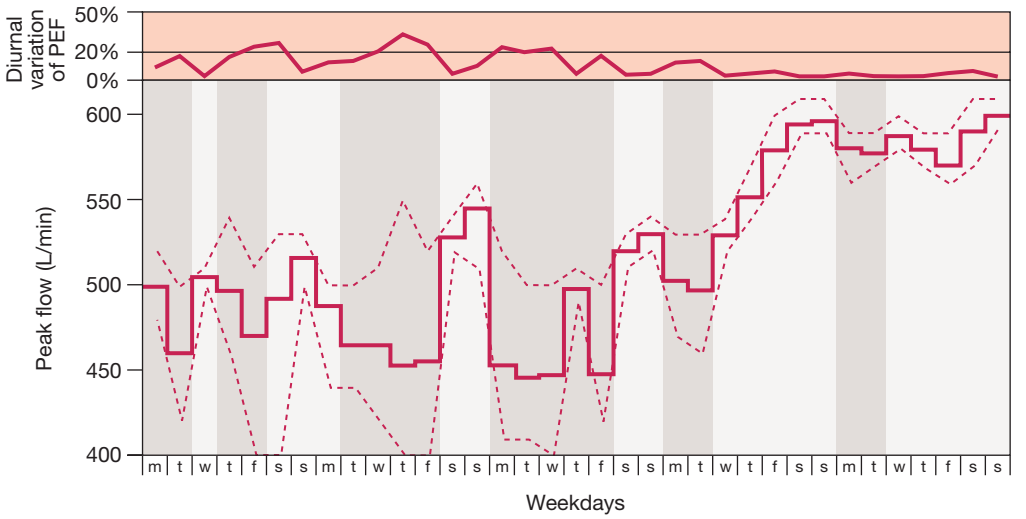

Fig. 19.62 Peak flow readings in occupational asthma. Subjects with suspected occupational asthma are asked to perform 2-hourly serial peak flows at, and away from, work. The maximum, mean and minimum values are plotted daily. Days at work are indicated by the shaded areas. The diurnal variation is displayed at the top. In this example, a period away from work is followed by a marked improvement in peak flow readings and a reduction in diurnal variation.

consideration of personal protective equipment and workplace hygiene may allow patients to retain their job and income. Specialist follow-up in such situations is highly advisable. A favourable prognosis is indicated by a short history of symptoms and normal lung function at diagnosis. Where reduction or avoidance of exposure fails to bring about resolution, the general management does not differ from that of other forms of asthma.

Reactive airways dysfunction syndrome

Reactive airways dysfunction syndrome or acute irritant-induced asthma refers to the development of a persistent asthma-like syndrome following the inhalation of an airway irritant: typically, a single specific exposure to a gas, smoke, fume or vapour in very high concentrations. Pulmonary function tests show airflow obstruction and airway hyper-reactivity, and the management is similar to that of asthma. Once developed, the condition often persists but it is common for symptoms to improve over years.

Chronic obstructive pulmonary disease

Whilst tobacco smoking remains the most important preventable cause of COPD, there is increasing recognition that other noxious particles and gases can both cause or aggravate the condition. Occupational COPD is recognised in workers exposed to coal dust, crystalline silica and cadmium. In many parts of the developing world, indoor air pollution from the burning of biomass fuels in confined spaces used for cooking contributes to the development of COPD.

Byssinosis

Byssinosis occurs in workers at cotton and flax mills who are exposed to cotton brack (dried leaf and plant debris). An acute form of the disease may occur but, more typically, byssinosis develops after 20–30 years' exposure. Typical symptoms include chest tightness or breathlessness, accompanied by a drop in lung function; classically, these are most severe on the first day of the working week ('Monday fever'), or on return to work following a period away. As the week progresses, symptoms improve and the fall in lung function becomes less dramatic. Continued exposure leads to the development of persistent symptoms and a progressive decline in FEV_1 similar to that observed in COPD.

Pneumoconiosis

Pneumoconiosis can be defined as a permanent alteration of lung structure due to the inhalation of mineral dust and the tissue reactions of the lung to its presence, excluding bronchitis and emphysema (Box 19.90). Not all dusts are pathogenic. For example, silica is highly fibrogenic, whereas iron (siderosis), tin (stannosis) and barium (baritosis) are almost inert. Beryllium causes an interstitial granulomatous disease similar to sarcoidosis. In many types of pneumoconiosis, a long period of dust exposure is required before radiological changes appear, and these may precede clinical symptoms. The most important pneumoconioses include coal worker's pneumoconiosis, silicosis and asbestosis.

Coal worker's pneumoconiosis

Coal worker's pneumoconiosis (CWP) follows prolonged inhalation of coal dust. Dust-laden alveolar macrophages aggregate to form macules in or near the centre of the secondary pulmonary lobule and a fibrotic reaction ensues, resulting in the appearance of scattered discrete fibrotic lesions. Classification is based on the size and extent of radiographic nodularity. Simple coal worker's pneumoconiosis (SCWP) refers to the appearance of small radiographic nodules in an otherwise asymptomatic individual. SCWP does not impair lung function and, once exposure ceases, will seldom progress. Progressive massive fibrosis (PMF) refers to the formation of conglomerate masses (mainly in the upper lobes), which may cavitate. The development of

19.90 Lung diseases caused by exposure to inorganic dusts

Cause	Occupation	Description	Characteristic pathological features
Coal dust	Coal mining	Coal worker's pneumoconiosis	Focal and interstitial fibrosis, centrilobular emphysema, progressive massive fibrosis
Silica	Mining, quarrying, stone dressing, metal grinding, pottery, boiler scaling	Silicosis	
Asbestos	Demolition, ship breaking, manufacture of fireproof insulating materials, pipe and boiler lagging	Asbestos-related disease	Pleural plaques, diffuse pleural thickening, acute benign pleurisy, carcinoma of lung, interstitial fibrosis, mesothelioma
Iron oxide	Arc welding	Siderosis	Mineral deposition only
Tin oxide	Tin mining	Stannosis	Tin-laden macrophages
Beryllium	Aircraft, atomic energy and electronics industries	Berylliosis	Granulomas, interstitial fibrosis

PMF is usually associated with cough, sputum that may be black (melanoptysis), and breathlessness. The chest X-ray appearances may be confused with lung cancer, tuberculosis and granulomatosis with polyangiitis. PMF may progress even after coal dust exposure ceases, and in extreme cases leads to respiratory failure and right ventricular failure.

Caplan's syndrome describes the coexistence of rheumatoid arthritis and rounded fibrotic nodules 0.5–5 cm in diameter. They show pathological features similar to a rheumatoid nodule, including central necrosis, palisading histiocytes, and a peripheral rim of lymphocytes and plasma cells. This syndrome may also occur in other types of pneumoconiosis.

Silicosis

Silicosis results from the inhalation of crystalline silica, usually in the form of quartz, by workers cutting, grinding and polishing stone. Classic silicosis is most common and usually manifests after 10–20 years of continuous silica exposure, during which time the patient remains asymptomatic. Accelerated silicosis is associated with a much shorter duration of dust exposure (typically 5–10 years), and may present as early as 1 year of exposure; as the name suggests, it follows a more aggressive course. Intense exposure to very fine crystalline silica dust can cause a more acute disease – silicoproteinosis, similar to alveolar proteinosis (see Box 19.88, p. 715).

Radiological features are similar to those of coal worker's pneumoconiosis, with multiple well-circumscribed 3–5-mm nodular opacities, predominantly in the mid- and upper zones. As the disease progresses, PMF may develop (Fig. 19.63). Enlargement of the hilar glands with an 'egg-shell' pattern of calcification is said to be characteristic but is uncommon and non-specific. Silica is highly fibrogenic and the disease is usually progressive, even when exposure ceases; hence the affected worker should always be removed from further exposure. Individuals with silicosis are at increased risk of tuberculosis (silicotuberculosis), lung cancer and COPD. Associations with renal and connective tissue disease have also been described.

Berylliosis

Exposure to beryllium is encountered in aircraft engineering and dentistry. The presence of cough, progressive breathlessness, night sweats and arthralgia in a worker exposed to dusts, fumes or vapours containing beryllium should raise suspicions of berylliosis. The radiographic appearances are similar in type and distribution to sarcoid, and biopsy shows sarcoid-like granulomas. The diagnosis may be confirmed by specialised tests of lymphocyte function.

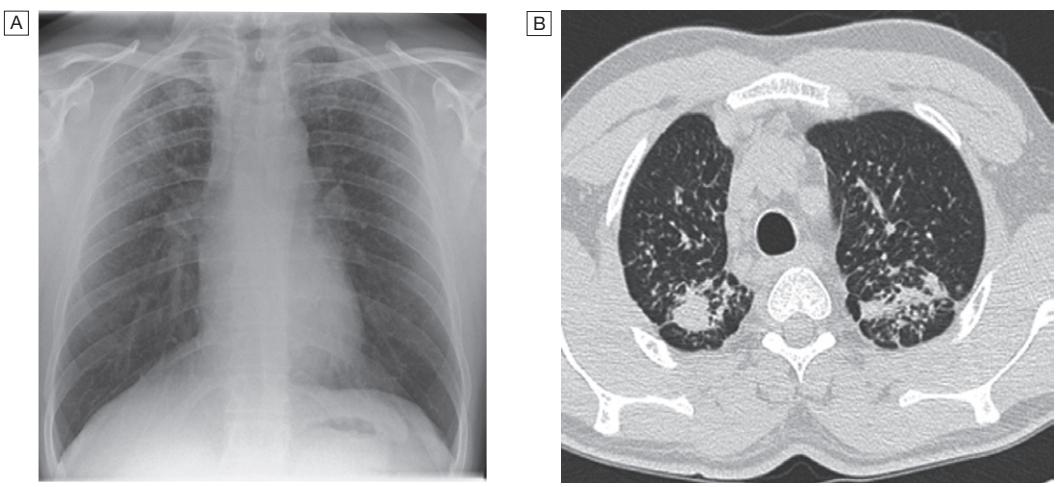

Fig. 19.63 Silicosis. A A chest X-ray from a patient with silicosis, showing the presence of small rounded nodules predominantly seen in the upper zones. B HRCT from the same patient, demonstrating conglomeration of nodules with posterior bias.

Less common pneumoconioses

Siderosis refers to the development of a benign iron oxide pneumoconiosis in welders and other iron foundry workers. Baritosis may be seen in barium process workers, and stannosis in tin refining; haematite lung occurs in iron ore miners and resembles silicosis but stains the lung red. Diamond polishers may develop hard metal disease; this condition is similar to UIP but the pathology shows a giant cell interstitial pneumonia. Popcorn worker's lung is a form of obliterative bronchiolitis following ingestion of diacetyl used in butter flavouring.

Asbestos-related lung and pleural diseases

Asbestos is a naturally occurring silicate. Its fibres may be classified as either chrysotile (white asbestos), which accounts for 90% of the world's production, or serpentine (crocidolite or blue asbestos, and amosite or brown asbestos). Its favourable thermal and chemical insulation properties led to its extensive use by the shipbuilding and construction industries throughout the latter part of the twentieth century. Exposure to asbestos may be followed by the development of both pleural and pulmonary disease, after a lengthy latent period.

Pleural plaques

Pleural plaques are the most common manifestation of past asbestos exposure, and are discrete circumscribed areas of hyaline fibrosis that may occur on the parietal pleura of the chest wall, diaphragm, pericardium or mediastinum. They are virtually always asymptomatic and are usually identified as an incidental finding on a chest X-ray (Fig. 19.64) or thoracic CT scan, particularly when partially calcified. They do not cause any impairment of lung function and are benign.

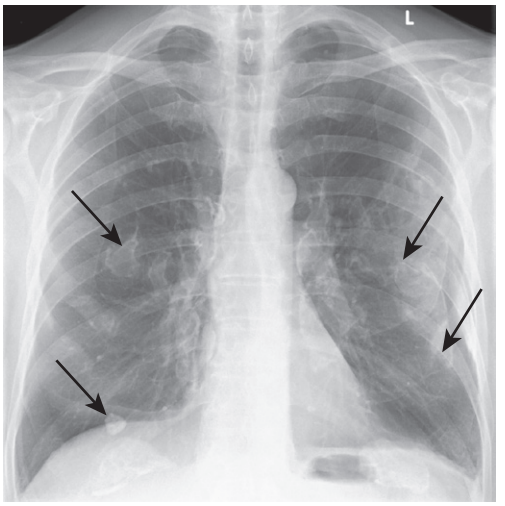

Fig. 19.64 Asbestos-related benign pleural plaques. Chest X-ray showing extensive calcified pleural plaques ('candle wax' appearance – arrows), particularly marked on the diaphragm and lateral pleural surfaces.

Acute benign asbestos pleurisy

Benign asbestos pleurisy is estimated to occur in around one-fifth of asbestos workers but many episodes are subclinical and pass unreported. When symptomatic, patients present with features of pleurisy, including mild fever and systemic disturbance. The diagnosis necessitates the exclusion of other known causes of pleurisy and pleural effusion. Repeated episodes may be followed by the development of diffuse (visceral) pleural thickening.

Diffuse pleural thickening

Diffuse pleural thickening (DPT) affects the visceral pleura and, if sufficiently extensive, may cause restrictive lung function impairment, exertional breathlessness and, occasionally, persistent chest pain. The typical appearances of DPT on chest X-ray include thickening of the pleura along the chest wall and obliteration of the costophrenic angles. Earlier manifestations of DPT, including parenchymal bands, may be detected by CT (Fig. 19.65). Occasionally, shrinkage of the visceral pleura results in the development of 'round atelectasis'. There is no treatment and the condition may progress in around one-third of individuals. In exceptionally severe cases, surgical decortication may be considered. A pleural biopsy may be required to exclude mesothelioma.

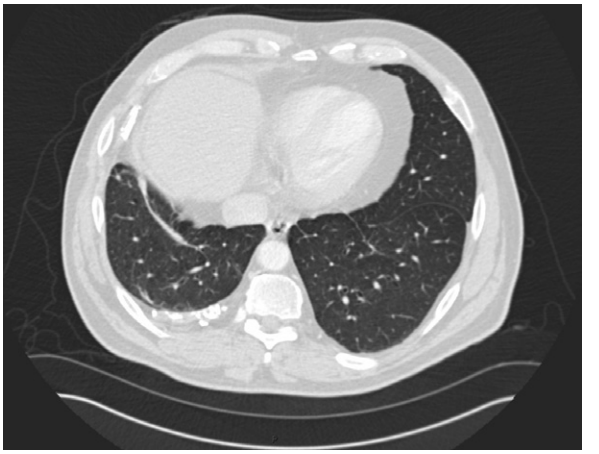

Fig. 19.65 Thoracic CT scan showing right-sided pleural thickening and an associated parenchymal band.

Asbestosis

Asbestosis is a diffuse parenchymal lung disease. Its development generally requires substantial exposure over several years, and is rare with low-level or bystander exposure. In common with other fibrosing lung diseases, asbestosis usually presents with exertional breathlessness and fine, late inspiratory crackles over the lower zones. Finger clubbing may be present. Pulmonary function tests and HRCT appearances are similar to those of UIP. These features, accompanied by a history of substantial asbestos exposure, are generally sufficient to establish the diagnosis; lung biopsy is rarely necessary. When biopsy is performed, the diagnosis is made when alveolar septal fibrosis is accompanied by an average of at least two asbestos bodies per square cm of lung tissue. In cases where there is doubt, asbestos fibre counts may

be performed on lung biopsy material to establish the diagnosis.

Asbestosis is usually slowly progressive but tends to be more indolent and associated with a better prognosis than UIP; in advanced cases, however, respiratory failure and cor pulmonale may still develop. About 40% of patients (who usually smoke) develop carcinoma of the lung and 10% may develop mesothelioma.

Mesothelioma

Mesothelioma is a malignant tumour affecting the pleura or, less commonly, the peritoneum. Its occurrence almost invariably suggests past asbestos exposure, which may be low-level. There is typically a long latent interval between first exposure and the onset of clinical manifestations, such that, even though asbestos control measures have now been implemented, deaths from mesothelioma continue to increase.

Pleural mesothelioma typically presents with increasing breathlessness resulting from pleural effusion, or unremitting chest pain when there is involvement of the chest wall. As the tumour progresses, it encases the underlying lung and may invade into the parenchyma, the mediastinum and the pericardium. Metastatic disease, although often not clinically detectable in life, is a common finding on post-mortem.

Mesothelioma is almost invariably fatal. Highly selected patients may be considered for radical surgery but, in the majority, therapy is invariably directed towards palliation of symptoms. The use of chemotherapy may improve quality of life and is accompanied by a small survival benefit of around 3 months. Radiotherapy can be used to control pain and limit the risk of tumour seeding at biopsy sites. Pleural effusions are managed with drainage and pleurodesis. Typical figures for survival from onset of symptoms are around 16 months for epithelioid tumours, 10 months for sarcomatoid tumours and 15 months for biphasic tumours, with only a minority of patients surviving longer periods.

Lung diseases due to organic dusts

A wide range of organic agents may cause respiratory disorders (Box 19.91). Disease results from a local immune response to animal proteins, or fungal antigens in mouldy vegetable matter. Hypersensitivity pneumonitis is the most common of these conditions.

Hypersensitivity pneumonitis

Hypersensitivity pneumonitis (HP; also called extrinsic allergic alveolitis) results from the inhalation of a wide variety of organic antigens, which give rise to a diffuse immune complex reaction in the alveoli and bronchioles. Common causes include farmer's lung and bird fancier's lung. Other examples are shown in Box 19.91. HP is not exclusively occupational or environmental, and other important causes include medications (see Box 19.86).

The pathology of hypersensitivity pneumonitis is consistent with both type III and type IV immunological mechanisms (p. 87). Precipitating IgG antibodies may be detected in the serum and a type III Arthus reaction is believed to occur in the lung, where the precipitation of immune complexes results in activation of complement and an inflammatory response in the alveolar walls, characterised by the influx of mononuclear cells and foamy histiocytes. The presence of poorly formed non-caseating granulomas in the alveolar walls suggests that type IV responses are also important. The distribution of the inflammatory infiltrate is predominantly peribronchiolar, which helps to distinguish the appearances from non-specific interstitial pneumonia and lymphocytic interstitial pneumonia. Chronic forms may be accompanied by fibrosis. For reasons that remain uncertain, there is a lower incidence of hypersensitivity pneumonitis in smokers than non-smokers.

19.91 Examples of lung diseases caused by organic dusts

Disorder	Source	Antigen/agent
Farmer's lung*	Mouldy hay, straw, grain	*Micropolyspora faeni* *Aspergillus fumigatus*
Bird fancier's lung*	Avian excreta, proteins and feathers	Avian serum proteins
Malt worker's lung*	Mouldy maltings	*Aspergillus clavatus*
Cheese worker's lung*	Mouldy cheese	*Aspergillus clavatus* *Penicillium casei*
Maple bark stripper's lung*	Bark from stored maple	*Cryptostroma corticale*
Saxophone player's lung*	Reed of any wind instrument	*Fusarium* spp. *Penicillium* spp. *Cladosporium* spp.
Byssinosis	Textile industries	Cotton, flax, hemp dust
Inhalation ('humidifier') fever	Contamination of air conditioning	Thermophilic actinomycetes

*Presents as hypersensitivity pneumonitis.

Clinical features

The presentation of HP varies from an acute form to a more indolent pattern, depending on the antigen load. For example, the farmer exposed to mouldy hay after it was gathered and stored damp during a wet summer, or the pigeon fancier cleaning a large pigeon loft, will report influenza-like symptoms within a few hours, accompanied by cough, breathlessness and wheeze. On the other hand, the individual with low-level antigen exposure, such as to an indoor pet bird, will typically present in a more indolent fashion with slowly progressive breathlessness, and, in some cases, established fibrosis may be present by the time the disease is recognised. Chest auscultation typically reveals widespread end-inspiratory crackles and squeaks.

Investigations

In cases of acute HP, the chest X-ray typically shows ill-defined patchy airspace shadowing which, given the systemic features, may be confused with pneumonia. HRCT is more likely to show bilateral ground glass shadowing and areas of consolidation superimposed on small centrilobar nodular opacities with an upper and middle lobe predominance (Fig. 19.66). In more

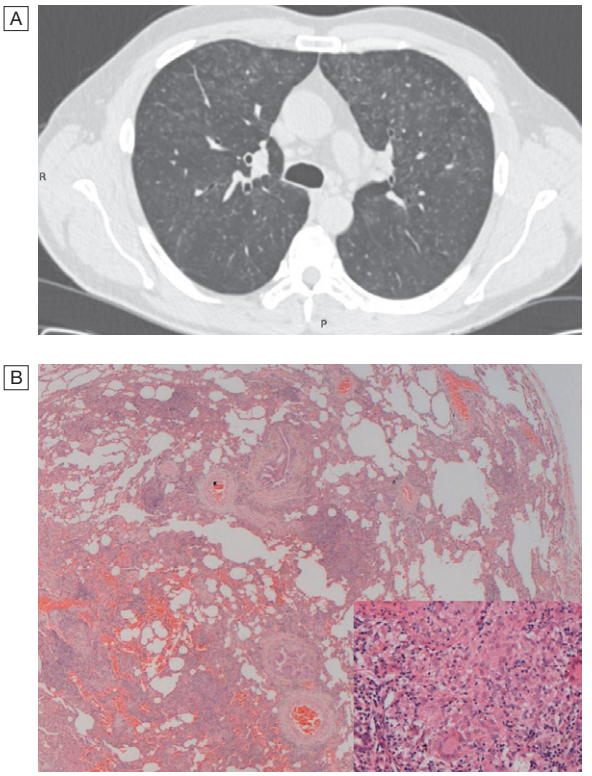

Fig. 19.66 Hypersensitivity pneumonitis. A HRCT showing typical patchy ground glass opacification. B Histology shows evidence of an interstitial inflammatory infiltrate in the lung, expanding alveolar walls, with a peribronchial distribution. Within the infiltrate, there are foci of small, poorly defined non-caseating granulomas (insert), which often lie adjacent to the airways. In this case, there is little in the way of established lung fibrosis, but this can be marked.

chronic disease, features of fibrosis, such as volume loss, linear opacities and architectural distortion, appear. In common with other fibrotic diseases, pulmonary function tests show a restrictive ventilatory defect with reduced lung volumes and impaired gas transfer, and dynamic tests may detect oxygen desaturation. In more advanced disease, type I respiratory failure is present at rest.

Diagnosis

The diagnosis of HP is usually based on the characteristic clinical and radiological features, together with the identification of a potential source of antigen in the patient's home or place of work (Box 19.92). It may be supported by a positive serum precipitin test or by more sensitive serological tests. However, the presence of precipitins without the other features does not signify a diagnosis; the great majority of farmers with positive precipitins do not have farmer's lung, and up to 15% of pigeon breeders may have positive serum precipitins yet remain healthy.

Where HP is suspected but the cause is not readily apparent, a visit to the patient's home or workplace should be made. Occasionally, if an agent previously unrecognised as causing HP is suspected, provocation testing may be necessary to prove the diagnosis; if positive, inhalation of the relevant antigen is followed after 3–6 hours by pyrexia and a reduction in VC and gas transfer factor. BAL fluid usually shows an increase in the number of CD8+ T lymphocytes, and transbronchial biopsy can occasionally provide sufficient tissue for a confident diagnosis; however, open lung biopsy may be necessary (Fig. 19.66B).

19.92 Predictive factors in the identification of hypersensitivity pneumonitis

- Exposure to a known offending antigen
- Positive precipitating antibodies to offending antigen
- Recurrent episodes of symptoms
- Inspiratory crackles on examination
- Symptoms occurring 4–8 hrs after exposure
- Weight loss

Management

If practical, the patient should cease exposure to the inciting agent. In some cases, however, this may be difficult, either because of implications for livelihood (e.g. farmers) or enthusiasm for hobbies (e.g. pigeon breeders). Dust masks with appropriate filters may minimise exposure and be combined with methods of reducing levels of antigen (e.g. drying hay before storage). In acute cases, prednisolone should be given for 3–4 weeks, starting with an oral dose of 40 mg per day. Severely hypoxaemic patients may require high-concentration oxygen therapy initially. Most patients recover completely but, if unchecked, fibrosis may progress to cause severe respiratory disability, hypoxaemia, pulmonary hypertension, cor pulmonale and eventually death.

Inhalation ('humidifier') fever

Inhalation fever shares similarities with HP. It occurs as a result of contaminated humidifiers or air-conditioning units that release a fine spray of microorganisms into the atmosphere. The illness is characterised by self-limiting fever and breathlessness; permanent sequelae are unusual. An identical syndrome can also develop after disturbing an accumulation of mouldy hay, compost or mulch. So-called 'hot tub lung' appears to be attributable to *Mycobacterium avium*. Outbreaks of HP in workers using metalworking fluids appear to be linked to *Acinetobacter* or *Ochrobactrum*.

Occupational lung cancer

Individuals exposed to substantial quantities of asbestos are at increased risk of lung cancer particularly if they smoke tobacco. Increased risks of lung cancer have also been reported in workers who develop silicosis and those exposed to radon gas, beryllium, diesel exhaust fumes, cadmium, chromium, and dust and fumes from coke plants.

Occupational pneumonia

Occupational and environmental exposures may be closely linked to the development of pneumonia. Welders appear to be at increased risk of pneumonia and pneumococcal vaccine is currently recommended for those in the trade. Farm, abattoir and hide factory workers may be exposed to *Coxiella burnetii*, the

causative agent of Q fever. The organisms are excreted from milk, urine, faeces and amniotic fluid, or may be transmitted by cattle ticks or contaminated dust from the milking floor, or by drinking milk that is inadequately pasteurised. Birds (often parrots or budgerigars) infected with *Chlamydia psittaci* can cause psittacosis in humans. Sewage workers, farmers, animal handlers and veterinarians run an increased risk of contracting leptospiral pneumonia. Contact with rabbits, hares, muskrats and ground squirrels is associated with tularaemic pneumonia, caused by *Francisella tularensis* (p. 340). Anthrax (wool-sorter's disease, p. 346) may occur in workers exposed to infected hides, hair, bristle, bonemeal and animal carcases.

PULMONARY VASCULAR DISEASE

Venous thromboembolism

Deep venous thrombosis (DVT, p. 1008) and pulmonary embolism (PE) are included under this heading. The majority (80%) of pulmonary emboli arise from the propagation of lower limb DVT. Rare causes include septic emboli (from endocarditis affecting the tricuspid or pulmonary valves), tumour (especially choriocarcinoma), fat, air, amniotic fluid and placenta.

The incidence of VTE in the community is unknown; it occurs in approximately 1% of all patients admitted to hospital and accounts for around 5% of in-hospital deaths. It is a common mode of death in patients with cancer, stroke and pregnancy.

Clinical features

VTE may be difficult to diagnose. It is helpful to consider:

- Is the clinical presentation consistent with PE?
- Does the patient have risk factors for PE?
- Are there any alternative diagnoses that can explain the patient's presentation?

Clinical presentation varies, depending on number, size and distribution of emboli and on underlying cardiorespiratory reserve (Box 19.93). A recognised risk factor is present in 80–90% (Box 19.94). The presence of one or more risk factors increases the risk further still.

19.94 Risk factors for venous thromboembolism

Surgery	
• Major abdominal/pelvic surgery	• Post-operative intensive care
• Hip/knee surgery	
Obstetrics	
• Pregnancy/puerperium	
Cardiorespiratory disease	
• COPD	• Other disabling disease
• Congestive cardiac failure	
Lower limb problems	
• Fracture	• Stroke/spinal cord injury
• Varicose veins	
Malignant disease	
• Abdominal/pelvic	• Concurrent chemotherapy
• Advanced/metastatic	
Miscellaneous	
• Increasing age	• Thrombotic disorders (p. 1054)
• Previous proven VTE	• Trauma
• Immobility	

19.93 Features of pulmonary thromboemboli

	Acute massive PE	Acute small/medium PE	Chronic PE
Pathophysiology	Major haemodynamic effects: ↓cardiac output; acute right heart failure	Occlusion of segmental pulmonary artery → infarction ± effusion	Chronic occlusion of pulmonary microvasculature, right heart failure
Symptoms	Faintness or collapse, crushing central chest pain, apprehension, severe dyspnoea	Pleuritic chest pain, restricted breathing, haemoptysis	Exertional dyspnoea. Late symptoms of pulmonary hypertension or right heart failure
Signs	Major circulatory collapse: tachycardia, hypotension, ↑JVP, RV gallop rhythm, loud P_2, severe cyanosis, ↓urinary output	Tachycardia, pleural rub, raised hemidiaphragm, crackles, effusion (often blood-stained), low-grade fever	May be minimal early in disease. Later: RV heave, loud P_2. Terminal: signs of right heart failure
Chest X-ray	Usually normal. May be subtle oligaemia	Pleuropulmonary opacities, pleural effusion, linear shadows, raised hemidiaphragm	Enlarged pulmonary artery trunk, enlarged heart, prominent right ventricle
ECG	$S_1Q_3T_3$ anterior T-wave inversion, RBBB	Sinus tachycardia	RV hypertrophy and strain
Arterial blood gases	Markedly abnormal with ↓PaO_2 and ↓$PaCO_2$. Metabolic acidosis	May be normal or ↓PaO_2 or ↓$PaCO_2$	Exertional ↓PaO_2 or desaturation on formal exercise testing
Alternative diagnoses	Myocardial infarction, pericardial tamponade, aortic dissection	Pneumonia, pneumothorax, musculoskeletal chest pain	Other causes of pulmonary hypertension

(JVP = jugular venous pressure; PE = pulmonary embolism; RBBB = right bundle branch block; RV = right ventricular)

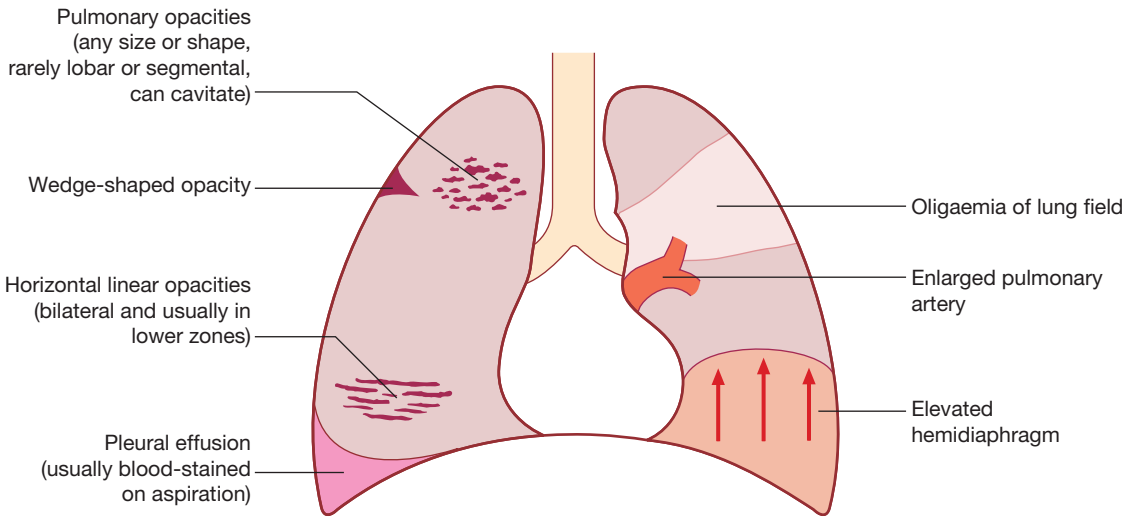

Fig. 19.67 Features of pulmonary thromboembolism/infarction on chest X-ray.

Investigations

A variety of non-specific radiographic appearances have been described (Fig. 19.67) but the chest X-ray is most useful in excluding key differential diagnoses, e.g. pneumonia or pneumothorax. Normal appearances in an acutely breathless and hypoxaemic patient should raise the suspicion of PE, as should bilateral changes in a patient presenting with unilateral pleuritic chest pain.

The ECG is often normal but is useful in excluding other important differential diagnoses, such as acute myocardial infarction and pericarditis. The most common findings in PE include sinus tachycardia and anterior T-wave inversion but these are non-specific; larger emboli may cause right heart strain revealed by an $S_1Q_3T_3$ pattern, ST-segment and T-wave changes, or the appearance of right bundle branch block.

Arterial blood gases typically show a reduced PaO_2 and a normal or low $PaCO_2$, and an increased alveolar–arterial oxygen gradient, but may be normal in a significant minority. A metabolic acidosis may be seen in acute massive PE with cardiovascular collapse.

D-dimer is a specific degradation product released into the circulation when cross-linked fibrin undergoes endogenous fibrinolysis (p. 1000). An elevated D-dimer is of limited value, as it may be raised in a variety of conditions including PE, myocardial infarction, pneumonia and sepsis. However, low levels (< 500 ng/mL, measured by ELISA), particularly where clinical risk is low, have a high negative predictive value and further investigation is usually unnecessary (Fig. 19.68). The D-dimer result should be disregarded in high-risk patients, as further investigation is mandatory even if it is normal. Other circulating markers that reflect right ventricular micro-infarction, such as troponin I and brain natriuretic peptide, are under investigation.

CT pulmonary angiography (CTPA, Fig. 19.69) is the first-line diagnostic test. It has the advantages of visualising the distribution and extent of the emboli, or highlighting an alternative diagnosis, such as consolidation, pneumothorax or aortic dissection. The sensitivity of CT scanning may be increased by simultaneous visualisation of the femoral and popliteal veins, although this is not widely practised. As the contrast media may be nephrotoxic, care should be taken in patients with renal impairment, and CTPA avoided in those with a history of allergy to iodinated contrast media.

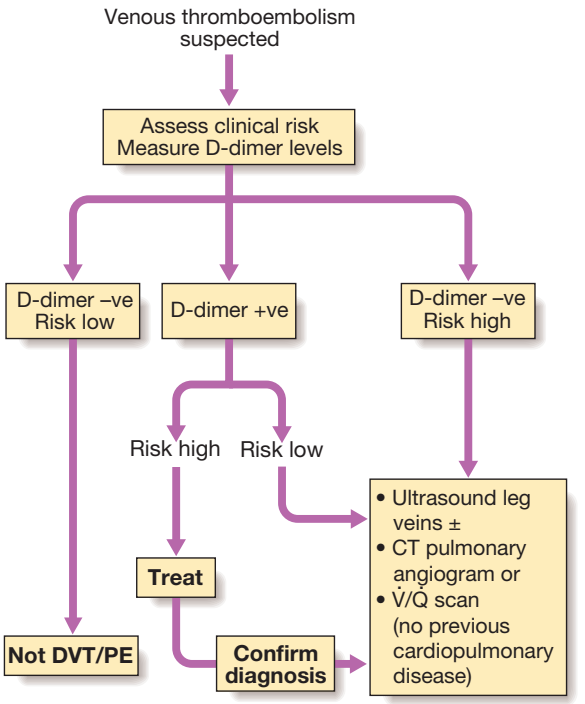

Fig. 19.68 **Algorithm for the investigation of patients with suspected pulmonary thromboembolism.** Clinical risk is based on the presence of risk factors for venous thromboembolism and the probability of another diagnosis.

Ventilation–perfusion scanning is seldom used nowadays, although a limited role remains in those without significant cardiopulmonary disease. Colour Doppler ultrasound of the leg veins remains the investigation of choice in patients with suspected DVT, but may also be used in patients with suspected PE, particularly if there are clinical signs in a limb, as many will have identifiable proximal thrombus in the leg veins.

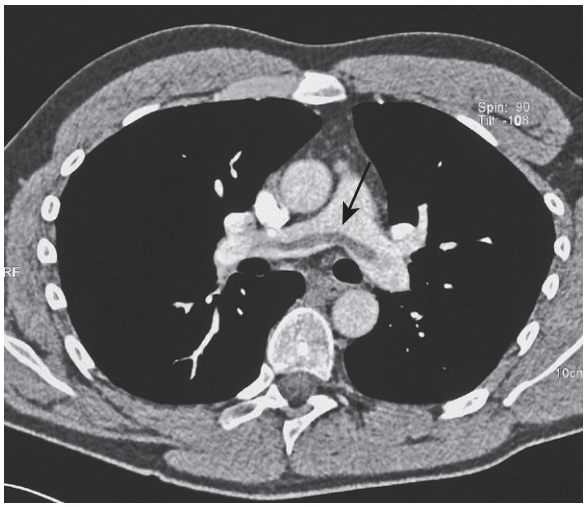

Fig. 19.69 CT pulmonary angiogram. The arrow points to a saddle embolism in the bifurcation of the pulmonary artery.

19.95 VTE and pregnancy

- **Maternal mortality**: VTE is the leading cause.
- **CTPA**: may be performed safely with fetal shielding (0.01–0.06 mGy). It is important to consider the risk of radiation to breast tissue (particularly if there is a family history of breast carcinoma) and the risk of iodinated contrast media to mother and fetus (neonatal hypothyroidism).
- **V̇ / Q̇ scanning**: greater radiation dose to fetus (0.11–0.22 mGy) but less to maternal breast tissue.
- **In utero radiation exposure**: estimated incidence of childhood malignancy is about 1 in 16 000 per mGy.
- **Warfarin**: teratogenic, so VTE should be treated with LMWH during pregnancy.

Bedside echocardiography is extremely helpful in the differential diagnosis and assessment of acute circulatory collapse (p. 544). Acute dilatation of the right heart is usually present in massive PE, and thrombus (embolism in transit) may be visible. Alternative diagnoses, including left ventricular failure, aortic dissection and pericardial tamponade, can also be identified.

Conventional pulmonary angiography has been largely superseded by CTPA but is still useful in selected settings or to deliver catheter-based therapies.

Management

General measures

Prompt recognition and treatment are potentially lifesaving. Sufficient oxygen should be given to hypoxaemic patients to maintain arterial oxygen saturation above 90%. Circulatory shock should be treated with intravenous fluids or plasma expander, but inotropic agents are of limited value as the hypoxic dilated right ventricle is already close to maximally stimulated by endogenous catecholamines. Diuretics and vasodilators should also be avoided, as they will reduce cardiac output. Opiates may be necessary to relieve pain and distress but should be used with caution in the hypotensive patient. External cardiac massage may be successful in the moribund patient by dislodging and breaking up a large central embolus.

Anticoagulation

Anticoagulation should be commenced immediately in patients with a high or intermediate probability of PE, but may be safely withheld in those with low clinical probability, pending investigation. Heparin reduces further propagation of clot and the risk of further emboli, and lowers mortality. It is most easily administered as subcutaneous low molecular weight heparin (LMWH). The dose is based on the patient's weight and there is usually no requirement to monitor tests of coagulation (p. 1018). Treatment with LMWH should continue for at least 5 days, during which time an oral anticoagulant is commenced. Fondaparinux, a synthetic pentasaccharide closely related to heparin, represents an alternative to LMWH. Warfarin – a vitamin K antagonist – remains the most commonly used oral anticoagulant. Therapy is initiated with a high loading dose, followed by a maintenance dose based on the international normalised ratio (INR). LMWH should not be discontinued until the INR is 2 or more for at least 24 hours. Due to the narrow therapeutic index of warfarin and its propensity to interact with other drugs and food, regular measurement of the INR is required throughout the duration of anticoagulation. Newer thrombin or activated factor X inhibitors offer more predictable dosing and have no requirement for coagulation monitoring; they may ultimately replace warfarin.

Decisions regarding the duration of anticoagulation represent a balance between the risk and consequences of recurrence, and the risks of prolonged anticoagulation. In patients with an identifiable and reversible risk factor, anticoagulation may be safely discontinued following 3 months of therapy. Those with persistent prothrombotic risks or a history of previous emboli should be anticoagulated for life. In patients with cancer-associated VTE, LMWH should be continued for at least 6 months before switching to warfarin. For patients with unprovoked VTE, the appropriate duration of anticoagulation should be at least 3 months, but prolonged therapy should be considered in males (who have a higher risk of recurrent VTE than females), those in whom the D-dimer remains elevated when measured 1 month after stopping anticoagulation, those with post-thrombotic syndrome, and those in whom recurrent PE may be fatal. The disadvantages of prolonged anticoagulation range from the inconvenience of long-term INR monitoring to the more serious risk of major haemorrhage (around 3% per year). Life-threatening haemorrhage occurs in around 1% of cases per year and fatal bleeding in 0.25% cases per year.

Thrombolytic and surgical therapy

Thrombolysis is indicated in any patient presenting with acute massive PE accompanied by cardiogenic shock. In the absence of shock, the benefits are less clear but thrombolysis may be considered in those presenting with right ventricular dilatation and hypokinesis or severe hypoxaemia. Patients must be screened carefully for haemorrhagic risk, as there is a high risk of intracranial haemorrhage. Surgical pulmonary embolectomy may be considered in selected patients but carries a high mortality.

19.96 Thromboembolic disease in old age

- **Risk**: rises by a factor of 2.5 over the age of 60 yrs.
- **Prophylaxis for VTE**: should be considered in all older patients who are immobile as a result of acute illness, except when this is due to acute stroke.
- **Association with cancer**: the prevalence of cancer among those with DVT increases with age but the relative risk of malignancy with DVT falls; therefore extensive investigation is not justified if initial assessment reveals no evidence of an underlying neoplasm.
- **Warfarin**: older patients are more sensitive to the anticoagulant effects of warfarin, partly due to the concurrent use of other drugs and the presence of other pathology. Life-threatening or fatal bleeds on warfarin are significantly more common in those aged over 80 yrs.
- **Chronic immobility**: long-term anticoagulant therapy is not required as there is no associated increase in thromboembolism.

Caval filters

A patient in whom anticoagulation is contraindicated, who has suffered massive haemorrhage on anticoagulation, or recurrent VTE despite anticoagulation, should be considered for an inferior vena caval filter. Retrievable caval filters are particularly useful in patients with temporary risk factors.

Prognosis

Immediate morality is greatest in those with echocardiographic evidence of right ventricular dysfunction or cardiogenic shock. Once anticoagulation is commenced, however, the risk of mortality rapidly falls. The risk of recurrence is highest in the first 6–12 months after the initial event, and at 10 years around one-third of individuals will have suffered a further event.

Pulmonary hypertension

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure of at least 25 mmHg at rest, as measured at right heart catheterisation. The definition may be further refined by consideration of the pulmonary wedge pressure, the cardiac output and the transpulmonary pressure gradient (mean PAP – mean PWP). The clinical classification of pulmonary hypertension is shown in Box 19.97. Further classification is based on the degree of functional disturbance, assessed using the New York Heart Association (NYHA) grades I–IV. Although respiratory failure due to intrinsic pulmonary disease is the most common cause of pulmonary hypertension, severe pulmonary hypertension may occur as a primary disorder, as a complication of connective tissue disease (e.g. systemic sclerosis), or as a result of chronic thromboembolic events.

Primary pulmonary hypertension (PPH) is a rare but important disease that affects predominantly women, aged between 20 and 30 years. Familial disease is rarer still but is known to be associated with mutations in the gene encoding type II bone morphogenetic protein receptor (*BMPR2*), a member of the TGF-β superfamily. Mutations in this gene have been identified in some patients with sporadic pulmonary hypertension.

19.97 Classification of pulmonary hypertension

Pulmonary arterial hypertension

- Primary pulmonary hypertension: sporadic and familial
- Secondary to: connective tissue disease (limited cutaneous systemic sclerosis), congenital systemic to pulmonary shunts, portal hypertension, HIV infection, exposure to various drugs or toxins, and persistent pulmonary hypertension of the newborn

Pulmonary venous hypertension

- Left-sided atrial or ventricular heart disease
- Left-sided valvular heart disease
- Pulmonary veno-occlusive disease
- Pulmonary capillary haemangiomatosis

Pulmonary hypertension associated with disorders of the respiratory system and/or hypoxaemia

- COPD
- Diffuse parenchymal lung disease
- Sleep-disordered breathing
- Alveolar hypoventilation disorders
- Chronic exposure to high altitude
- Neonatal lung disease
- Alveolar capillary dysplasia
- Severe kyphoscoliosis

Pulmonary hypertension caused by chronic thromboembolic disease

- Thromboembolic obstruction of the proximal pulmonary arteries
- In situ thrombosis
- Sickle cell disease

Miscellaneous

- Inflammatory conditions
- Extrinsic compression of central pulmonary veins

Adapted from Dana Point 2008. Simonneau G, et al. Updated clinical classification of pulmonary hypertension. J Am Coll Cardiol 2009; 54:S43–S54.

Pathological features include hypertrophy of both the media and the intima of the vessel wall, and a clonal expansion of endothelial cells which take on the appearance of plexiform lesions. There is marked narrowing of the vessel lumen and this, together with the frequently observed in situ thrombosis, leads to an increase in pulmonary vascular resistance and pulmonary hypertension.

Clinical features

PH presents insidiously and is often diagnosed late. Typical symptoms include breathlessness, chest pain, fatigue, palpitation and syncope. Important signs include elevation of the jugular venous pulse (with a prominent 'a' wave if in sinus rhythm), a parasternal heave (right ventricular hypertrophy), accentuation of the pulmonary component of the second heart sound and a right ventricular third heart sound. Signs of interstitial lung disease or cardiac, liver or connective tissue disease may suggest the underlying cause.

Investigations

PH is suspected if an electrocardiograph shows a right ventricular 'strain' pattern or a chest X-ray shows enlarged pulmonary arteries, peripheral pruning and right ventricle enlargement (Fig. 19.70). Doppler assessment of the tricuspid regurgitant jet by transthoracic echocardiography provides a non-invasive estimate of

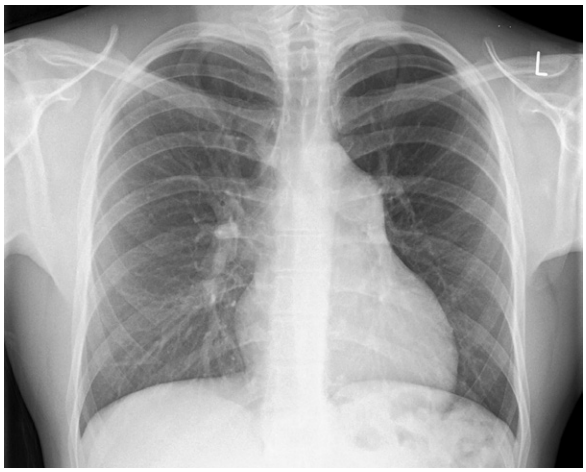

Fig. 19.70 Chest X-ray showing the typical appearance in pulmonary hypertension.

the pulmonary artery pressure, which is equal to 4 × (tricuspid regurgitation velocity)^2. Further assessment should be by right heart catheterisation to assess pulmonary haemodynamics, measure vasodilator responsiveness and thus guide further therapy.

Management

The management of PH should be guided by expert advice. General measures include diuretic therapy for right heart failure, and long-term oxygen therapy for those with chronic hypoxaemia. Unless there is an increased risk of bleeding, anticoagulation should be considered. Digoxin may be useful in patients who develop atrial tachyarrhythmias. Pregnancy carries a very high risk of death and women of child-bearing age should be counselled appropriately. Excessive physical activity that leads to distressing symptoms should be avoided but otherwise patients should be encouraged to remain active. Pneumococcal and influenza vaccination should be given.

Specific treatment options include high-dose calcium channel blockers, prostaglandins such as epoprostenol (prostacyclin) or iloprost therapy, the phosphodiesterase type 5 (PDE5) inhibitor sildenafil, and the oral endothelin antagonist bosentan. Selected patients are referred for heart–lung transplantation, and pulmonary thromboendarterectomy may be contemplated in those with chronic proximal pulmonary thromboembolic disease. Another alternative is atrial septostomy (the creation of a right-to-left shunt), which decompresses the right ventricle and improves haemodynamic performance.

DISEASES OF THE UPPER AIRWAY

Diseases of the nasopharynx

Allergic rhinitis

This is a disorder in which there are episodes of nasal congestion, watery nasal discharge and sneezing. It may be seasonal or perennial, and is due to an immediate hypersensitivity reaction in the nasal mucosa. Seasonal antigens include pollens from grasses, flowers, weeds or trees. Grass pollen is responsible for hay fever, the most common type of seasonal allergic rhinitis in northern Europe, which is at its peak between May and July. However this is a worldwide problem, which may be aggravated during harvest seasons.

Perennial allergic rhinitis may be a specific reaction to antigens derived from house dust, fungal spores or animal dander, but similar symptoms can be caused by physical or chemical irritants – for example, pungent odours or fumes, including strong perfumes, cold air and dry atmospheres. The phrase 'vasomotor rhinitis' is often used in this context, as the term 'allergic' is a misnomer.

Clinical features

In the seasonal type, there are frequent sudden attacks of sneezing, with profuse watery nasal discharge and nasal obstruction. These attacks last for a few hours and are often accompanied by smarting and watering of the eyes and conjunctival irritation. In perennial rhinitis, the symptoms are similar but more continuous and usually less severe. Skin hypersensitivity tests with the relevant antigen are usually positive in seasonal allergic rhinitis, but are less useful in perennial rhinitis.

Management

In those sensitised to house dust, simple measures, such as thorough dust removal from the bed area, leaving a window open and renewing old pillows, are often helpful. Avoidance of pollen and antigens from domestic pets, however desirable and beneficial, is usually impractical.

The following medications, singly or in combination, are usually effective in both seasonal and perennial allergic rhinitis:

- an antihistamine such as loratadine
- sodium cromoglicate nasal spray
- steroid nasal spray, e.g. beclometasone dipropionate, fluticasone, mometasone or budesonide.

In patients whose symptoms are very severe and seriously interfering with school, business or social activities, systemic corticosteroids are occasionally indicated, but adverse effects limit their usefulness. Vasomotor rhinitis is often difficult to treat, but may respond to ipratropium bromide, administered into each nostril 3 times daily.

Sleep-disordered breathing

A variety of respiratory disorders affect sleep or are affected by sleep. Cough and wheeze disturbing sleep are characteristic of asthma, while the hypoventilation that accompanies normal sleep can precipitate respiratory failure in patients with disordered ventilation due to kyphoscoliosis, diaphragmatic palsy or muscle disease (e.g. muscular dystrophy).

In contrast, a small but important group of disorders cause problems only during sleep. Patients with these may have normal lungs and daytime respiratory function, but during sleep have either abnormalities of ventilatory drive (central sleep apnoea) or upper airway obstruction (obstructive sleep apnoea). Of these, the obstructive sleep apnoea/hypopnoea syndrome is by far the most common and important. When this coexists

with COPD, severe respiratory failure can result even if the COPD is mild.

The sleep apnoea/hypopnoea syndrome

It is now recognised that 2–4% of the middle-aged population suffer from recurrent upper airway obstruction during sleep. The resulting sleep fragmentation causes daytime sleepiness, especially in monotonous situations, resulting in a threefold increased risk of road traffic accidents and a ninefold increased risk of single-vehicle accidents.

Aetiology

Sleep apnoea results from recurrent occlusion of the pharynx during sleep, usually at the level of the soft palate. Inspiration results in negative pressure within the pharynx. During wakefulness, upper airway dilating muscles, including palatoglossus and genioglossus, contract actively during inspiration to preserve airway patency. During sleep, muscle tone declines, impairing the ability of these muscles to maintain pharyngeal patency. In a minority of people, a combination of an anatomically narrow palatopharynx and underactivity of the dilating muscles during sleep results in inspiratory airway obstruction. Incomplete obstruction causes turbulent flow, resulting in snoring (around 40% of middle-aged men and 20% of middle-aged women snore). More severe obstruction triggers increased inspiratory effort and transiently wakes the patient, allowing the dilating muscles to re-open the airway. These awakenings are so brief that patients have no recollection of them. After a series of loud deep breaths that may wake their bed partner, the patient rapidly returns to sleep, snores and becomes apnoeic once more. This cycle of apnoea and awakening may repeat itself many hundreds of times per night and results in severe sleep fragmentation and secondary variations in blood pressure, which may predispose over time to cardiovascular disease.

Predisposing factors to the sleep apnoea/hypopnoea syndrome include male gender, which doubles the risk, and obesity, which is found in about 50%, because parapharyngeal fat deposits tend to narrow the pharynx. Nasal obstruction or a recessed mandible can further exacerbate the problem. Acromegaly and hypothyroidism also predispose by causing submucosal infiltration and narrowing of the upper airway. Sleep apnoea is often familial, where the maxilla and mandible are back-set, narrowing the upper airway. Alcohol and sedatives predispose to snoring and apnoea by relaxing the upper airway dilating muscles. As a result of marked sympathetic activation during apnoea, sleep-disordered breathing is associated over time with sustained hypertension and an increased risk of coronary events and stroke. An association has also been described with insulin resistance, the metabolic syndrome and type II diabetes. Treatment of sleep apnoea reduces sympathetic drive and blood pressure, and may also improve these associated metabolic disorders.

Clinical features

Excessive daytime sleepiness is the principal symptom and snoring is virtually universal. The patient usually feels that he or she has been asleep all night but wakes unrefreshed. Bed partners report loud snoring in all body positions and often have noticed multiple breathing pauses (apnoeas). Difficulty with concentration, impaired cognitive function and work performance, depression, irritability and nocturia are other features.

Investigations

Provided that the sleepiness does not result from inadequate time in bed or from shift work, anyone who repeatedly falls asleep during the day when not in bed, who complains that his or her work is impaired by sleepiness, or who is a habitual snorer with multiple witnessed apnoeas should be referred for a sleep assessment. A more quantitative assessment of daytime sleepiness can be obtained by questionnaire (Box 19.98).

Overnight studies of breathing, oxygenation and sleep quality are diagnostic (Fig. 19.71) but the level of

19.98 Epworth sleepiness scale

How likely are you to doze off or fall asleep in the situations described below? Choose the most appropriate number for each situation from the following scale:

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

- Sitting and reading
- Watching TV
- Sitting inactive in a public place (e.g. a theatre or a meeting)
- As a passenger in a car for an hour without a break
- Lying down to rest in the afternoon when circumstances permit
- Sitting and talking to someone
- Sitting quietly after a lunch without alcohol
- In a car, while stopped for a few minutes in the traffic

Normal subjects average 5.9 (SD 2.2) and patients with severe obstructive sleep apnoea average 16.0 (SD 4.4).

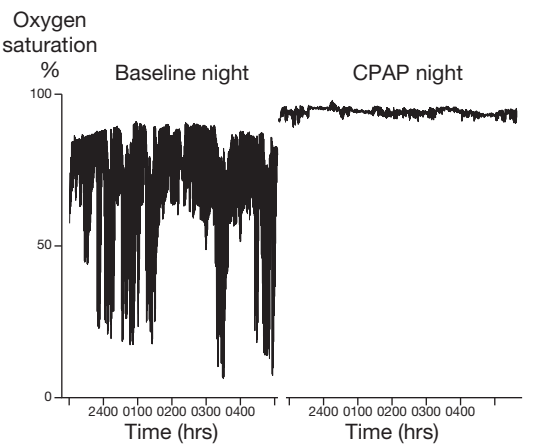

Fig. 19.71 Sleep apnoea/hypopnoea syndrome: overnight oxygen saturation trace. The left-hand panel shows the trace of a patient who had 53 apnoeas plus hypopnoeas/hour, 55 brief awakenings/hour and marked oxygen desaturation. The right-hand panel shows the effect of continuous positive airway pressure (CPAP) of 10 cm H_2O delivered through a tight-fitting nasal mask: it abolished his breathing irregularity and awakenings, and improved oxygenation.

19.99 Differential diagnosis of persistent sleepiness

Lack of sleep

- Inadequate time in bed
- Extraneous sleep disruption (e.g. babies/children)
- Shift work
- Excessive caffeine intake
- Physical illness (e.g. pain)

Sleep disruption

- Sleep apnoea/hypopnoea syndrome
- Periodic limb movement disorder (recurrent limb movements during non-REM sleep, frequent nocturnal awakenings)

Sleepiness with relatively normal sleep

- Narcolepsy
- Idiopathic hypersomnolence (rare)
- Neurological lesions (e.g. hypothalamic or upper brainstem infarcts or tumours)
- Drugs

Psychological/psychiatric

- Depression

investigations depends on local resources and the probability of the diagnosis. The current threshold for diagnosing moderate sleep apnoea/hypopnoea syndrome is 15 apnoeas/hypopnoeas per hour of sleep, where an apnoea is defined as a 10-second or longer breathing pause and a hypopnoea a 10-second or longer 50% reduction in breathing.

Several other conditions can cause daytime sleepiness but can usually be excluded by a careful history (Box 19.99). Narcolepsy is a rare cause of sleepiness, occurring in 0.05% of the population (p. 1187). Idiopathic hypersomnolence occurs in younger individuals and is characterised by long nocturnal sleeps.

Management

The major hazard to patients and those around them is traffic accidents, so all drivers must be advised not to drive until treatment has relieved their sleepiness. In a minority, relief of nasal obstruction or the avoidance of alcohol may prevent obstruction. Advice to obese patients to lose weight is often unheeded, and the majority of patients need to use continuous positive airway pressure (CPAP) delivered by a nasal mask every night to splint the upper airway open. When CPAP is tolerated, the effect is often dramatic (see Fig. 19.71), with relief of somnolence and improved daytime performance, quality of life and survival. Unfortunately, 30–50% of patients do not tolerate CPAP. Mandibular advancement devices that fit over the teeth and hold the mandible forward, thus opening the pharynx, are an alternative that is effective in some patients. There is no evidence that palatal surgery is of benefit.

Laryngeal disorders

The larynx is commonly affected by acute self-limiting infections (p. 681). Other disorders include chronic laryngitis, laryngeal tuberculosis, laryngeal paralysis and laryngeal obstruction. Tumours of the larynx are relatively common, particularly in smokers. For further details, the reader should refer to an otolaryngology text.

19.100 Causes of chronic laryngitis

- Repeated attacks of acute laryngitis
- Excessive use of the voice, especially in dusty atmospheres
- Heavy tobacco smoking
- Mouth-breathing from nasal obstruction
- Chronic infection of nasal sinuses

Chronic laryngitis

The common causes are listed in Box 19.100. The chief symptoms are hoarseness or loss of voice (aphonia). There is irritation of the throat and a spasmodic cough. The disease pursues a chronic course, frequently uninfluenced by treatment, and the voice may become permanently impaired. Other causes of chronic hoarseness include use of inhaled corticosteroid treatment, tuberculosis, laryngeal paralysis or tumour.

In some patients, a chest X-ray may reveal an unsuspected bronchial carcinoma or pulmonary tuberculosis. If these are not found, laryngoscopy should be performed to exclude a local structural cause.

When no specific treatable cause is found, the voice must be rested completely. This is particularly important in public speakers and singers. Smoking should be avoided. Some benefit may be obtained from frequent inhalations of medicated steam.

Laryngeal paralysis

Interruption of the motor nerve supply of the larynx is nearly always unilateral and, because of the intrathoracic course of the left recurrent laryngeal nerve, usually left-sided. One or both recurrent laryngeal nerves may be damaged at thyroidectomy, by carcinoma of the thyroid or by anterior neck injury. Rarely, the vagal trunk itself is involved by tumour, aneurysm or trauma.

Clinical features and management

Hoarseness always accompanies laryngeal paralysis, whatever its cause. Paralysis of organic origin is seldom reversible, but when only one vocal cord is affected, hoarseness may improve or even disappear after a few weeks, as the normal cord compensates by crossing the midline to approximate with the paralysed cord on phonation.

'Bovine cough' is a characteristic feature of organic laryngeal paralysis, and lacks the explosive quality of normal coughing because the cords fail to close the glottis. Sputum clearance may also be impaired. A normal cough in patients with partial loss of voice or aphonia virtually excludes laryngeal paralysis. Stridor is occasionally present but seldom severe, except when laryngeal paralysis is bilateral.

Laryngoscopy is required to establish the diagnosis of laryngeal paralysis. The paralysed cord lies in the so-called 'cadaveric' position, midway between abduction and adduction.

The cause should be treated, if possible. In unilateral paralysis, persistent dysphonia may be improved by the injection of Teflon into the affected vocal cord. In bilateral organic paralysis, tracheal intubation, tracheostomy or plastic surgery on the larynx may be necessary.

Psychogenic hoarseness and aphonia

Psychogenic causes of hoarseness or aphonia may be suggested by associated symptoms in the history (p. 236). However, laryngoscopy may be necessary to exclude a physical cause. In psychogenic aphonia, only the voluntary movement of adduction of the vocal cords is seen to be impaired. Speech therapy may be helpful.

Laryngeal obstruction

Laryngeal obstruction is more liable to occur in children than in adults because of the smaller size of the glottis. Important causes are given in Box 19.101. Sudden complete laryngeal obstruction by a foreign body produces the clinical picture of acute asphyxia: violent but ineffective inspiratory efforts with indrawing of the intercostal spaces and the unsupported lower ribs, accompanied by cyanosis. Unrelieved, the condition progresses to coma and death within a few minutes. When, as in most cases, the obstruction is incomplete at first, the main clinical features are progressive breathlessness accompanied by stridor and cyanosis. Urgent treatment to prevent complete obstruction is needed.

Management

Transient laryngeal obstruction due to exudate and spasm, which may occur with acute pharyngitis in children and with whooping cough, is potentially dangerous but can usually be relieved by steam inhalation. Laryngeal obstruction from all other causes carries a high mortality and demands prompt treatment.

When a foreign body causes laryngeal obstruction in children, it can often be dislodged by turning the patient head downwards, and squeezing the chest vigorously. In adults, a sudden forceful compression of the upper abdomen (Heimlich manœuvre) may be effective. Otherwise, the cause of the obstruction should be investigated by direct laryngoscopy, which may also permit the removal of an unsuspected foreign body or the insertion of a tube past the obstruction into the trachea. Tracheostomy must be performed without delay if these procedures fail to relieve obstruction but, except in dire emergencies, this should be performed in theatre by a surgeon.

In diphtheria, antitoxin should be administered, and for other infections the appropriate antibiotic should be given. In angioedema, complete laryngeal occlusion can usually be prevented by treatment with adrenaline (epinephrine) 0.5–1 mg (0.5–1 mL of 1:1000) IM, chlorphenamine maleate (10–20 mg by slow intravenous injection) and intravenous hydrocortisone sodium succinate (200 mg).

19.101 Causes of laryngeal obstruction

- Inflammatory or allergic oedema, or exudate
- Spasm of laryngeal muscles
- Inhaled foreign body
- Inhaled blood clot or vomitus in an unconscious patient
- Tumours of the larynx
- Bilateral vocal cord paralysis
- Fixation of both cords in rheumatoid disease

Tracheal disorders

Tracheal obstruction

External compression by lymph nodes containing metastases, usually from a bronchial carcinoma, is a more frequent cause of tracheal obstruction than primary benign or malignant tumours. The trachea may also be compressed by a retrosternal goitre (see Fig. 19.11, p. 657). Rare causes include an aneurysm of the aortic arch and (in children) tuberculous mediastinal lymph nodes. Tracheal stenosis is an occasional complication of tracheostomy, prolonged intubation, granulomatosis with polyangiitis (Wegener's granulomatosis, p. 1118) or trauma.

Clinical features and management

Stridor can be detected in every patient with severe tracheal narrowing. Bronchoscopic examination of the trachea should be undertaken without delay to determine the site, degree and nature of the obstruction.

Localised tumours of the trachea can be resected, but reconstruction after resection may be technically difficult. Endobronchial laser therapy, bronchoscopically placed tracheal stents, chemotherapy and radiotherapy are alternatives to surgery. The choice of treatment depends upon the nature of the tumour and the general health of the patient. Benign tracheal strictures can sometimes be dilated but may require resection.

Tracheo-oesophageal fistula

This may be present in newborn infants as a congenital abnormality. In adults, it is usually due to malignant lesions in the mediastinum, such as carcinoma or lymphoma, eroding both the trachea and oesophagus to produce a communication between them. Swallowed liquids enter the trachea and bronchi through the fistula and provoke coughing.

Surgical closure of a congenital fistula, if undertaken promptly, is usually successful. There is usually no curative treatment for malignant fistulae, and death from overwhelming pulmonary infection rapidly supervenes.

PLEURAL DISEASE

Pleurisy, pleural effusion, empyema and asbestos-associated pleural disease have been described above.

Pneumothorax

Pneumothorax is the presence of air in the pleural space, which can either occur spontaneously, or result from iatrogenic injury or trauma to the lung or chest wall (Box 19.102). Primary spontaneous pneumothorax occurs in patients with no history of lung disease. Smoking, tall stature and the presence of apical subpleural blebs are risk factors. Secondary pneumothorax affects patients with pre-existing lung disease and is associated with higher mortality rates (Fig. 19.72).

Where the communication between the airway and the pleural space seals off as the lung deflates and does not re-open, the pneumothorax is referred to as 'closed'

(Fig. 19.73A). The mean pleural pressure remains negative, spontaneous reabsorption of air and re-expansion of the lung occur over a few days or weeks, and infection is uncommon. This contrasts with an 'open' pneumothorax, where the communication fails to seal and air continues to pass freely between the bronchial tree and pleural space (Fig. 19.73B). An example of the latter is a bronchopleural fistula, which, if large, can facilitate the transmission of infection from the airways into the pleural space, leading to empyema. An open pneumothorax is commonly seen following rupture of an emphysematous bulla, tuberculous cavity or lung abscess into the pleural space.

Occasionally, the communication between the airway and the pleural space acts as a one-way valve, allowing air to enter the pleural space during inspiration but not to escape on expiration. Large amounts of trapped air accumulate progressively in the pleural space and the intrapleural pressure rises to well above atmospheric levels. This is a tension pneumothorax. The pressure causes mediastinal displacement towards the opposite side, with compression of the opposite normal lung and impairment of systemic venous return, causing cardiovascular compromise (Fig. 19.73C).

19.102 Classification of pneumothorax

Spontaneous

Primary
- No evidence of overt lung disease. Air escapes from the lung into the pleural space through rupture of a small pleural bleb, or the pulmonary end of a pleural adhesion

Secondary
- Underlying lung disease, most commonly COPD and tuberculosis; also seen in asthma, lung abscess, pulmonary infarcts, bronchogenic carcinoma, and all forms of fibrotic and cystic lung disease

Traumatic
- Iatrogenic (e.g. following thoracic surgery or biopsy) or chest wall injury

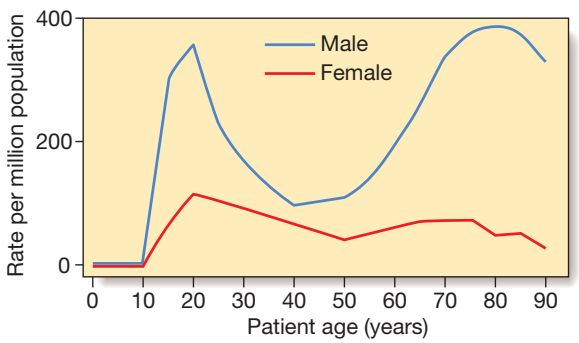

Fig. 19.72 Bimodal age distribution for hospital admissions for pneumothorax in England. The incidence of primary spontaneous pneumothorax peaks in males aged 15–30 years. Secondary spontaneous pneumothorax occurs mainly in males over 55 years.

Clinical features

The most common symptoms are sudden-onset unilateral pleuritic chest pain or breathlessness. In those individuals with underlying chest disease, breathlessness can be severe and may not resolve spontaneously. In patients with a small pneumothorax, physical examination may be normal. A larger pneumothorax (> 15% of the hemithorax) results in decreased or absent breath sounds (p. 645). The combination of absent breath sounds and resonant percussion note is diagnostic of pneumothorax.

By contrast, in tension pneumothorax there is rapidly progressive breathlessness associated with a marked tachycardia, hypotension, cyanosis and tracheal displacement away from the side of the silent hemithorax. Occasionally, tension pneumothorax may occur without mediastinal shift, if malignant disease or scarring has splinted the mediastinum.

Investigations

The chest X-ray shows the sharply defined edge of the deflated lung with complete translucency (no lung markings) between this and the chest wall (p. 645). Care must be taken to differentiate between a large pre-existing emphysematous bulla and a pneumothorax. CT is used in difficult cases to avoid misdirected attempts

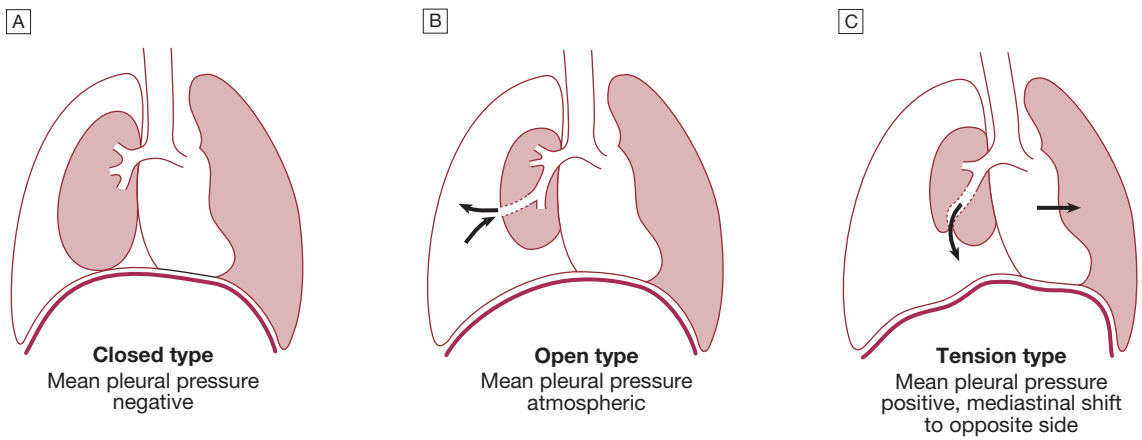

Fig. 19.73 Types of spontaneous pneumothorax. A Closed type. B Open type. C Tension (valvular) type.

at aspiration. X-rays may also show the extent of any mediastinal displacement and reveal any pleural fluid or underlying pulmonary disease.

Management

Primary pneumothorax, in which the lung edge is less than 2 cm from the chest wall and the patient is not breathless, normally resolves without intervention. In young patients presenting with a moderate or large spontaneous primary pneumothorax, percutaneous needle aspiration of air is a simple and well-tolerated alternative to intercostal tube drainage, with a 60–80% chance of avoiding the need for a chest drain (Fig. 19.74). In patients with significant underlying chronic lung disease, however, secondary pneumothorax may cause respiratory distress. In these patients, the success rate of aspiration is much lower, and intercostal tube drainage and inpatient observation are usually required, particularly in those individuals over 50 years old and those with respiratory compromise. If there is a tension pneumothorax, immediate release of the positive pressure by insertion of a blunt cannula into the pleural space may be beneficial, allowing time to prepare for chest drain insertion.

When needed, intercostal drains are inserted in the 4th, 5th or 6th intercostal space in the mid-axillary line, connected to an underwater seal or one-way Heimlich valve, and secured firmly to the chest wall. Clamping of an intercostal drain is potentially dangerous and rarely indicated. The drain should be removed the morning after the lung has fully re-inflated and bubbling has stopped. Continued bubbling after 5–7 days is an indication for surgery. If bubbling in the drainage bottle stops before full re-inflation, the tube is either blocked, kinked or displaced. Supplemental oxygen may speed resolution, as it accelerates the rate at which nitrogen is reabsorbed by the pleura.

Patients with a closed pneumothorax should be advised not to fly, as the trapped gas expands at altitude. After complete resolution, there is no clear evidence to indicate how long patients should avoid flying, although guidelines suggest that waiting 1–2 weeks, with confirmation of full inflation prior to flight, is prudent. Patients should also be advised to stop smoking and informed about the risks of a recurrent pneumothorax. Diving is potentially dangerous after pneumothorax, unless a surgical pleurodesis has sealed the lung to the chest wall.

Recurrent spontaneous pneumothorax

After primary spontaneous pneumothorax, recurrence occurs within a year of either aspiration or tube drainage in approximately 25% of patients, and should prompt definitive treatment. Surgical pleurodesis is recommended in all patients following a second pneumothorax and should be considered following the first episode of secondary pneumothorax if low respiratory reserve makes recurrence hazardous. Pleurodesis can be achieved by pleural abrasion or parietal pleurectomy at thoracotomy or thoracoscopy.

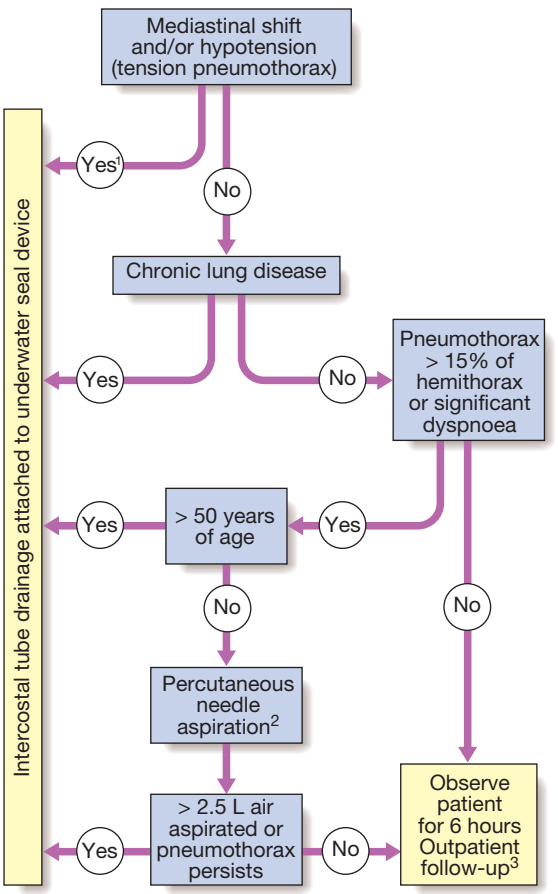

Fig. 19.74 Management of spontaneous pneumothorax.
(1) Immediate decompression prior to insertion of the intercostal drain. (2) Aspirate in the 2nd intercostal space anteriorly in the mid-clavicular line using a 16 F cannula; discontinue if resistance is felt, the patient coughs excessively, or more than 2.5 L of air are removed. (3) The post-aspiration chest X-ray is not a reliable indicator of whether a pleural leak remains, and all patients should be told to attend again immediately in the event of deterioration.

19.103 Pleural disease in old age

- **Spontaneous pneumothorax**: invariably associated with underlying lung disease in old age and has a significant mortality. Surgical or chemical pleurodesis is advised in all such patients.
- **Rib fracture**: common cause of pleural-type pain; may be spontaneous (due to coughing), traumatic or pathological. Underlying osteomalacia may contribute to poor healing, especially in the housebound with no exposure to sunlight.
- **Tuberculosis**: should always be considered and actively excluded in any elderly patient presenting with a unilateral pleural effusion.
- **Mesothelioma**: more common in older individuals than younger people due to a long latency period between asbestos exposure (often more than 20 yrs) and the development of disease.
- **Analgesia**: frail older people are particularly sensitive to the respiratory depressant effects of opiate-based analgesia and careful monitoring is required when using these agents for pleural pain.

DISEASES OF THE DIAPHRAGM AND CHEST WALL

Disorders of the diaphragm

Congenital disorders

Diaphragmatic hernias

Congenital defects of the diaphragm can allow herniation of abdominal viscera. Posteriorly situated hernias through the foramen of Bochdalek are more common than anterior hernias through the foramen of Morgagni.

Eventration of the diaphragm

Abnormal elevation or bulging of one hemidiaphragm, more often the left, results from total or partial absence of muscular development of the septum transversum. Most eventrations are asymptomatic and are detected by chance on X-ray in adult life, but severe respiratory distress can be caused in infancy if the diaphragmatic muscular defect is extensive.

Acquired disorders

Elevation of a hemidiaphragm may result from paralysis or other structural causes (Box 19.104). The phrenic nerve may be damaged by bronchial carcinoma, disease of cervical vertebrae, tumours of the cervical cord, shingles, trauma (including road traffic and birth injuries), surgery, and stretching of the nerve by mediastinal masses and aortic aneurysms. Idiopathic diaphragmatic paralysis occasionally occurs in otherwise fit patients. Paralysis of one hemidiaphragm results in loss of around 20% of ventilatory capacity, but may not be noticed by otherwise healthy individuals. Ultrasound screening can be used to demonstrate paradoxical upward movement of the paralysed hemidiaphragm on sniffing. CT of the chest and neck is the best way to exclude occult disease affecting the phrenic nerve.

Bilateral diaphragmatic weakness occurs in peripheral neuropathies of any type, including Guillain–Barré syndrome (p. 1224), in disorders affecting the anterior horn cells, e.g. poliomyelitis (p. 1207), in muscular dystrophies, and in connective tissue disorders such as SLE and polymyositis (pp. 1109 and 1114).

Hiatus hernia is common (p. 865). Diaphragmatic rupture is usually caused by a crush injury and may not be detected until years later. Respiratory disorders that cause pulmonary hyperinflation, e.g. emphysema, and those that result in small stiff lungs, e.g. diffuse pulmonary fibrosis, compromise diaphragmatic function and predispose to fatigue.

19.104 Causes of elevation of a hemidiaphragm

- Phrenic nerve paralysis
- Eventration of the diaphragm
- Decrease in volume of one lung (e.g. lobectomy, unilateral pulmonary fibrosis)
- Severe pleuritic pain
- Pulmonary infarction
- Subphrenic abscess
- Large volume of gas in the stomach or colon
- Large tumours or cysts of the liver

Deformities of the chest wall

Thoracic kyphoscoliosis

Abnormalities of alignment of the dorsal spine and their consequent effects on thoracic shape may be caused by:

- congenital abnormality
- vertebral disease, including tuberculosis, osteoporosis and ankylosing spondylitis
- trauma
- neuromuscular disease such as poliomyelitis.

Simple kyphosis (increased anteroposterior curvature) causes less pulmonary embarrassment than kyphoscoliosis (anteroposterior and lateral curvature). Kyphoscoliosis, if severe, restricts and distorts expansion of the chest wall and impairs diaphragmatic function, causing ventilation–perfusion mismatch in the lungs. Patients with severe deformity may develop type II respiratory failure (initially manifest during sleep), pulmonary hypertension and right ventricular failure. They can often be successfully treated with non-invasive ventilatory support (p. 193).

Pectus excavatum

Pectus excavatum (funnel chest) is an idiopathic condition in which the body of the sternum, usually only the lower end, is curved inwards. The heart is displaced to the left and may be compressed between the sternum and the vertebral column but only rarely is there associated disturbance of cardiac function. The deformity may restrict chest expansion and reduce vital capacity. Operative correction is rarely performed, and then only for cosmetic reasons.

Pectus carinatum

Pectus carinatum (pigeon chest) is frequently caused by severe asthma during childhood. Very occasionally, this deformity can be produced by rickets or be idiopathic.

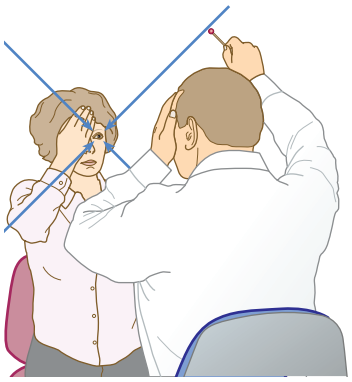
Testicular volume

12 Legs
Proximal myopathy
Myxoedema

Pretibial myxoedema in Graves' disease



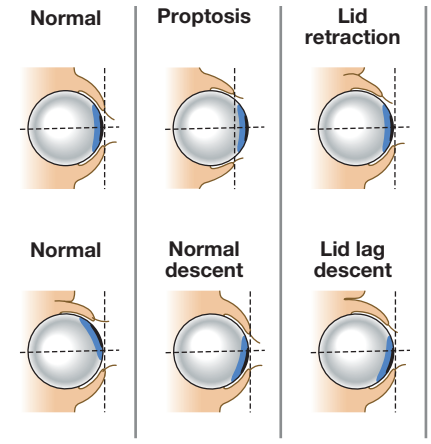
Observation

- Most examination in endocrinology is by observation
- Astute observation can often yield 'spot' diagnosis of endocrine disorders
- The emphasis of examination varies depending on which gland or hormone is thought to be involved

Endocrine disease causes clinical syndromes with symptoms and signs involving many organ systems, reflecting the diverse effects of hormone deficiency and excess. The emphasis of the clinical examination depends on the gland or hormone that is thought to be abnormal.

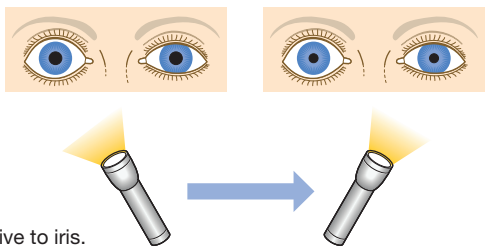
Diabetes mellitus (described in detail in Ch. 21) and thyroid disease are the most common endocrine disorders.

6 Examination of the visual fields by confrontation



- Sit opposite patient
- You and patient cover opposite eyes
- Bring red pin (or wiggling finger) slowly into view from extreme of your vision, as shown
- Ask patient to say 'now' when it comes into view
- Continue to move pin into centre of vision and ask patient to tell you if it disappears
- Repeat in each of four quadrants
- Repeat in other eye

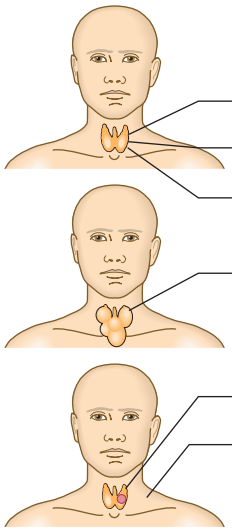
A bitemporal hemianopia is the classical finding in pituitary macroadenomas (p. 789)



6 Examination in Graves' ophthalmopathy

- **Inspect** from front and side
  - Periorbital oedema (Fig. 20.7)
  - Conjunctival inflammation (chemosis)
  - Corneal ulceration
  - Proptosis (exophthalmos)*
  - Lid retraction*
- **Range of eye movements**
  - Lid lag on descending gaze*
  - Diplopia on lateral gaze
- **Pupillary reflexes**
  - Afferent defect (pupils constrict further on swinging light to unaffected eye, Box 26.28)
- **Vision**
  - Visual acuity impaired
  - Loss of colour vision
  - Visual field defects
- **Ophthalmoscopy**
  - Optic disc pallor
  - Papilloedema

*Note position of eyelids relative to iris.



Right proptosis and afferent pupillary defect

7 Examination of the thyroid gland

- **Inspect** from front to side
- **Palpate** from behind
  - Thyroid moves on swallowing
  - Cervical lymph nodes
  - Tracheal deviation
- **Auscultate** for bruit
  - Ask patient to hold breath
  - If present, check for radiating murmur
- **Percuss** for retrosternal thyroid
- Consider systemic signs of thyroid dysfunction (Box 20.7) incl. tremor, palmar erythema, warm peripheries, tachycardia, lid lag
- Consider signs of Graves' disease incl. ophthalmopathy, pretibial myxoedema

Abnormal findings

- Diffuse soft goitre with bruit
  - Graves' disease (p. 747)
- Diffuse firm goitre
  - Hashimoto's thyroiditis (p. 751)
- Diffuse tender goitre
  - Subacute thyroiditis (p. 751)
- Multinodular goitre (p. 752)
  - ± Retrosternal extension, tracheal compression
- Solitary nodule (p. 746)
  - Adenoma, cyst or carcinoma
- Cervical lymphadenopathy
  - Suggests carcinoma

Endocrinology concerns the synthesis, secretion and action of hormones. These are chemical messengers released from endocrine glands that coordinate the activities of many different cells. Endocrine diseases can therefore affect multiple organs and systems. This chapter describes the principles of endocrinology before dealing with the function and diseases of each gland in turn.

Some endocrine disorders are common, particularly those of the thyroid, parathyroid glands, reproductive system and β cells of the pancreas (Ch. 21). For example, thyroid dysfunction occurs in more than 10% of the population in areas with iodine deficiency, such as the Himalayas, and 4% of women aged 20–50 years in the UK. Some endocrine diseases are becoming more common in association with emerging diseases; HIV infection is associated in particular with adrenal insufficiency. Less common endocrine syndromes are described later in the chapter.

Few endocrine therapies have been evaluated by randomised controlled trials, in part because hormone replacement therapy (for example, with levothyroxine) has obvious clinical benefits and placebo-controlled trials would be unethical, and in part because many endocrine diseases are rare, making trials difficult to perform. Recommendations for 'evidence-based medicine' are, therefore, relatively scarce. They relate mainly to use of therapy that is 'optional' and/or recently available, such as oestrogen replacement in post-menopausal women, androgen therapy in older men and growth hormone replacement.

AN OVERVIEW OF ENDOCRINOLOGY

Functional anatomy and physiology

Some endocrine glands, such as the parathyroids and pancreas, respond directly to metabolic signals, but most are controlled by hormones released from the pituitary gland. Anterior pituitary hormone secretion is controlled in turn by substances produced in the hypothalamus and released into portal blood, which drains directly down the pituitary stalk (Fig. 20.1). Posterior pituitary hormones are synthesised in the hypothalamus and transported down nerve axons, to be released from the posterior pituitary. Hormone release in the hypothalamus and pituitary is regulated by numerous stimuli and through feedback control by hormones produced by the target glands (thyroid, adrenal cortex and gonads). These integrated endocrine systems are called 'axes', and are listed in Figure 20.2.

A wide variety of molecules can act as hormones, including peptides such as insulin and growth hormone, glycoproteins such as thyroid-stimulating hormone, and amines such as noradrenaline (norepinephrine). The biological effects of hormones are mediated by binding to receptors. Many receptors are located on the cell surface. These interact with various intracellular signalling molecules on the cytosolic side of the plasma membrane to affect cell function, usually through changes in gene expression (p. 48). Some hormones, most notably steroids, triiodothyronine and vitamin D, bind to specific intracellular receptors, which directly bind to response elements on DNA to regulate gene expression (p. 42).

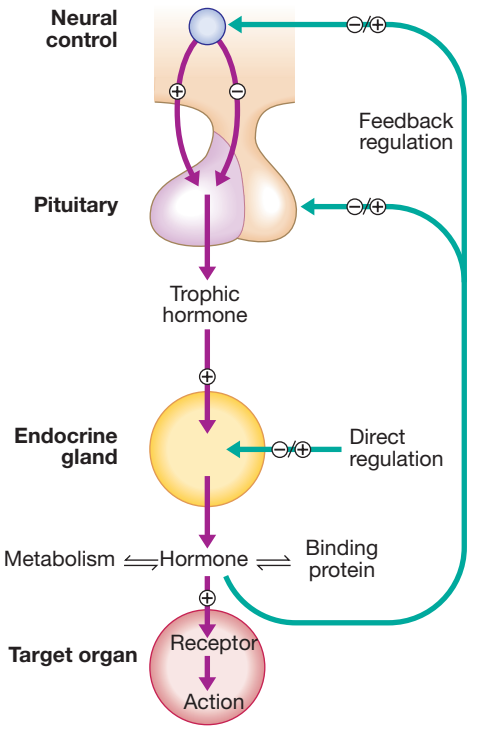


Fig. 20.1 An archetypal endocrine axis. Regulation by negative feedback and direct control is shown, along with the equilibrium between active circulating free hormone and bound or metabolised hormone.

The classical model of endocrine function involves hormones synthesised in endocrine glands, which are released into the circulation and act at sites distant from those of secretion (as in Fig. 20.1). However, additional levels of regulation are now recognised. Many other organs secrete hormones or contribute to the peripheral metabolism and activation of pro-hormones. A notable example is the production of oestrogens from adrenal androgens in adipose tissue by the enzyme aromatase. Some hormones, such as neurotransmitters, act in a paracrine fashion to affect adjacent cells, or act in an autocrine way to affect behaviour of the cell that produces the hormone.

Endocrine pathology

For each endocrine axis or major gland, diseases can be classified as shown in Box 20.1. Pathology arising within the gland is often called 'primary' disease (for example, primary hypothyroidism in Hashimoto's thyroiditis), while abnormal stimulation of the gland is often called 'secondary' disease (for example, secondary hypothyroidism in patients with a pituitary tumour and thyroid-stimulating hormone deficiency). Some pathological processes can affect multiple endocrine glands (p. 795); these may have a genetic basis (such as organ-specific autoimmune endocrine disorders and the multiple endocrine neoplasia (MEN) syndromes) or be a consequence of therapy for another disease (for example, following treatment of childhood cancer with chemotherapy and/or radiotherapy).

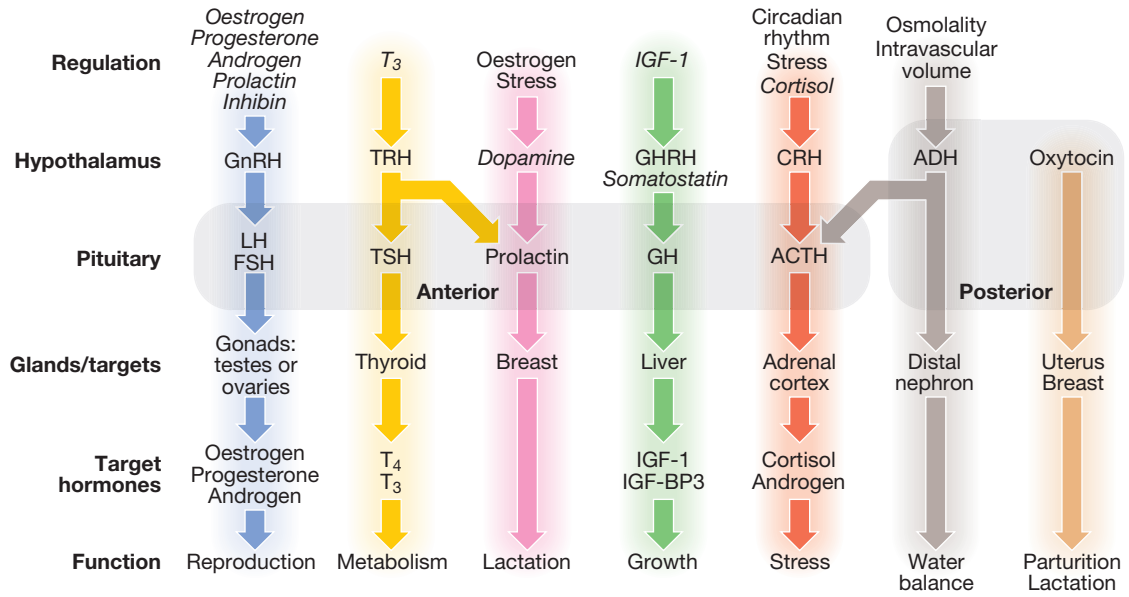

Fig. 20.2 The principal endocrine 'axes'. Some major endocrine glands are not controlled by the pituitary. These include the parathyroid glands (regulated by calcium concentrations, p. 766), the adrenal zona glomerulosa (regulated by the renin–angiotensin system, p. 771) and the endocrine pancreas (Ch. 21). Italics show negative regulation. (ACTH = adrenocorticotrophic hormone; ADH = antidiuretic hormone, arginine vasopressin; CRH = corticotrophin-releasing hormone; FSH = follicle-stimulating hormone; GH = growth hormone; GHRH = growth hormone-releasing hormone; GnRH = gonadotrophin-releasing hormone; IGF-1 = insulin-like growth factor-1; IGF-BP3 = IGF-binding protein-3; LH = luteinising hormone: T_3 = triiodothyronine; T_4 = thyroxine; TRH = thyrotrophin-releasing hormone; TSH = thyroid-stimulating hormone).

20.1 Classification of endocrine disease

Hormone excess
- Primary gland over-production
- Secondary to excess trophic substance

Hormone deficiency
- Primary gland failure
- Secondary to deficient trophic hormone

Hormone hypersensitivity
- Failure of inactivation of hormone
- Target organ over-activity/hypersensitivity

Hormone resistance
- Failure of activation of hormone
- Target organ resistance

Non-functioning tumours

Investigation of endocrine disease

Biochemical investigations play a central role in endocrinology. Most hormones can be measured in blood, but the circumstances in which the sample is taken are often crucial, especially for hormones with pulsatile secretion, such as growth hormone; those that show diurnal variation, such as cortisol; or those that demonstrate monthly variation, such as oestrogen or progesterone. Other investigations, such as imaging and biopsy, are more frequently reserved for patients who present with a tumour. The principles of investigation are shown in Box 20.2. The choice of test is often pragmatic, taking local access to reliable sampling facilities and laboratory measurements into account.

20.2 Principles of endocrine investigation

Timing of measurement
- Release of many hormones is rhythmical (pulsatile, circadian or monthly), so random measurement may be invalid and sequential or dynamic tests may be required

Choice of dynamic biochemical tests
- Abnormalities are often characterised by loss of normal regulation of hormone secretion
- If hormone deficiency is suspected, choose a stimulation test
- If hormone excess is suspected, choose a suppression test
- The more tests there are to choose from, the less likely it is that any single test is infallible, so avoid interpreting one result in isolation

Imaging
- Secretory cells also take up substrates, which can be labelled
- Most endocrine glands have a high prevalence of 'incidentalomas', so do not scan unless the biochemistry confirms endocrine dysfunction or the primary problem is a tumour

Biopsy
- Many endocrine tumours are difficult to classify histologically (e.g. adrenal carcinoma and adenoma)

Presenting problems in endocrine disease

Endocrine diseases present in many different ways and to clinicians in many different disciplines. Classical syndromes are described in relation to individual glands in the following sections. Often, however, the

20.3 Examples of non-specific presentations of endocrine disease

Symptom	Most likely endocrine disorder(s)
Lethargy and depression	Hypothyroidism, diabetes mellitus, hyperparathyroidism, hypogonadism, adrenal insufficiency, Cushing's syndrome
Weight gain	Hypothyroidism, Cushing's syndrome
Weight loss	Thyrotoxicosis, adrenal insufficiency, diabetes mellitus
Polyuria and polydipsia	Diabetes mellitus, diabetes insipidus, hyperparathyroidism, hypokalaemia (Conn's syndrome)
Heat intolerance	Thyrotoxicosis, menopause
Palpitations	Thyrotoxicosis, phaeochromocytoma
Headache	Acromegaly, pituitary tumour, phaeochromocytoma
Muscle weakness (usually proximal)	Thyrotoxicosis, Cushing's syndrome, hypokalaemia (e.g. Conn's syndrome), hyperparathyroidism, hypogonadism
Coarsening of features	Acromegaly, hypothyroidism

20.4 Classification of thyroid disease

	Primary	Secondary
Hormone excess	Graves' disease Multinodular goitre Adenoma Subacute thyroiditis	TSHoma
Hormone deficiency	Hashimoto's thyroiditis Atrophic hypothyroidism	Hypopituitarism
Hormone hypersensitivity	–	
Hormone resistance	Thyroid hormone resistance syndrome 5′-monodeiodinase deficiency	
Non-functioning tumours	Differentiated carcinoma Medullary carcinoma Lymphoma	

presentation is with non-specific symptoms (Box 20.3) or with asymptomatic biochemical abnormalities. In addition, endocrine diseases are encountered in the differential diagnosis of common complaints discussed in other chapters of this book, including electrolyte abnormalities (Ch. 16), hypertension (Ch. 18), obesity (Ch. 5) and osteoporosis (Ch. 25). Although diseases of the adrenal glands, hypothalamus and pituitary are relatively rare, their diagnosis often relies on astute clinical observation in a patient with non-specific complaints, so it is important that clinicians are familiar with their key features.

THE THYROID GLAND

Diseases of the thyroid predominantly affect females and are common, occurring in about 5% of the population. The thyroid axis is involved in the regulation of cellular differentiation and metabolism in virtually all nucleated cells, so that disorders of thyroid function have diverse manifestations. Structural diseases of the thyroid gland, such as goitre, commonly occur in patients with normal thyroid function. Diseases of the thyroid are summarised in Box 20.4.

Functional anatomy, physiology and investigations

Thyroid physiology is illustrated in Figure 20.3. The parafollicular C cells secrete calcitonin, which is of no apparent physiological significance in humans. The follicular epithelial cells synthesise thyroid hormones by incorporating iodine into the amino acid tyrosine on the surface of thyroglobulin (Tg), a protein secreted into the colloid of the follicle. Iodide is a key substrate for thyroid hormone synthesis; a dietary intake in excess of 100 μg/day is required to maintain thyroid function in adults. The thyroid secretes predominantly thyroxine (T_4) and only a small amount of triiodothyronine (T_3); approximately 85% of T_3 in blood is produced from T_4 by a family of monodeiodinase enzymes which are active in many tissues, including liver, muscle, heart and kidney. Selenium is an integral component of these monodeiodinases. T_4 can be regarded as a pro-hormone, since it has a longer half-life in blood than T_3 (approximately 1 week compared with approximately 18 hours), and binds and activates thyroid hormone receptors less effectively than T_3. T_4 can also be converted to the inactive metabolite, reverse T_3.

T_3 and T_4 circulate in plasma almost entirely (> 99%) bound to transport proteins, mainly thyroxine-binding globulin (TBG). It is the unbound or free hormones which diffuse into tissues and exert diverse metabolic actions. Some laboratories use assays which measure total T_4 and T_3 in plasma, but it is increasingly common to measure free T_4 and free T_3. The advantage of the free hormone measurements is that they are not influenced by changes in the concentration of binding proteins; in pregnancy, for example, TBG levels are increased and total T_3 and T_4 may be raised, but free thyroid hormone levels are normal.

Production of T_3 and T_4 in the thyroid is stimulated by thyrotrophin (thyroid-stimulating hormone, TSH), a glycoprotein released from the thyrotroph cells of the anterior pituitary in response to the hypothalamic tripeptide, thyrotrophin-releasing hormone (TRH). A circadian rhythm of TSH secretion can be demonstrated with a peak at 0100 hrs and trough at 1100 hrs, but the variation is small so that thyroid function can be assessed reliably from a single blood sample taken at any time of day and does not usually require any dynamic stimulation or suppression tests. There is a negative feedback of thyroid hormones on the hypothalamus and pituitary such that in thyrotoxicosis, when plasma concentrations of T_3 and T_4 are raised, TSH secretion is suppressed. Conversely, in hypothyroidism due to disease of the thyroid gland, low T_3 and T_4 are associated with high

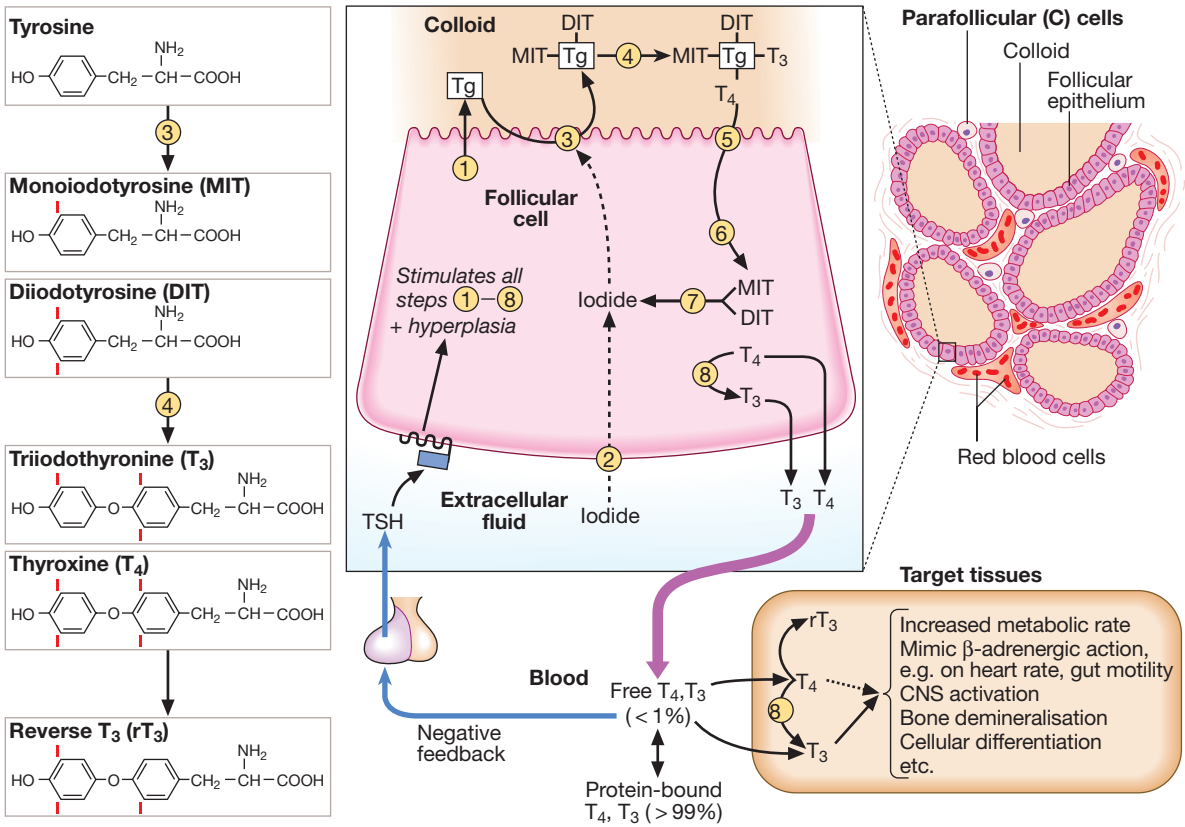

Fig. 20.3 Structure and function of the thyroid gland. (1) Thyroglobulin (Tg) is synthesised and secreted into the colloid of the follicle. (2) Inorganic iodide (I^-) is actively transported into the follicular cell ('trapping'). (3) Iodide is transported on to the colloidal surface by a transporter (pendrin, defective in Pendred's syndrome) and 'organified' by the thyroid peroxidase enzyme, which incorporates it into the amino acid tyrosine on the surface of Tg to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). (4) Iodinated tyrosines couple to form T_3 and T_4. (5) Tg is endocytosed. (6) Tg is cleaved by proteolysis to free the iodinated tyrosine and thyroid hormones. (7) Iodinated tyrosine is dehalogenated to recycle the iodide. (8) T_4 is converted to T_3 by 5′-monodeiodinase.

20.5 How to interpret thyroid function test results

TSH	T_4	T_3	Most likely interpretation(s)
U.D.	Raised	Raised	Primary thyrotoxicosis
U.D.	Normal[1]	Raised	Primary T_3-toxicosis
U.D.	Normal[1]	Normal[1]	Subclinical thyrotoxicosis
U.D. or low	Raised	Low or normal	Non-thyroidal illness, amiodarone therapy
U.D.	Low	Low	Secondary hypothyroidism[4] Transient thyroiditis in evolution
Normal	Low	Low[2]	Secondary hypothyroidism[4]
Mildly elevated 5–20 mU/L	Low	Low[2]	Primary hypothyroidism Secondary hypothyroidism[4]
Elevated > 20 mU/L	Low	Low[2]	Primary hypothyroidism
Mildly elevated 5–20 mU/L	Normal[3]	Normal[2]	Subclinical hypothyroidism
Elevated 20–500 mU/L	Normal	Normal	Artefact Endogenous IgG antibodies which interfere with TSH assay
Elevated	Raised	Raised	Non-compliance with T_4 replacement – recent 'loading' dose Secondary thyrotoxicosis[4] Thyroid hormone resistance

[1]Usually upper part of reference range. [2]T_3 is not a sensitive indicator of hypothyroidism and should not be requested.
[3]Usually lower part of reference range. [4]i.e. Secondary to pituitary or hypothalamic disease. Note that TSH assays may report detectable TSH.
(U.D. = undetectable)

circulating TSH levels. The anterior pituitary is very sensitive to minor changes in thyroid hormone levels within the reference range. Although the reference range for free T_4 is 9–21 pmol/L (700–1632 pg/dL), a rise or fall of 5 pmol/L in an individual in whom the level is usually 15 pmol/L would be associated on the one hand with undetectable TSH, and on the other hand with a raised TSH. For this reason, TSH is usually regarded as the most useful investigation of thyroid function. However, interpretation of TSH values without considering thyroid hormone levels may be misleading in patients with pituitary disease (see Box 20.58, p. 787). Moreover, TSH may take several weeks to 'catch up' with T_4 and T_3 levels, for example, when prolonged suppression of TSH in thyrotoxicosis is relieved by antithyroid therapy. Heterophilic antibodies can also interfere with the TSH assay and cause a spuriously high measurement. Common patterns of abnormal thyroid function test results and their interpretation are shown in Box 20.5.

Other modalities commonly employed in the investigation of thyroid disease include measurement of antibodies against the TSH receptor or other thyroid antigens (see Box 20.8, p. 741), radioisotope imaging, fine needle aspiration biopsy and ultrasound. Their use is described below.

Presenting problems in thyroid disease

The most common presentations are hyperthyroidism (thyrotoxicosis), hypothyroidism and enlargement of the thyroid (goitre or thyroid nodule). Widespread availability of thyroid function tests has led to the increasingly frequent identification of patients with abnormal results who are either asymptomatic or have non-specific complaints such as tiredness and weight gain.

Thyrotoxicosis

Thyrotoxicosis describes a constellation of clinical features arising from elevated circulating levels of thyroid hormone. The most common causes are Graves' disease, multinodular goitre and autonomously functioning thyroid nodules (toxic adenoma) (Box 20.6). Thyroiditis is more common in parts of the world where relevant viral infections occur, such as North America.

Clinical assessment

The clinical manifestations of thyrotoxicosis are shown in Box 20.7 and an approach to differential diagnosis is given in Figure 20.4. The most common symptoms are weight loss with a normal or increased appetite, heat intolerance, palpitations, tremor and irritability. Tachycardia, palmar erythema and lid lag are common signs. Not all patients have a palpable goitre, but experienced clinicians can discriminate the diffuse soft goitre of Graves' disease from the irregular enlargement of a multinodular goitre. All causes of thyrotoxicosis can cause lid retraction and lid lag, due to potentiation of sympathetic innervation of the levator palpebrae muscles, but only Graves' disease causes other features of ophthalmopathy, including periorbital oedema, conjunctival irritation, exophthalmos and diplopia. Pretibial myxoedema (p. 751) and the rare thyroid acropachy (a periosteal hypertrophy, indistinguishable from finger clubbing) are also specific to Graves' disease.

20.6 Causes of thyrotoxicosis and their relative frequencies

Cause	Frequency[1] (%)
Graves' disease	76
Multinodular goitre	14
Solitary thyroid adenoma	5
Thyroiditis	
Subacute (de Quervain's)[2]	3
Post-partum[2]	0.5
Iodide-induced	
Drugs (amiodarone)[2]	1
Radiographic contrast media[2]	–
Iodine prophylaxis programme[2]	–
Extrathyroidal source of thyroid hormone	
Factitious thyrotoxicosis[2]	0.2
Struma ovarii[2,3]	–
TSH-induced	
TSH-secreting pituitary adenoma	0.2
Choriocarcinoma and hydatidiform mole[4]	–
Follicular carcinoma ± metastases	0.1

[1]In a series of 2087 patients presenting to the Royal Infirmary of Edinburgh over a 10-year period.
[2]Characterised by negligible radio-isotope uptake.
[3]i.e. Ovarian teratoma containing thyroid tissue.
[4]Human chorionic gonadotrophin has thyroid-stimulating activity.

Investigations

The first-line investigations are serum T_3, T_4 and TSH. If abnormal values are found, the tests should be repeated and the abnormality confirmed in view of the likely need for prolonged medical treatment or destructive therapy. In most patients, serum T_3 and T_4 are both elevated, but T_4 is in the upper part of the reference range and T_3 raised (T_3 toxicosis) in about 5%. Serum TSH is undetectable in primary thyrotoxicosis, but values can be raised in the very rare syndrome of secondary thyrotoxicosis caused by a TSH-producing pituitary adenoma. When biochemical thyrotoxicosis has been confirmed, further investigations should be undertaken to determine the underlying cause, including measurement of TSH receptor antibodies (TRAb, elevated in Graves' disease, Box 20.8) and isotope scanning, as shown in Figure 20.4. Other non-specific abnormalities are common (Box 20.9). An ECG may demonstrate sinus tachycardia or atrial fibrillation.

Radio-iodine uptake tests measure the proportion of isotope that is trapped in the whole gland, but have been largely superseded by ^{99m}technetium scintigraphy scans, which also indicate trapping, are quicker to perform with a lower dose of radioactivity, and provide a higher-resolution image. In low-uptake thyrotoxicosis, the cause is usually a transient thyroiditis (p. 751). Occasionally, patients induce 'factitious thyrotoxicosis' by consuming excessive amounts of a thyroid hormone preparation, most often levothyroxine. The exogenous thyroxine suppresses pituitary TSH secretion and hence iodine uptake, serum thyroglobulin and release of endogenous thyroid hormones. The T_4:T_3 ratio (typically

20.7 Clinical features of thyroid dysfunction

Thyrotoxicosis		Hypothyroidism	
Symptoms	**Signs**	**Symptoms**	**Signs**
Common			
Weight loss despite normal or increased appetite Heat intolerance, sweating Palpitations, tremor Dyspnoea, fatigue Irritability, emotional lability	Weight loss Tremor Palmar erythema Sinus tachycardia Lid retraction, lid lag	Weight gain Cold intolerance Fatigue, somnolence Dry skin Dry hair Menorrhagia	Weight gain
Less common			
Osteoporosis (fracture, loss of height) Diarrhoea, steatorrhoea Angina Ankle swelling Anxiety, psychosis Muscle weakness Periodic paralysis (predominantly in Chinese) Pruritus, alopecia Amenorrhoea/oligomenorrhoea Infertility, spontaneous abortion Loss of libido, impotence Excessive lacrimation	Goitre with bruit[1] Atrial fibrillation[2] Systolic hypertension/ increased pulse pressure Cardiac failure[2] Hyper-reflexia Ill-sustained clonus Proximal myopathy Bulbar myopathy[2]	Constipation Hoarseness Carpal tunnel syndrome Alopecia Aches and pains Muscle stiffness Deafness Depression Infertility	Hoarse voice Facial features: Purplish lips Malar flush Periorbital oedema Loss of lateral eyebrows Anaemia Carotenaemia Erythema ab igne Bradycardia hypertension Delayed relaxation of reflexes Dermal myxoedema
Rare			
Vomiting Apathy Anorexia Exacerbation of asthma	Gynaecomastia Spider naevi Onycholysis Pigmentation	Psychosis (myxoedema madness) Galactorrhoea Impotence	Ileus, ascites Pericardial and pleural effusions Cerebellar ataxia Myotonia

[1]In Graves' disease only. [2]Features found particularly in elderly patients.

20.8 Prevalence of thyroid autoantibodies (%)

	Antibodies to:		
	Thyroid peroxidase[1]	**Thyroglobulin**	**TSH receptor[2]**
Normal population	8–27	5–20	0
Graves' disease	50–80	50–70	80–95
Autoimmune hypothyroidism	90–100	80–90	10–20
Multinodular goitre	~30–40	~30–40	0
Transient thyroiditis	~30–40	~30–40	0

[1]Thyroid peroxidase (TPO) antibodies are the principal component of what was previously measured as thyroid 'microsomal' antibodies.
[2]TSH receptor antibodies (TRAb) can be agonists (stimulatory, causing Graves' thyrotoxicosis) or antagonists ('blocking', causing hypothyroidism)

20.9 Non-specific laboratory abnormalities in thyroid dysfunction*

Thyrotoxicosis

- Serum enzymes: raised alanine aminotransferase, γ-glutamyl transferase (GGT), and alkaline phosphatase from liver and bone
- Raised bilirubin
- Mild hypercalcaemia
- Glycosuria: associated diabetes mellitus, 'lag storage' glycosuria

Hypothyroidism

- Serum enzymes: raised creatine kinase, aspartate aminotransferase, lactate dehydrogenase (LDH)
- Hypercholesterolaemia
- Anaemia: normochromic normocytic or macrocytic
- Hyponatraemia

*These abnormalities are not useful in differential diagnosis, so the tests should be avoided and any further investigation undertaken only if abnormalities persist when the patient is euthyroid.

30:1 in conventional thyrotoxicosis) is increased to above 70:1 because circulating T_3 in factitious thyrotoxicosis is derived exclusively from the peripheral monodeiodination of T_4 and not from thyroid secretion. The combination of negligible iodine uptake, high T_4:T_3 ratio and a low or undetectable thyroglobulin is diagnostic.

Management

Definitive treatment of thyrotoxicosis depends on the underlying cause and may include antithyroid drugs, radioactive iodine or surgery. A non-selective β-adrenoceptor antagonist (β-blocker), such as propranolol

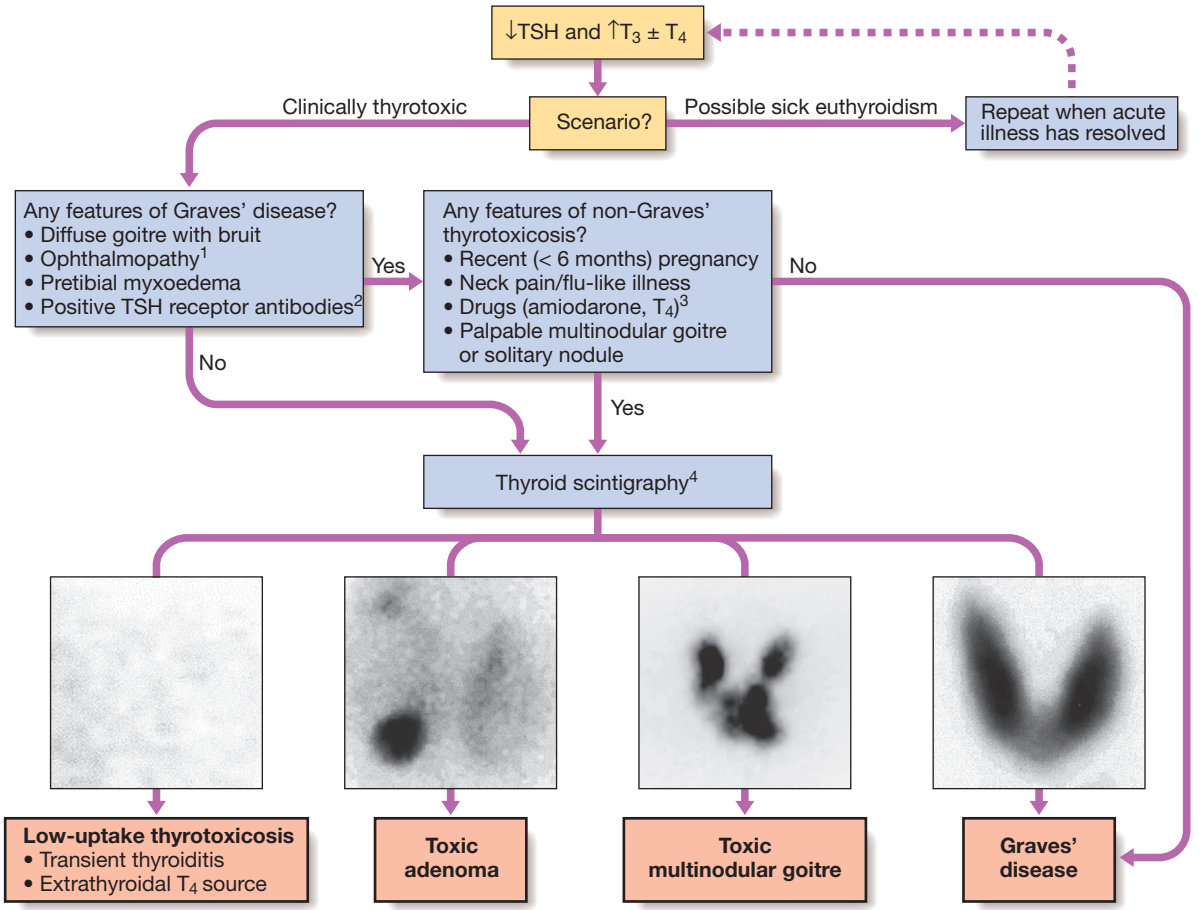

Fig. 20.4 Establishing the differential diagnosis in thyrotoxicosis. (1) Graves' ophthalmopathy refers to clinical features of exophthalmos and periorbital and conjunctival oedema, not simply the lid lag and lid retraction which can occur in all forms of thyrotoxicosis. (2) TSH receptor antibodies are very rare in patients without autoimmune thyroid disease, but only occur in 80–95% of patients with Graves' disease; a positive test is therefore confirmatory, but a negative test does not exclude Graves' disease. Other thyroid antibodies (e.g. anti-peroxidase and anti-thyroglobulin antibodies) are unhelpful in the differential diagnosis since they occur frequently in the population and are found with several of the disorders which cause thyrotoxicosis. (3) Scintigraphy is not necessary in most cases of drug-induced thyrotoxicosis. (4) ^{99m}Technetium pertechnetate scans of patients with thyrotoxicosis. In low-uptake thyrotoxicosis, most commonly due to a viral, post-partum or iodine-induced thyroiditis, there is negligible isotope detected in the region of the thyroid, although uptake is apparent in nearby salivary glands (not shown here). In a toxic adenoma there is lack of uptake of isotope by the rest of the thyroid gland due to suppression of serum TSH. In multinodular goitre there is relatively low, patchy uptake within the nodules; such an appearance is not always associated with a palpable thyroid. In Graves' disease there is diffuse uptake of isotope.

(160 mg daily) or nadolol (40–80 mg daily), will alleviate but not abolish symptoms in most patients within 24–48 hours. Beta-blockers should not be used for long-term treatment of thyrotoxicosis but are extremely useful in the short term, whilst patients are awaiting hospital consultation or following ^{131}I therapy.

Atrial fibrillation in thyrotoxicosis

Atrial fibrillation occurs in about 10% of patients with thyrotoxicosis. The incidence increases with age, so that almost half of all males with thyrotoxicosis over the age of 60 are affected. Moreover, subclinical thyrotoxicosis (p. 745) is a risk factor for atrial fibrillation. Characteristically, the ventricular rate is little influenced by digoxin, but responds to the addition of a β-blocker. Thromboembolic vascular complications are particularly common in thyrotoxic atrial fibrillation so that anticoagulation with warfarin is required, unless contraindicated. Once thyroid hormone and TSH concentrations have been returned to normal, atrial fibrillation will spontaneously revert to sinus rhythm in about 50% of patients, but cardioversion may be required in the remainder.

Thyrotoxic crisis ('thyroid storm')

This is a rare but life-threatening complication of thyrotoxicosis. The most prominent signs are fever, agitation, confusion, tachycardia or atrial fibrillation and, in the older patient, cardiac failure. It is a medical emergency, which has a mortality of 10% despite early recognition and treatment. Thyrotoxic crisis is most commonly precipitated by infection in a patient with previously unrecognised or inadequately treated thyrotoxicosis. It may also develop shortly after subtotal thyroidectomy in an ill-prepared patient or within a few days of ^{131}I therapy, when acute irradiation damage may lead to a transient rise in serum thyroid hormone levels.

Patients should be rehydrated and given propranolol, either orally (80 mg 4 times daily) or intravenously (1–5 mg 4 times daily). Sodium ipodate (500 mg per day orally) will restore serum T_3 levels to normal in

48–72 hours. This is a radiographic contrast medium which not only inhibits the release of thyroid hormones, but also reduces the conversion of T_4 to T_3 and is, therefore, more effective than potassium iodide or Lugol's solution. Dexamethasone (2 mg 4 times daily) and amiodarone have similar effects. Oral carbimazole 40–60 mg daily (p. 748) should be given to inhibit the synthesis of new thyroid hormone. If the patient is unconscious or uncooperative, carbimazole can be administered rectally with good effect, but no preparation is available for parenteral use. After 10–14 days the patient can usually be maintained on carbimazole alone.

Hypothyroidism

Hypothyroidism is a common condition with various causes (Box 20.10), but autoimmune disease (Hashimoto's thyroiditis) and thyroid failure following ^{131}I or surgical treatment of thyrotoxicosis account for over 90% of cases, except in areas where iodine deficiency is endemic. Women are affected approximately six times more frequently than men.

Clinical assessment

The clinical presentation depends on the duration and severity of the hypothyroidism. Those in whom complete thyroid failure has developed insidiously over months or years may present with many of the clinical features listed in Box 20.7. A consequence of prolonged hypothyroidism is the infiltration of many body tissues by the mucopolysaccharides, hyaluronic acid and chondroitin sulphate, resulting in a low-pitched voice, poor hearing, slurred speech due to a large tongue, and compression of the median nerve at the wrist (carpal tunnel syndrome). Infiltration of the dermis gives rise to non-pitting oedema (myxoedema), which is most marked in the skin of the hands, feet and eyelids. The resultant periorbital puffiness is often striking and may be combined with facial pallor due to vasoconstriction and anaemia, or a lemon-yellow tint to the skin caused by carotenaemia, along with purplish lips and malar flush. Most cases of hypothyroidism are not clinically obvious, however, and a high index of suspicion needs to be maintained so that the diagnosis is not overlooked in individuals complaining of non-specific symptoms such as tiredness, weight gain, depression or carpal tunnel syndrome.

The key discriminatory features in the history and examination are highlighted in Figure 20.5. Care must be taken to identify patients with transient hypothyroidism, in whom life-long levothyroxine therapy is inappropriate. This is often observed during the first 6 months after subtotal thyroidectomy or ^{131}I treatment of Graves' disease, in the post-thyrotoxic phase of subacute thyroiditis and in post-partum thyroiditis. In these conditions, levothyroxine treatment is not always necessary, as the patient may be asymptomatic during the short period of thyroid failure.

20.10 Causes of hypothyroidism

Causes	Anti-TPO antibodies[1]	Goitre[2]
Autoimmune		
Hashimoto's thyroiditis	++	±
Spontaneous atrophic hypothyroidism	–	–
Graves' disease with TSH receptor-blocking antibodies	+	±
Iatrogenic		
Radioactive iodine ablation	+	±
Thyroidectomy	+	–
Drugs

[1]As shown in Box 20.8, thyroid autoantibodies are common in the healthy population, so might be present in anyone. ++ high titre; + more likely to be detected than in the healthy population; – not especially likely.
[2]Goitre: – absent; ± may be present; ++ characteristic.

Investigations

In the vast majority of cases, hypothyroidism results from an intrinsic disorder of the thyroid gland (primary hypothyroidism). In this situation, serum T_4 is low and TSH is elevated, usually in excess of 20 mU/L. Measurements of serum T_3 are unhelpful since they do not discriminate reliably between euthyroidism and hypothyroidism. Secondary hypothyroidism is rare and is caused by failure of TSH secretion in an individual with hypothalamic or anterior pituitary disease. Other non-specific abnormalities are shown in Box 20.9. In severe, prolonged hypothyroidism, the electrocardiogram (ECG) classically demonstrates sinus bradycardia with low-voltage complexes and ST segment and T-wave abnormalities. Measurement of thyroid peroxidase antibodies is helpful but further investigations are rarely required (see Fig. 20.5).

Management

Treatment is with levothyroxine replacement. It is customary to start with a low dose of 50 µg per day for 3 weeks, increasing thereafter to 100 µg per day for a further 3 weeks and finally to a maintenance dose of 100–150 µg per day. In younger patients, it is safe to initiate levothyroxine at a higher dose (for example, 100 µg per day), to allow a more rapid normalisation of thyroid hormone levels. Levothyroxine has a half-life of 7 days so it should always be taken as a single daily dose and at least 6 weeks should pass before repeating thyroid function tests and adjusting the dose, usually by 25 µg per day. Patients feel better within 2–3 weeks. Reduction in weight and periorbital puffiness occurs quickly, but the restoration of skin and hair texture and

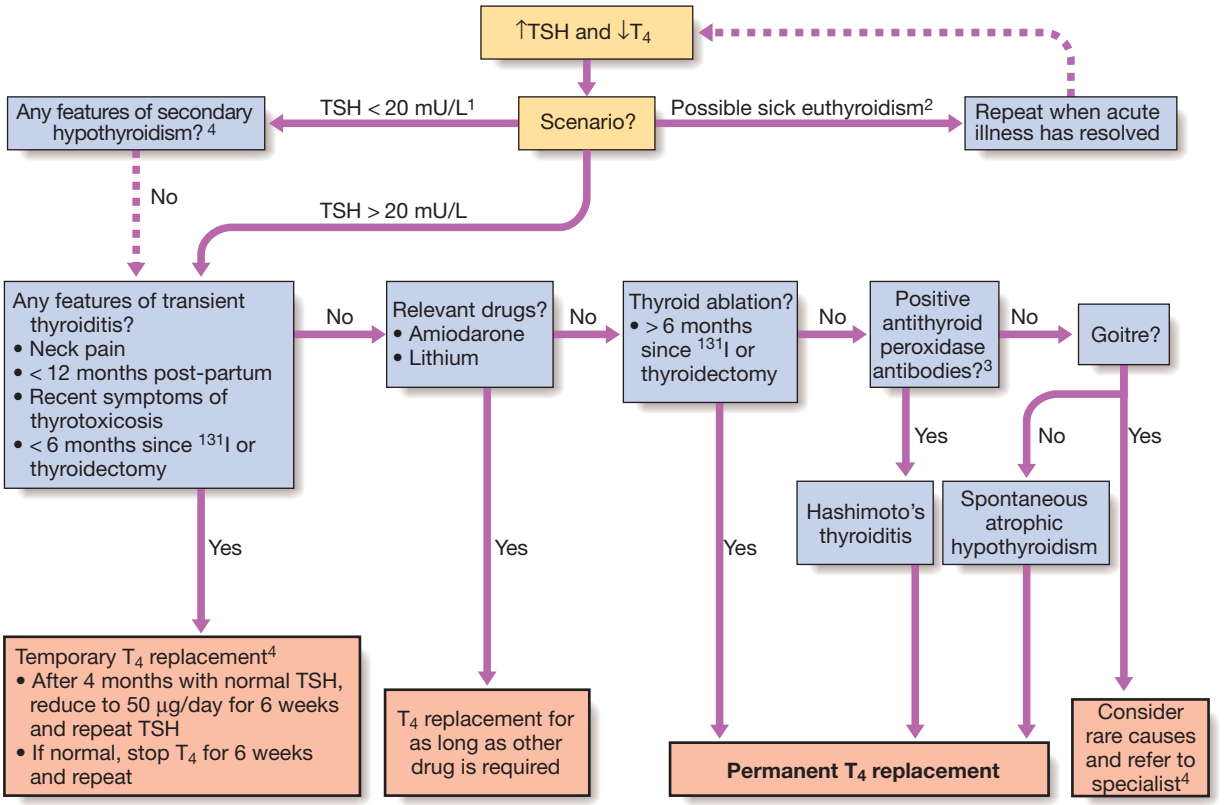

Fig. 20.5 An approach to adults with suspected primary hypothyroidism. This scheme ignores congenital causes of hypothyroidism (see Box 20.10), such as thyroid aplasia and dyshormonogenesis (associated with nerve deafness in Pendred's syndrome), which are usually diagnosed in childhood. (1) Immunoreactive TSH may be detected at normal or even modestly elevated levels in patients with pituitary failure; unless T_4 is only marginally low, TSH should be > 20 mU/L to confirm the diagnosis of primary hypothyroidism. (2) The usual abnormality in sick euthyroidism is a low TSH but any pattern can occur. (3) Thyroid peroxidase antibodies are highly sensitive but not very specific for autoimmune thyroid disease (see Boxes 20.8 and 20.10). (4) Specialist advice is most appropriate where indicated. Secondary hypothyroidism is rare, but is suggested by deficiency of pituitary hormones or by clinical features of pituitary tumour such as headache or visual field defect (p. 789). Rare causes of hypothyroidism with goitre include dyshormonogenesis and infiltration of the thyroid (see Box 20.10).

resolution of any effusions may take 3–6 months. As illustrated in Figure 20.5, most patients do not require specialist review but will require life-long levothyroxine therapy.

The dose of levothyroxine should be adjusted to maintain serum TSH within the reference range. To achieve this, serum T_4 often needs to be in the upper part of the reference range or even slightly raised, because the T_3 required for receptor activation is derived exclusively from conversion of T_4 within the target tissues, without the usual contribution from thyroid secretion. Some physicians advocate combined replacement with T_4 and T_3 or preparations of animal thyroid extract, but this approach remains controversial and is not supported by robust evidence. Some patients remain symptomatic despite normalisation of TSH and may wish to take extra levothyroxine, which suppresses TSH. However, suppressed TSH is a risk factor for osteoporosis and atrial fibrillation (p. 745; subclinical thyrotoxicosis), so this approach cannot be recommended.

It is important to measure thyroid function every 1–2 years once the dose of levothyroxine is stabilised. This encourages patient compliance with therapy and allows adjustment for variable underlying thyroid activity and other changes in levothyroxine requirements (Box 20.11). Some patients have a persistent elevation of serum TSH despite an ostensibly adequate replacement dose of levothyroxine; most commonly, this is a consequence of suboptimal compliance with therapy. There may be differences in bioavailability between the numerous generic preparations of levothyroxine and so, if an individual is experiencing marked changes in serum TSH despite optimal compliance, the prescription of a branded preparation of levothyroxine could be considered. Levothyroxine absorption is maximal when the medication is taken before bed and may be further optimised by taking a vitamin C supplement.

In some poorly compliant patients, levothyroxine is taken diligently or even in excess for a few days prior to a clinic visit, resulting in the seemingly anomalous combination of a high serum T_4 and high TSH (see Box 20.5, p. 739).

Levothyroxine replacement in ischaemic heart disease

Hypothyroidism and ischaemic heart disease are common conditions that often occur together. Although angina may remain unchanged in severity or paradoxically disappear with restoration of metabolic rate, exacerbation of myocardial ischaemia, infarction and

20.11 Situations in which an adjustment of the dose of levothyroxine may be necessary

Increased dose required

Use of other medication
- Increase T_4 clearance: phenobarbital, phenytoin, carbamazepine, rifampicin, sertraline*, chloroquine*
- Interfere with intestinal T_4 absorption: colestyramine, sucralfate, aluminium hydroxide, ferrous sulphate, dietary fibre supplements, calcium carbonate

Pregnancy or oestrogen therapy
- Increases concentration of serum thyroxine-binding globulin

After surgical or ^{131}I ablation of Graves' disease
- Reduces thyroidal secretion with time

Malabsorption

Decreased dose required

Ageing
- Decreases T_4 clearance

Graves' disease developing in patient with long-standing primary hypothyroidism
- Switch from production of blocking to stimulating TSH receptor antibodies

*Mechanism not fully established.

sudden death are recognised complications of levothyroxine replacement, even using doses as low as 25 µg per day. In patients with known ischaemic heart disease, thyroid hormone replacement should be introduced at low dose and increased very slowly under specialist supervision. It has been suggested that T_3 has an advantage over T_4, since T_3 has a shorter half-life and any adverse effect will reverse more quickly, but the more distinct peak in hormone levels after each dose of T_3 is a disadvantage. Coronary angioplasty or bypass surgery may be required if angina is exacerbated by levothyroxine replacement therapy.

Hypothyroidism in pregnancy

Most pregnant women with primary hypothyroidism require an increase in the dose of levothyroxine of approximately 25–50 µg daily to maintain normal TSH levels. This may reflect increased metabolism of thyroxine by the placenta and increased serum thyroxine-binding globulin during pregnancy, resulting in an increase in the total thyroid hormone pool to maintain the same free T_4 and T_3 concentrations. Inadequate maternal T_4 therapy may be associated with impaired cognitive development in an unborn child and so women are usually advised to increase their daily levothyroxine dose by 25 µg when pregnancy is confirmed. Serum TSH and free T_4 should be measured during each trimester and the dose of levothyroxine adjusted to maintain a normal TSH. See also Box 20.20 (p. 756).

Myxoedema coma

This is a very rare presentation of hypothyroidism in which there is a depressed level of consciousness, usually in an elderly patient who appears myxoedematous. Body temperature may be as low as 25°C, convulsions are not uncommon and cerebrospinal fluid (CSF) pressure and protein content are raised. The mortality rate is 50% and survival depends on early recognition and treatment of hypothyroidism and other factors contributing to the altered consciousness level, such as medication, cardiac failure, pneumonia, dilutional hyponatraemia and respiratory failure.

Myxoedema coma is a medical emergency and treatment must begin before biochemical confirmation of the diagnosis. Suspected cases should be treated with an intravenous injection of 20 µg triiodothyronine, followed by further injections of 20 µg 3 times daily until there is sustained clinical improvement. In survivors, there is a rise in body temperature within 24 hours and, after 48–72 hours, it is usually possible to switch patients to oral levothyroxine in a dose of 50 µg daily. Unless it is apparent that the patient has primary hypothyroidism, the thyroid failure should also be assumed to be secondary to hypothalamic or pituitary disease and treatment given with hydrocortisone 100 mg IM 3 times daily, pending the results of T_4, TSH and cortisol measurement (p. 787). Other measures include slow rewarming (p. 105), cautious use of intravenous fluids, broad-spectrum antibiotics and high-flow oxygen. Occasionally, assisted ventilation may be necessary.

Symptoms of hypothyroidism with normal thyroid function tests

The classic symptoms of hypothyroidism are, by their very nature, non-specific (see Box 20.3). There is a wide differential diagnosis for symptoms such as 'fatigue', 'weight gain' and 'low mood'. As has been noted, outside the context of pituitary and hypothalamic disease, serum TSH is an excellent measure of an individual's thyroid hormone status. However, some individuals believe that they have hypothyroidism despite normal serum TSH concentrations. There are a large number of websites which claim that serum TSH is not a good measure of thyroid hormone status and suggest that other factors, such as abnormalities of T_4 to T_3 conversion, may lead to low tissue levels of active thyroid hormones. Such websites often advocate a variety of tests of thyroid function of dubious scientific validity, including measurement of serum reverse T_3, 24-hour urine T_3, basal body temperature, skin iodine absorption, and levels of selenium in blood and urine. Individuals who believe they have hypothyroidism, despite normal conventional tests of thyroid function, can be difficult to manage. They require reassurance that their symptoms are being taken seriously and that organic disease has been carefully considered; if their symptoms persist, then referral to a team specialising in medically unexplained symptoms should be considered.

Asymptomatic abnormal thyroid function tests

One of the most common problems in medical practice is how to manage patients with abnormal thyroid function tests who have no obvious signs or symptoms of thyroid disease. These can be divided into three categories.

Subclinical thyrotoxicosis

Serum TSH is undetectable, and serum T_3 and T_4 are at the upper end of the reference range. This combination is most often found in older patients with multinodular goitre. These patients are at increased risk of

atrial fibrillation and osteoporosis, and hence the consensus view is that they have mild thyrotoxicosis and require therapy, usually with ^{131}I. Otherwise, annual review is essential, as the conversion rate to overt thyrotoxicosis with elevated T_4 and/or T_3 concentrations is 5% each year.

Subclinical hypothyroidism

Serum TSH is raised, and serum T_3 and T_4 concentrations are at the lower end of the reference range. This may persist for many years, although there is a risk of progression to overt thyroid failure, particularly if antibodies to thyroid peroxidase are present or if the TSH rises above 10 mU/L. In patients with non-specific symptoms, a trial of levothyroxine therapy may be appropriate. In those with positive autoantibodies or TSH greater than 10 mU/L, it is better to treat the thyroid failure early rather than risk loss to follow-up and subsequent presentation with profound hypothyroidism. Levothyroxine should be given in a dose sufficient to restore the serum TSH concentration to normal.

Non-thyroidal illness ('sick euthyroidism')

This typically presents with a low serum TSH, raised T_4 and normal or low T_3, in a patient with systemic illness who does not have clinical evidence of thyroid disease. These abnormalities are caused by decreased peripheral conversion of T_4 to T_3, altered levels of binding proteins and their affinity for thyroid hormones, and often reduced secretion of TSH. During convalescence, serum TSH concentrations may increase to levels found in primary hypothyroidism. As thyroid function tests are difficult to interpret in patients with non-thyroidal illness, it is wise to avoid performing thyroid function tests unless there is clinical evidence of concomitant thyroid disease. If an abnormal result is found, treatment should only be given with specialist advice and the diagnosis should be re-evaluated after recovery.

Thyroid lump or swelling

A lump or swelling in the thyroid gland can be a source of considerable anxiety for patients. There are numerous causes but, broadly speaking, a thyroid swelling is either a solitary nodule, a multinodular goitre or a diffuse goitre (Box 20.12). Nodular thyroid disease is more common in women and occurs in approximately 30% of the adult female population. The majority of thyroid nodules are impalpable but may be identified when imaging of the neck is performed for another reason, such as during Doppler ultrasonography of the carotid arteries or computed tomographic pulmonary angiography. Increasingly, thyroid nodules are identified during staging of patients with cancer with computed tomography (CT), magnetic resonance imaging (MRI) or positron emission tomography (PET) scans. Palpable thyroid nodules occur in 4–8% of adult women and 1–2% of adult men, and classically present when the individual (or a friend or relative) notices a lump in the neck. Multinodular goitres and solitary nodules sometimes present with acute painful enlargement due to haemorrhage into a nodule.

Patients with thyroid nodules often worry that they have cancer, but the reality is that only 5–10% of thyroid nodules are malignant. A solitary nodule presenting in childhood or adolescence, particularly if there is a past history of head and neck irradiation, or one presenting in the elderly should heighten suspicion of a primary thyroid malignancy (p. 754). The presence of cervical lymphadenopathy also increases the likelihood of malignancy. Rarely, a secondary deposit from a renal, breast or lung carcinoma presents as a painful, rapidly growing, solitary thyroid nodule. Thyroid nodules identified on PET scanning have an approximately 33% chance of being malignant.

20.12 Causes of thyroid enlargement

Diffuse goitre
- Simple goitre
- Hashimoto's thyroiditis[1]
- Graves' disease
- Drugs
  Iodine, amiodarone, lithium
- Iodine deficiency (endemic goitre)[1]
- Suppurative thyroiditis[2]
- Transient thyroiditis[2]
- Dyshormonogenesis[1]
- Infiltrative
  Amyloidosis, sarcoidosis etc.
- Riedel's thyroiditis[2]

Multinodular goitre

Solitary nodule
- Colloid cyst
- Hyperplastic nodule
- Follicular adenoma
- Papillary carcinoma
- Follicular carcinoma
- Medullary cell carcinoma
- Anaplastic carcinoma
- Lymphoma
- Metastasis

[1]Goitre likely to shrink with levothyroxine therapy. [2]Usually tender.

Clinical assessment and investigations

Swellings in the anterior part of the neck most commonly originate in the thyroid and this can be confirmed by demonstrating that the swelling moves on swallowing (p. 735). It is often possible to distinguish clinically between the three main causes of thyroid swelling. There is a broad differential diagnosis of anterior neck swellings, which includes lymphadenopathy, branchial cysts, dermoid cysts and thyroglossal duct cysts (the latter are classically located in the midline and move on protrusion of the tongue). An ultrasound scan should be performed urgently, if there is any doubt as to the aetiology of an anterior neck swelling.

Serum T_3, T_4 and TSH should be measured in all patients with a goitre or solitary thyroid nodule. The finding of biochemical thyrotoxicosis or hypothyroidism (both of which may be subclinical) should lead to investigations, as already described on pages 740 and 743.

Thyroid scintigraphy

Thyroid scintigraphy with ^{99m}technetium should be performed in an individual with a low serum TSH and a nodular thyroid to confirm the presence of an autonomously functioning ('hot') nodule (see Fig. 20.4, p. 742). In such circumstances, further evaluation by fine needle aspiration is not necessary. 'Cold nodules' on scintigraphy have a much higher likelihood of malignancy, but the majority are benign and so scintigraphy is not routinely used in the evaluation of thyroid nodules when TSH is normal.

Thyroid ultrasound

If thyroid function tests are normal, an ultrasound scan will determine the nature of the thyroid swelling. Ultrasound can establish whether there is generalised or localised swelling of the thyroid. Inflammatory disorders causing a diffuse goitre, such as Graves' disease and Hashimoto's thyroiditis, demonstrate a diffuse pattern of hypoechogenicity and, in the case of Graves' disease, increased thyroid blood flow may be seen on colour flow Doppler. The presence of thyroid autoantibodies will support the diagnosis of Graves' disease or Hashimoto's thyroiditis, while their absence in a younger patient with a diffuse goitre and normal thyroid function suggests a diagnosis of 'simple goitre' (p. 752).

Ultrasound can also readily determine the size and number of nodules within the thyroid and can distinguish solid nodules from those with a cystic element. It cannot reliably distinguish benign from malignant nodules but, in experienced hands, there are some ultrasound characteristics which are associated with a higher likelihood of malignancy. These include: hypervascularity of the nodule, the presence of microcalcification and irregular, infiltrative margins. A pure cystic nodule is highly unlikely to be malignant and a 'spongiform' appearance is also highly predicative of a benign aetiology.

Fine needle aspiration

Cytological examination of a thyroid nodule, following fine needle aspiration, is recommended for most thyroid nodules over 1 cm in size. Smaller nodules should be aspirated if there is a high suspicion of malignancy on clinical or ultrasound grounds, while some clinicians will be happy to observe a nodule up to 2 cm in size with a spongiform appearance. Individuals with a multinodular goitre have the same risk of malignancy as those with a solitary nodule. Sometimes, one of the nodules in a multinodular goitre is much larger than any other (a 'dominant' nodule), but ultimately the choice of nodule to biopsy should be based on ultrasound characteristics.

Fine needle aspiration of a thyroid nodule can be performed in the outpatient clinic using a standard 21-gauge needle and a 20 mL syringe, usually making several passes through different parts of the lesion. Ultrasound-guided needle aspiration is necessary for impalpable nodules and to permit targeting of the solid component of a mixed cystic/solid nodule. Aspiration may be therapeutic in the small proportion of patients in whom the swelling is a cyst, although recurrence on more than one occasion is an indication for surgery. Cytological examination can differentiate benign (80%) from definitely malignant or indeterminate nodules (20%), of which 25–50% are confirmed as cancers at surgery. The limitations of fine needle aspiration are that it cannot differentiate between follicular adenoma and carcinoma, and that in 10–20% of cases an inadequate specimen is obtained.

Management

Solitary nodules with a solid component in which cytology either is inconclusive or shows malignant cells are treated by surgical excision. Molecular techniques may, in the future, improve the diagnostic accuracy of thyroid cytology and allow a more conservative strategy for individuals with an indeterminate biopsy (Box 20.13). Nodules in which malignancy is confirmed by formal histology are treated as described on page 754. Those which have benign cytology and a reassuring ultrasound appearance may by observed by interval ultrasound scans. In parts of the world with borderline low iodine intake, there is evidence that levothyroxine therapy, in doses that suppress serum TSH, may reduce the size of some nodules. This should not be routine practice in iodine-sufficient populations.

A diffuse or multinodular goitre may also require surgical treatment for cosmetic reasons or if there is compression of local structures (resulting in stridor or dysphagia). Levothyroxine therapy may shrink the goitre of Hashimoto's disease, particularly if serum TSH is elevated.

EBM 20.13 Molecular techniques in cytologically indeterminate thyroid nodules

'Between 60 and 70% of differentiated thyroid cancers have at least one somatic gene mutation. Using a microarray of messenger RNA transcripts from 167 genes on cytologically indeterminate thyroid nodules, the negative predictive value for lesions with a low likelihood for cancer was 94–95%. Use of this technology could, in theory, avoid unnecessary surgery.'

Autoimmune thyroid disease

Thyroid diseases are amongst the most prevalent antibody-mediated autoimmune diseases and are associated with other organ-specific autoimmunity (Ch. 4 and p. 795). Autoantibodies may produce inflammation and destruction of thyroid tissue, resulting in hypothyroidism, goitre (in Hashimoto's thyroiditis) or sometimes even transient thyrotoxicosis ('Hashitoxicosis'), or they may stimulate the TSH receptor to cause thyrotoxicosis (in Graves' disease). There is overlap between these conditions, since some patients have multiple autoantibodies.

Graves' disease

Graves' disease can occur at any age but is unusual before puberty and most commonly affects women aged 30–50 years. The most common manifestation is thyrotoxicosis with or without a diffuse goitre. The clinical features and differential diagnosis are described on page 740. Graves' disease also causes ophthalmopathy and, rarely, pretibial myxoedema (p. 734). These extrathyroidal features usually occur in thyrotoxic patients, but can occur in the absence of thyroid dysfunction.

Graves' thyrotoxicosis

Pathophysiology

The thyrotoxicosis results from the production of IgG antibodies directed against the TSH receptor on the thyroid follicular cell, which stimulate thyroid hormone production and proliferation of follicular cells, leading to goitre in the majority of patients. These antibodies

are termed thyroid-stimulating immunoglobulins or TSH receptor antibodies (TRAb) and can be detected in the serum of 80–95% of patients with Graves' disease. The concentration of TRAb in the serum is presumed to fluctuate to account for the natural history of Graves' thyrotoxicosis (Fig. 20.6). The thyroid failure seen in some patients may result from the presence of blocking antibodies against the TSH receptor, and from tissue destruction by cytotoxic antibodies and cell-mediated immunity.

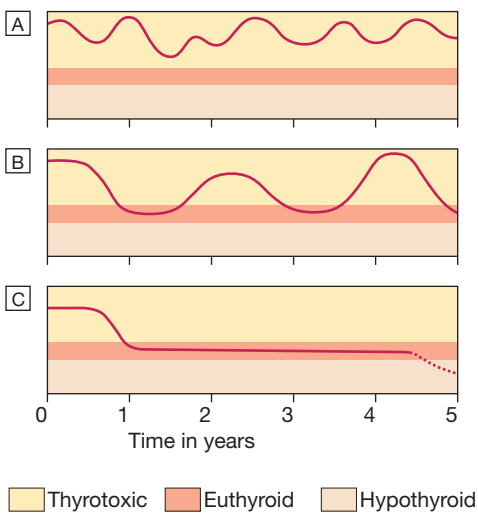

Fig. 20.6 Natural history of the thyrotoxicosis of Graves' disease. A and B The majority (60%) of patients have either prolonged periods of thyrotoxicosis of fluctuating severity, or periods of alternating relapse and remission. C It is the minority who experience a single short-lived episode followed by prolonged remission and, in some cases, by the eventual onset of hypothyroidism.

Graves' disease has a strong genetic component. There is 50% concordance for thyrotoxicosis between monozygotic twins but only 5% concordance between dizygotic twins. Genome-wide association studies have identified polymorphisms at the *MHC*, *CTLA4*, *PTPN22*, *TSHR1* and *FCRL3* loci as predisposing genetic variants. Many of these loci have been implicated in the pathogenesis of other autoimmune diseases.

A suggested trigger for the development of thyrotoxicosis in genetically susceptible individuals may be infection with viruses or bacteria. Certain strains of the gut organisms *Escherichia coli* and *Yersinia enterocolitica* possess cell membrane TSH receptors and it has been suggested that antibodies to these microbial antigens may cross-react with the TSH receptors on the host thyroid follicular cell. In regions of iodine deficiency (p. 752), iodine supplementation can precipitate thyrotoxicosis, but only in those with pre-existing subclinical Graves' disease. Smoking is weakly associated with Graves' thyrotoxicosis but strongly linked with the development of ophthalmopathy.

Management

Symptoms of thyrotoxicosis respond to β-blockade (p. 741) but definitive treatment requires control of thyroid hormone secretion. The different options are compared in Box 20.14. For patients under 40 years of age, most clinicians adopt the empirical approach of prescribing a course of carbimazole and recommending surgery if relapse occurs, while ^{131}I is employed as first- or second-line treatment in those aged over 40. A number of observational studies have linked therapeutic ^{131}I with increased incidence of some malignancies, particularly of the thyroid and gastrointestinal tract, but the results have been inconsistent; the association may be with Graves' disease rather than its therapy, and the magnitude of the effect, if any, is small. Experience from the

20.14 Comparison of treatments for the thyrotoxicosis of Graves' disease

Management	Common indications	Contraindications	Disadvantages/complications
Antithyroid drugs (carbimazole, propylthiouracil)	First episode in patients < 40 yrs	Breastfeeding (propylthiouracil suitable)	Hypersensitivity rash 2% Agranulocytosis 0.2% Hepatotoxicity (with propylthiouracil) – very rare but potentially fatal > 50% relapse rate usually within 2 yrs of stopping drug
Subtotal thyroidectomy[1]	Large goitre Poor drug compliance, especially in young patients Recurrent thyrotoxicosis after course of antithyroid drugs in young patients	Previous thyroid surgery Dependence on voice, e.g. opera singer, lecturer[2]	Hypothyroidism (~25%) Transient hypocalcaemia (10%) Permanent hypoparathyroidism (1%) Recurrent laryngeal nerve palsy[2] (1%)
Radio-iodine	Patients > 40 yrs[3] Recurrence following surgery irrespective of age Other serious comorbidity	Pregnancy or planned pregnancy within 6 mths of treatment Active Graves' ophthalmopathy[4]	Hypothyroidism, ~40% in first year, 80% after 15 yrs Most likely treatment to result in exacerbation of ophthalmopathy[4]

[1]A near-total thyroidectomy is now the favoured operation for Graves' thyrotoxicosis in many institutions and is associated with a higher risk of some complications, including hypothyroidism (nearly 100%), but a reduced risk of persistent or recurrent thyrotoxicosis.
[2]It is not only vocal cord palsy due to recurrent laryngeal nerve damage which alters the voice following thyroid surgery; the superior laryngeal nerves are frequently transected and this results in minor changes in voice quality.
[3]In many institutions, ^{131}I is used more liberally and is prescribed for much younger patients.
[4]The extent to which radio-iodine exacerbates ophthalmopathy is controversial and practice varies; some use prednisolone to reduce this risk.

Chernobyl disaster suggests that younger people are more sensitive to radiation-induced thyroid cancer. In many centres, however, ^{131}I is used extensively, even in young patients.

Antithyroid drugs. The most commonly used are carbimazole and its active metabolite, methimazole (not available in the UK). Propylthiouracil is equally effective. These drugs reduce the synthesis of new thyroid hormones by inhibiting the iodination of tyrosine (see Fig. 20.3, p. 739). Carbimazole also has an immunosuppressive action, leading to a reduction in serum TRAb concentrations, but this is not enough to influence the natural history of the thyrotoxicosis significantly.

Antithyroid drugs should be introduced at high doses (carbimazole 40–60 mg daily or propylthiouracil 400–600 mg daily). Usually, this results in subjective improvement within 10–14 days and renders the patient clinically and biochemically euthyroid at 3–4 weeks. At this point, the dose can be reduced and titrated to maintain T_4 and TSH within their reference range. In most patients, carbimazole is continued at 5–20 mg per day for 12–18 months in the hope that remission will occur. Patients with thyrotoxicosis relapse in at least 50% of cases, usually within 2 years of stopping treatment. Rarely, T_4 and TSH levels fluctuate between those of thyrotoxicosis and hypothyroidism at successive review appointments, despite good drug compliance, presumably due to rapidly changing concentrations of TRAb. In these patients, satisfactory control can be achieved by blocking thyroid hormone synthesis with carbimazole 30–40 mg daily and adding levothyroxine 100–150 μg daily as replacement therapy (a 'block and replace' regime).

Antithyroid drugs can have adverse effects. The most common is a rash. Agranulocytosis is a rare but potentially serious complication that cannot be predicted by routine measurement of white blood cell count, but which is reversible on stopping treatment. Patients should be warned to stop the drug and seek medical advice immediately, should a severe sore throat or fever develop whilst on treatment. Propylthiouracil is associated with a small but definite risk of hepatotoxicity, which, in some instances, has resulted in liver failure requiring liver transplantation, and even in death. It should, therefore, be considered second-line therapy to carbimazole and only be used during pregnancy or breastfeeding (see below), or if an adverse reaction to carbimazole has occurred.

Thyroid surgery. Patients should be rendered euthyroid with antithyroid drugs before operation. Potassium iodide, 60 mg 3 times daily orally, is often added for 2 weeks before surgery to inhibit thyroid hormone release and reduce the size and vascularity of the gland, making surgery technically easier. Traditionally, a 'subtotal' thyroidectomy is performed, in which a portion of one lobe of the thyroid is left in situ, with the aim of rendering the patient euthyroid post-operatively. While complications of surgery are rare and 80% of patients are euthyroid, 15% are permanently hypothyroid and 5% remain thyrotoxic. As a consequence, many endocrine surgeons now opt to perform a 'near-total' thyroidectomy, leaving behind only a small portion of gland adjacent to the recurrent laryngeal nerves. This strategy invariably results in permanent hypothyroidism and is probably associated with a higher risk of hypoparathyroidism, but maximises the potential for cure of thyrotoxicosis.

Radioactive iodine. ^{131}I is administered orally as a single dose, and is trapped and organified in the thyroid (see Fig. 20.3, p. 739). Although ^{131}I decays within a few weeks, it has long-lasting inhibitory effects on survival and replication of follicular cells. The variable radioiodine uptake and radiosensitivity of the gland means that the choice of dose is empirical; in most centres, approximately 400 MBq (10 mCi) is given orally. This regimen is effective in 75% of patients within 4–12 weeks. During the lag period, symptoms can be controlled by a β-blocker or, in more severe cases, by carbimazole. However, carbimazole reduces the efficacy of ^{131}I therapy because it prevents organification of ^{131}I in the gland, and so should be avoided until 48 hours after radio-iodine administration. If thyrotoxicosis persists after 6 months, a further dose of ^{131}I can be given. The disadvantage of ^{131}I treatment is that the majority of patients eventually develop hypothyroidism. ^{131}I is usually avoided in patients with Graves' ophthalmopathy and evidence of significant active orbital inflammation. It can be administered with caution in those with mild or 'burnt-out' eye disease, when it is customary to cover the treatment with a 6-week tapering course of oral prednisolone. In women of reproductive age, pregnancy must be excluded before administration of ^{131}I and avoided for 6 months thereafter; men are also advised against fathering children for 6 months after receiving ^{131}I.

Thyrotoxicosis in pregnancy

The coexistence of pregnancy and thyrotoxicosis is unusual, as anovulatory cycles are common in thyrotoxic patients and autoimmune disease tends to remit during pregnancy, when the maternal immune response is suppressed. Thyroid function tests must be interpreted in the knowledge that thyroid-binding globulin, and hence total T_4 and T_3 levels, are increased in pregnancy and that TSH reference ranges may be lower (see Box 20.20, p. 756); a fully suppressed TSH with elevated free thyroid hormone levels indicates thyrotoxicosis. The thyrotoxicosis is almost always caused by Graves' disease. Both mother and fetus must be considered, since maternal thyroid hormones, TRAb and antithyroid drugs can all cross the placenta to some degree, exposing the fetus to the risks of thyrotoxicosis, iatrogenic hypothyroidism and goitre. Poorly controlled maternal thyrotoxicosis can result in fetal tachycardia, intrauterine growth retardation, prematurity, stillbirth and possibly even congenital malformations.

Antithyroid drugs are the treatment of choice for thyrotoxicosis in pregnancy. Carbimazole has been associated with rare cases of embryopathy, particularly a skin defect known as aplasia cutis, and should be avoided in the first trimester. Propylthiouracil should be used in its place but, because of its potential hepatotoxicity, should be replaced with carbimazole from the beginning of the second trimester. Both drugs cross the placenta and will effectively treat thyrotoxicosis in the fetus caused by transplacental passage of TRAb. To avoid fetal hypothyroidism (which could affect brain development) and a resultant goitre, it is important to use the smallest dose of antithyroid drug (optimally, less than 150 mg propylthiouracil or 15 mg carbimazole per

day) that will maintain maternal (and presumably fetal) free T_4, T_3 and TSH within their respective reference ranges. Frequent review of mother and fetus (monitoring heart rate and growth) is important. TRAb levels can be measured in the third trimester to predict the likelihood of neonatal thyrotoxicosis. When TRAb levels are not elevated, the antithyroid drug can be discontinued 4 weeks before the expected date of delivery to minimise the risk of fetal hypothyroidism at the time of maximum brain development. After delivery, if antithyroid drug is required and the patient wishes to breastfeed, then propylthiouracil is the drug of choice, as it is excreted in the milk to a much lesser extent than carbimazole. Thyroid function should be monitored periodically in the breastfed child.

If thyroid surgery is necessary because of poor drug compliance or drug hypersensitivity, it is most safely performed in the second trimester. Radioactive iodine is absolutely contraindicated, as it invariably induces fetal hypothyroidism.

Thyrotoxicosis in adolescence

Thyrotoxicosis can occasionally occur in adolescence and is almost always due to Graves' disease. The presentation may be atypical and management challenging, as summarised in Box 20.15.

20.15 Thyrotoxicosis in adolescence

- **Presentation**: may present with a deterioration in school performance or symptoms suggestive of attention deficit hyperactivity disorder.
- **Anti-thyroid drug therapy**: prolonged courses may be required because remission rates following an 18-month course of therapy are much lower than in adults.
- **Compliance**: compliance with anti-thyroid drug therapy is often suboptimal, resulting in poor disease control which may adversely affect performance at school.
- **Radio-iodine therapy**: usually avoided in adolescents because of concerns about risk of future malignancy.

Graves' ophthalmopathy

This condition is immunologically mediated but the autoantigen has not been identified. Within the orbit (and the dermis) there is cytokine-mediated proliferation of fibroblasts which secrete hydrophilic glycosaminoglycans. The resulting increase in interstitial fluid content, combined with a chronic inflammatory cell infiltrate, causes marked swelling and ultimately fibrosis of the extraocular muscles (Fig. 20.7) and a rise in retrobulbar pressure. The eye is displaced forwards (proptosis, exophthalmos; p. 735) and in severe cases there is optic nerve compression.

Ophthalmopathy, like thyrotoxicosis (see Fig. 20.6), typically follows an episodic course and it is helpful to distinguish patients with active inflammation (periorbital oedema and conjunctival inflammation with changing orbital signs) from those in whom the inflammation has 'burnt out'. Eye disease is detectable in up to 50% of thyrotoxic patients at presentation, but active ocular inflammation may occur before or after thyrotoxic episodes (exophthalmic Graves' disease). It is more common in cigarette smokers and is exacerbated by poor

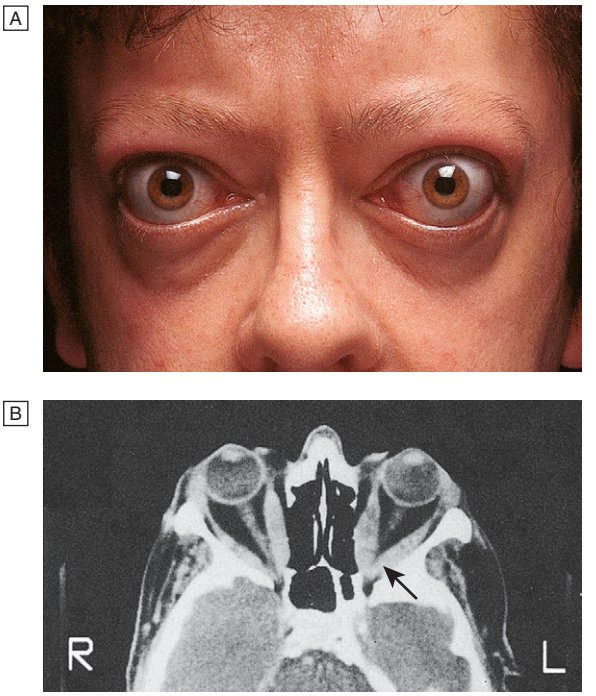

Fig. 20.7 Graves' disease. A Bilateral ophthalmopathy in a 42-year-old man. The main symptoms were diplopia in all directions of gaze and reduced visual acuity in the left eye. The periorbital swelling is due to retrobulbar fat prolapsing into the eyelids, and increased interstitial fluid as a result of raised intraorbital pressure. B Transverse CT of the orbits, showing the enlarged extraocular muscles. This is most obvious at the apex of the left orbit (arrow), where compression of the optic nerve caused reduced visual acuity.

control of thyroid function, especially hypothyroidism. The most frequent presenting symptoms are related to increased exposure of the cornea, resulting from proptosis and lid retraction. There may be excessive lacrimation made worse by wind and bright light, a 'gritty' sensation in the eye, and pain due to conjunctivitis or corneal ulceration. In addition, there may be reduction of visual acuity and/or visual fields as a consequence of corneal oedema or optic nerve compression. Other signs of optic nerve compression include reduced colour vision and a relative afferent pupillary defect (pp. 735 and 1169). If the extraocular muscles are involved and do not act in concert, diplopia results.

The majority of patients require no treatment other than reassurance. Smoking cessation should be actively encouraged. Methylcellulose eye drops and gel counter the gritty discomfort of dry eyes, and tinted glasses or side shields attached to spectacle frames reduce the excessive lacrimation triggered by sun or wind. In patients with mild Graves' ophthalmopathy, oral selenium (100 µg twice daily for 6 months) improves quality of life, reduces ocular involvement and slows progression of disease; the mechanism of action is not known but may relate to an antioxidant effect (Box 20.16). More severe inflammatory episodes are treated with glucocorticoids (e.g. daily oral prednisolone or pulsed IV methylprednisolone) and sometimes orbital radiotherapy. There is also an increasing trend to use immunosuppressant therapies, such as ciclosporin, in combination with glucocorticoids. Loss of visual acuity

EBM 20.16 Effects of selenium supplementation in mild Graves' ophthalmopathy

'Selenium therapy for 6 months was associated with improvement of both the appearance score and the visual-functioning score. The benefits persisted 6 months following cessation of therapy.'

- Marcocci C, et al. N Engl J Med 2012; 364:1920–1931.

For further information: www.thyroid.org

is an indication for urgent surgical decompression of the orbit. In 'burnt-out' disease, surgery to the eyelids and/or ocular muscles may improve conjunctival exposure, cosmetic appearance and diplopia.

Pretibial myxoedema

This infiltrative dermopathy occurs in fewer than 10% of patients with Graves' disease and has similar pathological features as occur in the orbit. It takes the form of raised pink-coloured or purplish plaques on the anterior aspect of the leg, extending on to the dorsum of the foot (p. 734). The lesions may be itchy and the skin may have a 'peau d'orange' appearance with growth of coarse hair; less commonly, the face and arms are affected. Treatment is rarely required, but in severe cases topical glucocorticoids may be helpful.

Hashimoto's thyroiditis

Hashimoto's thyroiditis is characterised by destructive lymphoid infiltration of the thyroid, ultimately leading to a varying degree of fibrosis and thyroid enlargement. There is an increased risk of thyroid lymphoma (p. 755), although this is exceedingly rare. The nomenclature of autoimmune hypothyroidism is confusing. Some authorities reserve the term 'Hashimoto's thyroiditis' for patients with positive antithyroid peroxidase autoantibodies and a firm goitre who may or may not be hypothyroid, and use the term 'spontaneous atrophic hypothyroidism' for hypothyroid patients without a goitre in whom TSH receptor-blocking antibodies may be more important than antiperoxidase antibodies. However, these syndromes can both be considered as variants of the same underlying disease process.

Hashimoto's thyroiditis increases in incidence with age and affects approximately 3.5 per 1000 women and 0.8 per 1000 men each year. Many present with a small or moderately sized diffuse goitre, which is characteristically firm or rubbery in consistency. The goitre may be soft, however, and impossible to differentiate from simple goitre (p. 752) by palpation alone. Around 25% of patients are hypothyroid at presentation. In the remainder, serum T_4 is normal and TSH normal or raised, but these patients are at risk of developing overt hypothyroidism in future years. Antithyroid peroxidase antibodies are present in the serum in more than 90% of patients with Hashimoto's thyroiditis. In those under the age of 20 years, antinuclear factor (ANF) may also be positive.

Levothyroxine therapy is indicated as treatment for hypothyroidism (p. 743), and also to shrink an associated goitre. In this context, the dose of thyroxine should be sufficient to suppress serum TSH to low but detectable levels.

Transient thyroiditis

Subacute (de Quervain's) thyroiditis

In its classical painful form, subacute thyroiditis is a transient inflammation of the thyroid gland occurring after infection with Coxsackie, mumps or adenoviruses. There is pain in the region of the thyroid that may radiate to the angle of the jaw and the ears, and is made worse by swallowing, coughing and movement of the neck. The thyroid is usually palpably enlarged and tender. Systemic upset is common. Affected patients are usually females aged 20–40 years. Painless transient thyroiditis can also occur after viral infection and in patients with underlying autoimmune disease. The condition can also be precipitated by drugs, including interferon-α and lithium.

Irrespective of the clinical presentation, inflammation in the thyroid gland occurs and is associated with release of colloid and stored thyroid hormones, but also with damage to follicular cells and impaired synthesis of new thyroid hormones. As a result, T_4 and T_3 levels are raised for 4–6 weeks until the pre-formed colloid is depleted. Thereafter, there is usually a period of hypothyroidism of variable severity before the follicular cells recover and normal thyroid function is restored within 4–6 months (Fig. 20.8). In the thyrotoxic phase, the iodine uptake is low, because the damaged follicular cells are unable to trap iodine and because TSH secretion is suppressed. Low-titre thyroid autoantibodies appear transiently in the serum, and the erythrocyte sedimentation rate (ESR) is usually raised. High-titre autoantibodies suggest an underlying autoimmune pathology and greater risk of recurrence and ultimate progression to hypothyroidism.

The pain and systemic upset usually respond to simple measures such as non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally, however, it may be necessary to prescribe prednisolone 40 mg daily for 3–4 weeks. The thyrotoxicosis is mild and treatment with a β-blocker is usually adequate. Antithyroid drugs are of no benefit because thyroid hormone synthesis is impaired rather than enhanced. Careful monitoring of thyroid function and symptoms is required so that

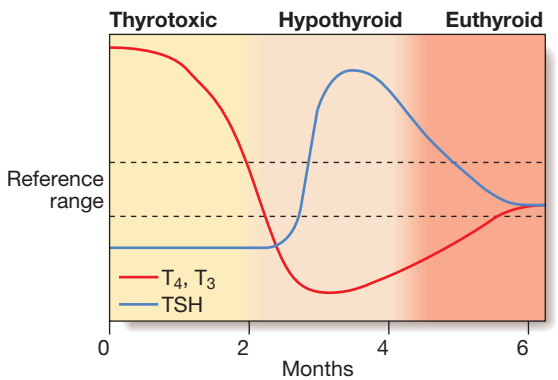

Fig. 20.8 Thyroid function tests in an episode of transient thyroiditis. This pattern might be observed in classical subacute (de Quervain's) thyroiditis, painless thyroiditis or post-partum thyroiditis. The duration of each phase varies between patients.

levothyroxine can be prescribed temporarily in the hypothyroid phase. Care must be taken to identify patients presenting with hypothyroidism who are in the later stages of a transient thyroiditis, since they are unlikely to require life-long levothyroxine therapy (see Fig. 20.5, p. 744).

Post-partum thyroiditis

The maternal immune response, which is modified during pregnancy to allow survival of the fetus, is enhanced after delivery and may unmask previously unrecognised subclinical autoimmune thyroid disease. Surveys have shown that transient biochemical disturbances of thyroid function occur in 5–10% of women within 6 months of delivery (see Box 20.20, p. 756). Those affected are likely to have anti-thyroid peroxidase antibodies in the serum in early pregnancy. Symptoms of thyroid dysfunction are rare and there is no association between postnatal depression and abnormal thyroid function tests. However, symptomatic thyrotoxicosis presenting for the first time within 12 months of childbirth is likely to be due to post-partum thyroiditis and the diagnosis is confirmed by a negligible radio-isotope uptake. The clinical course and treatment are similar to those of painless subacute thyroiditis (see above). Post-partum thyroiditis tends to recur after subsequent pregnancies, and eventually patients progress over a period of years to permanent hypothyroidism.

Iodine-associated thyroid disease

Iodine deficiency

Thyroid enlargement is extremely common in certain mountainous parts of the world, such as the Andes, the Himalayas and central Africa, where there is dietary iodine deficiency (endemic goitre). Most patients are euthyroid with normal or raised TSH levels, although hypothyroidism can occur with severe iodine deficiency. Iodine supplementation programmes have abolished this condition in most developed countries.

Iodine-induced thyroid dysfunction

Iodine has complex effects on thyroid function. Very high concentrations of iodine inhibit thyroid hormone release and this forms the rationale for iodine treatment of thyroid storm (p. 742) and prior to thyroid surgery for thyrotoxicosis (p. 748). Iodine administration initially enhances, but then inhibits, iodination of tyrosine and thyroid hormone synthesis (see Fig. 20.3, p. 739). The resulting effect of iodine on thyroid function varies according to whether the patient has an iodine-deficient diet or underlying thyroid disease. In iodine-deficient parts of the world, transient thyrotoxicosis may be precipitated by prophylactic iodinisation programmes. In iodine-sufficient areas, thyrotoxicosis can be precipitated by radiographic contrast medium or expectorants in individuals who have underlying thyroid disease predisposing to thyrotoxicosis, such as multinodular goitre or Graves' disease in remission. Induction of thyrotoxicosis by iodine is called the Jod–Basedow effect. Chronic excess iodine administration can, however, result in hypothyroidism. Increased iodine within the thyroid gland down-regulates iodine trapping, so that uptake is low in all circumstances.

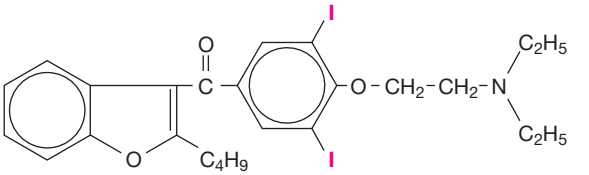

Fig. 20.9 The structure of amiodarone. Note the similarities to T_4 (see Fig. 20.3, p. 739).

Amiodarone

The anti-arrhythmic agent amiodarone has a structure that is analogous to that of T_4 (Fig. 20.9) and contains huge amounts of iodine; a 200 mg dose contains 75 mg iodine, compared with a daily dietary requirement of just 125 µg. Amiodarone also has a cytotoxic effect on thyroid follicular cells and inhibits conversion of T_4 to T_3. Most patients receiving amiodarone have normal thyroid function, but up to 20% develop hypothyroidism or thyrotoxicosis and so thyroid function should be monitored regularly. The ratio of T_4:T_3 is elevated and TSH provides the best indicator of thyroid function.

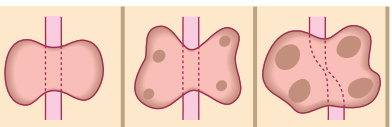
The thyrotoxicosis can be classified as either:

- type I: iodine-induced excess thyroid hormone synthesis in patients with an underlying thyroid disorder, such as nodular goitre or latent Graves' disease
- type II: thyroiditis due to a direct cytotoxic effect if amiodarone administration results in a transient thyrotoxicosis.

These patterns can overlap and can be difficult to distinguish clinically, as iodine uptake is low in both. There is no widely accepted management algorithm, although the iodine excess renders the gland resistant to radio-iodine. Antithyroid drugs may be effective in patients with the type I form, but are ineffective in type II thyrotoxicosis. Prednisolone is beneficial in the type II form. A pragmatic approach is to commence combination therapy with an antithyroid drug and glucocorticoid in patients with significant thyrotoxicosis. A rapid response (within 1–2 weeks) usually indicates a type II picture and permits withdrawal of the antithyroid therapy; a slower response suggests a type I picture, when antithyroid drugs may be continued and prednisolone withdrawn. Potassium perchlorate can also be used to inhibit iodine trapping in the thyroid. If the cardiac state allows, amiodarone should be discontinued, but it has a long half-life (50–60 days) and so its effects are long-lasting. To minimise the risk of type I thyrotoxicosis, thyroid function should be measured in all patients prior to commencement of amiodarone therapy, and amiodarone should be avoided if TSH is suppressed.

Hypothyroidism should be treated with levothyroxine, which can be given while amiodarone is continued.

Simple and multinodular goitre



These terms describe diffuse or multinodular enlargement of the thyroid, which occurs sporadically and is of unknown aetiology.

Simple diffuse goitre

This form of goitre usually presents between the ages of 15 and 25 years, often during pregnancy, and tends to be noticed by friends and relatives rather than the patient. Occasionally, there is a tight sensation in the neck, particularly when swallowing. The goitre is soft and symmetrical, and the thyroid enlarged to two or three times normal. There is no tenderness, lymphadenopathy or overlying bruit. Concentrations of T_3, T_4 and TSH are normal and no thyroid autoantibodies are detected in the serum. No treatment is necessary and the goitre usually regresses. In some, however, the unknown stimulus to thyroid enlargement persists and, as a result of recurrent episodes of hyperplasia and involution during the following 10–20 years, the gland becomes multinodular with areas of autonomous function.

Multinodular goitre

The natural history is shown in Figure 20.10. Patients with thyroid enlargement in the absence of thyroid dysfunction or positive autoantibodies (i.e. with 'simple goitre', see above) as young adults may progress to develop nodules. These nodules grow at varying rates and secrete thyroid hormone 'autonomously', thereby suppressing TSH-dependent growth and function in the rest of the gland. Ultimately, complete suppression of TSH occurs in about 25% of cases, with T_4 and T_3 levels often within the reference range (subclinical thyrotoxicosis, p. 745) but sometimes elevated (toxic multinodular goitre; see Fig. 20.4, p. 742).

Age (in years)	15–25	35–55	> 55
Goitre	Diffuse	Nodular	Nodular
Tracheal compression/ deviation	No	Minimal	Yes
T_3, T_4	Normal	Normal	Raised
TSH	Normal	Normal or undetectable	Undetectable

Fig. 20.10 Natural history of simple goitre.

Clinical features and investigations

Multinodular goitre is usually diagnosed in patients presenting with thyrotoxicosis, a large goitre with or without tracheal compression, or sudden painful swelling caused by haemorrhage into a nodule or cyst. The goitre is nodular or lobulated on palpation and may extend retrosternally; however, not all multinodular goitres causing thyrotoxicosis are easily palpable. Very large goitres may cause mediastinal compression with stridor (Fig. 20.11), dysphagia and obstruction of the superior vena cava. Hoarseness due to recurrent laryngeal nerve palsy can occur, but is far more suggestive of thyroid carcinoma.

The diagnosis can be confirmed by ultrasonography and/or thyroid scintigraphy (see Fig. 20.4, p. 742). In patients with large goitres, a flow-volume loop is a good screening test for significant tracheal compression (see Fig. 20.11). If intervention is contemplated, a CT or MRI of the thoracic inlet should be performed to quantify the degree of tracheal displacement or compression and the extent of retrosternal extension. Nodules should be evaluated for the possibility of thyroid neoplasia, as described on page 754.

Management

If the goitre is small, no treatment is necessary but annual thyroid function testing should be arranged, as the natural history is progression to a toxic multinodular goitre. Thyroid surgery is indicated for large goitres which cause mediastinal compression or which are cosmetically unattractive. ^{131}I can result in a significant reduction in thyroid size and may be of value in

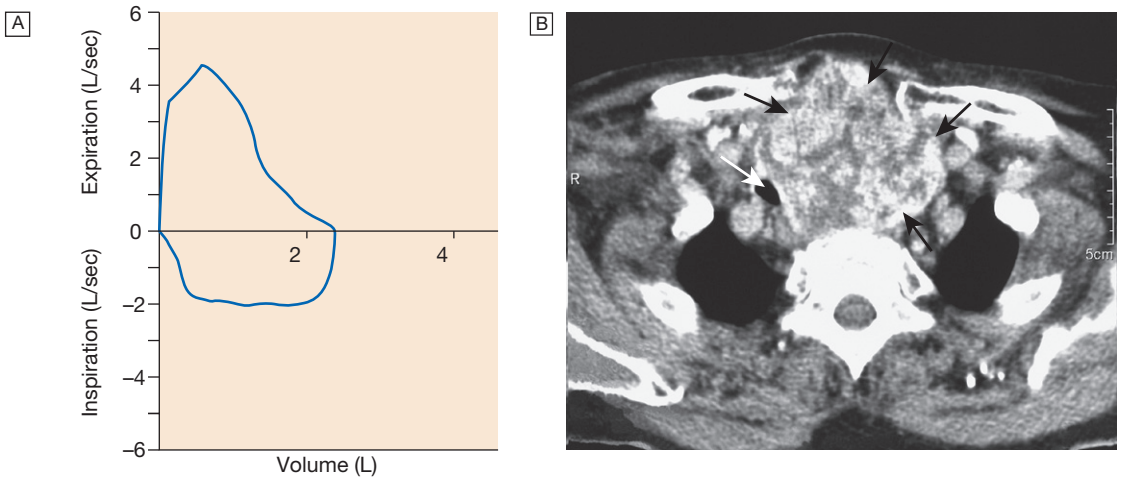


Fig. 20.11 **Multinodular goitre with tracheal compression.** A A flow-volume loop (p. 653) showing a square-shaped inspiratory curve indicating extrathoracic airflow obstruction. B A CT scan of the neck showing a large retrosternal goitre (black arrows) with marked deviation and compression of the trachea (white arrow).

elderly patients. Levothyroxine therapy is of no benefit in shrinking multinodular goitres in iodine-sufficient countries and may simply aggravate any associated thyrotoxicosis.

In toxic multinodular goitre, treatment is usually with ^{131}I. The iodine uptake is lower than in Graves' disease, so a higher dose may be administered (up to 800 Mbq (approximately 20 mCi)) and hypothyroidism is less common. In thyrotoxic patients with a large goitre, thyroid surgery may be indicated. Long-term treatment with antithyroid drugs is not usually employed, as relapse is invariable after drug withdrawal.

Asymptomatic patients with subclinical thyrotoxicosis (p. 745) are increasingly being treated with ^{131}I on the grounds that a suppressed TSH is a risk factor for atrial fibrillation and, particularly in post-menopausal women, osteoporosis.

Thyroid neoplasia

Patients with thyroid tumours usually present with a solitary nodule (p. 746). Most are benign and a few of these, called 'toxic adenomas', secrete excess thyroid hormones. Primary thyroid malignancy is rare, accounting for less than 1% of all carcinomas, and has an incidence of 25 per million per annum. As shown in Box 20.17, it can be classified according to the cell type of origin. With the exception of medullary carcinoma, thyroid cancer is more common in females.

Toxic adenoma

A solitary toxic nodule is the cause of less than 5% of all cases of thyrotoxicosis. The nodule is a follicular adenoma, which autonomously secretes excess thyroid hormones and inhibits endogenous TSH secretion, with subsequent atrophy of the rest of the thyroid gland. The adenoma is usually greater than 3 cm in diameter.

Most patients are female and over 40 years of age. Although many nodules are palpable, the diagnosis can be made with certainty only by thyroid scintigraphy (see Fig. 20.4, p. 742). The thyrotoxicosis is usually mild and in almost 50% of patients the plasma T_3 alone is elevated (T_3 thyrotoxicosis). ^{131}I (400–800 MBq (10–20 mCi)) is highly effective and is an ideal treatment since the atrophic cells surrounding the nodule do not take up iodine and so receive little or no radiation. For this reason, permanent hypothyroidism is unusual. A surgical hemithyroidectomy is an alternative.

Differentiated carcinoma

Papillary carcinoma

This is the most common of the malignant thyroid tumours and accounts for 90% of irradiation-induced thyroid cancer. It may be multifocal and spread is initially to regional lymph nodes. Some patients present with cervical lymphadenopathy and no apparent thyroid enlargement; in such instances, the primary lesion may be less than 10 mm in diameter.

Follicular carcinoma

This is always a single encapsulated lesion. Spread to cervical lymph nodes is rare. Metastases are blood-borne and are most often found in bone, lungs and brain.

Management

This is usually by total thyroidectomy followed by a large dose of ^{131}I (3700 MBq (approximately 100 mCi)) in order to ablate any remaining thyroid tissue, normal or malignant. Recent data indicate that a ^{131}I dose of 1100 MBq (approximately 30 mCi) may be equally as effective at thyroid ablation (Box 20.18). Thereafter, long-term treatment with levothyroxine in a dose sufficient to suppress TSH (usually 150–200 µg daily) is important, as there is evidence that growth of differentiated thyroid carcinomas is TSH-dependent. Follow-up is by measurement of serum thyroglobulin, which should be undetectable in patients whose normal thyroid has been ablated and who are taking a suppressive dose of levothyroxine. Detectable thyroglobulin is suggestive of tumour recurrence or metastases, which may be localised by ultrasound, CT, MRI or whole-body scanning with ^{131}I, and may respond to further radio-iodine therapy. Radio-iodine treatment in thyroid cancer and isotope scanning both require serum TSH concentrations to be elevated (> 20 mU/L). This may be achieved by stopping levothyroxine for 4–6 weeks, inducing symptomatic hypothyroidism, or by administering intramuscular injections of recombinant human TSH. Patients usually find the latter approach preferable but it is more expensive. Clinical

20.17 Malignant thyroid tumours

Type of tumour	Frequency (%)	Age at presentation (years)	10-year survival (%)
Follicular cells			
Differentiated carcinoma			
Papillary	75–85	20–40	98
Follicular	10–20	40–60	94
Anaplastic	< 5	> 60	9
Parafollicular C cells			
Medullary carcinoma	5–8	> 40*	78
Lymphocytes			
Lymphoma	< 5	> 60	45

*Patients with medullary carcinoma as part of MEN type 2 (p. 795) may present in childhood.

EBM 20.18 Ablative radio-iodine following thyroidectomy for differentiated thyroid cancer

'Ablative radioactive iodine has been associated with an increased risk of second malignancies. Two randomised controlled clinical trials have shown that 1100 MBq radio-iodine (30 mCi) is as effective at ablating thyroid tissue as 3700 MBq (100 mCi). Both trials also showed that preparation of patients for radio-iodine treatment with recombinant TSH was as effective as levothyroxine withdrawal.'

- Mallick U, et al. N Engl J Med 2012; 366:1674–1685.

For further information: www.thyroid.org

trials are currently ongoing with novel anti-cancer agents, such as tyrosine kinase inhibitors, in patients with advanced papillary and follicular carcinoma that is refractive to radio-iodine.

Prognosis

Most patients with papillary and thyroid cancer will be cured with appropriate treatment. Adverse prognostic factors include older age at presentation, the presence of distant metastases, male sex and the identification of certain histological subtypes. However, radio-iodine therapy can be effective in treating even those with distant metastases, particularly small-volume disease in the lungs, and so prolonged survival is quite common.

Anaplastic carcinoma and lymphoma

These two conditions are difficult to distinguish clinically but are distinct cytologically and histologically. Patients are usually over 60 years of age and present with rapid thyroid enlargement over 2–3 months. The goitre is hard and there may be stridor due to tracheal compression and hoarseness due to recurrent laryngeal nerve palsy. There is no effective treatment for anaplastic carcinoma, although surgery and radiotherapy may be considered in some circumstances. In older patients, median survival is only 7 months.

The prognosis for lymphoma, which may arise from pre-existing Hashimoto's thyroiditis, is better (p. 1041), with a median survival of 9 years. Some 98% are non-Hodgkin's lymphomas, usually the diffuse large B-cell subtype. Treatment is with combination chemotherapy, such as the CHOP regime (p. 1045), and external beam radiotherapy.

Medullary carcinoma

This tumour arises from the parafollicular C cells of the thyroid. In addition to calcitonin, the tumour may secrete 5-hydroxytryptamine (5-HT, serotonin), various peptides of the tachykinin family, adrenocorticotrophic hormone (ACTH) and prostaglandins. As a consequence, carcinoid syndrome (p. 784) and Cushing's syndrome (p. 773) may occur.

Patients usually present in middle age with a firm thyroid mass. Cervical lymph node involvement is common but distant metastases are rare initially. Serum calcitonin levels are raised and are useful in monitoring response to treatment. Despite the very high levels of calcitonin found in some patients, hypocalcaemia is extremely rare; however, hypercalcitoninaemia can be associated with severe, watery diarrhoea.

Treatment is by total thyroidectomy with removal of regional cervical lymph nodes. Since the C cells do not concentrate iodine and are not responsive to TSH, there is no role for ^{131}I therapy or TSH suppression with levothyroxine. External beam radiotherapy may be considered in some patients at high risk of local recurrence. Vandetanib, a tyrosine kinase inhibitor, is licensed for patients with advanced medullary cancer. The prognosis is less good than for papillary and follicular carcinoma, but individuals can live for many decades with persistent disease which behaves in an indolent fashion.

20.19 The thyroid gland in old age

Thyrotoxicosis

- **Causes**: commonly due to multinodular goitre.
- **Clinical features**: apathy, anorexia, proximal myopathy, atrial fibrillation and cardiac failure predominate.
- **Non-thyroidal illness**: thyroid function tests are performed more frequently in the elderly, but interpretation may be altered by intercurrent illness.

Hypothyroidism

- **Clinical features**: non-specific features, such as physical and mental slowing, are often attributed to increasing age and the diagnosis is delayed.
- **Myxoedema coma** (p. 745): more likely in the elderly.
- **Levothyroxine dose**: to avoid exacerbating latent or established heart disease, the starting dose should be 25 μg daily. Levothyroxine requirements fall with increasing age and few patients need more than 100 μg daily.
- **Other medication** (see Box 20.11, p. 745): may interfere with absorption or metabolism of levothyroxine, necessitating an increase in dose.

Medullary carcinoma of the thyroid may occur sporadically, or in families as part of the MEN type 2 syndrome (p. 795).

Riedel's thyroiditis

This is not a form of thyroid cancer, but the presentation is similar and the differentiation can usually only be made by thyroid biopsy. It is an exceptionally rare condition of unknown aetiology, in which there is extensive infiltration of the thyroid and surrounding structures with fibrous tissue. There may be associated mediastinal and retroperitoneal fibrosis. Presentation is with a slow-growing goitre which is irregular and stony-hard. There is usually tracheal and oesophageal compression necessitating partial thyroidectomy. Other recognised complications include recurrent laryngeal nerve palsy, hypoparathyroidism and eventually hypothyroidism.

Congenital thyroid disease

Early treatment with levothyroxine is essential to prevent irreversible brain damage in children (cretinism) with congenital hypothyroidism. Routine screening of TSH levels in heelprick blood samples obtained 5–7 days after birth (as part of the Guthrie test) has revealed an incidence of approximately 1 in 3000, resulting from thyroid agenesis, ectopic or hypoplastic glands, or dyshormonogenesis. Congenital hypothyroidism is thus six times more common than phenylketonuria. It is now possible to start thyroid replacement therapy within 2 weeks of birth. Developmental assessment of infants treated at this early stage has revealed no differences between cases and controls in most children.

Dyshormonogenesis

Several autosomal recessive defects in thyroid hormone synthesis have been described; the most common results from deficiency of the intrathyroidal peroxidase

enzyme. Homozygous individuals present with congenital hypothyroidism; heterozygotes present in the first two decades of life with goitre, normal thyroid hormone levels and a raised TSH. The combination of dyshormonogenetic goitre and nerve deafness is known as Pendred's syndrome and is due to mutations in pendrin, the protein which transports iodide to the luminal surface of the follicular cell (see Fig. 20.3, p. 739).

Thyroid hormone resistance

This is a rare disorder in which the pituitary and hypothalamus are resistant to feedback suppression of TSH by T_3, sometimes due to mutations in the thyroid hormone receptor β or because of defects in monodeiodinase activity. The result is high levels of TSH, T_4 and T_3, often with a moderate goitre which may not be noted until adulthood. Thyroid hormone signalling is highly complex and involves different isozymes of both monodeiodinases and thyroid hormone receptors in different tissues. For that reason, other tissues may or may not share the resistance to thyroid hormone and there may be features of thyrotoxicosis (e.g. tachycardia). This condition can be difficult to distinguish from an equally rare TSH-producing pituitary tumour (see Box 20.5, p. 739); administration of TRH results in elevation of TSH in thyroid hormone resistance and not in TSHoma, but an MRI scan of the pituitary may be necessary to exclude a macroadenoma.

20.20 Thyroid disease in pregnancy

Normal pregnancy

- **Trimester-specific reference ranges**: should be used to interpret thyroid function test results in pregnancy. In the first trimester, TSH is lower and free T_4 and T_3 higher, in part due to thyroid stimulation by human chorionic gonadotrophin (hCG). In later pregnancy, free T_4 and T_3 are lower. Binding globulin levels are induced by oestrogen, so total T_4 and T_3 levels are invariably high.
- **Iodine requirements**: increased in pregnancy. The World Health Organization (WHO) recommends minimum intake of 200 μg/day.
- **Screening of thyroid function and autoantibodies**: not recommended for every woman, but should be performed in the first trimester in those with a personal or family history of thyroid disease, goitre, other autoimmune disease including type 1 diabetes, or when there is clinical suspicion of thyroid dysfunction.

Thyrotoxicosis

- **Hyperemesis gravidarum**: associated with thyrotoxic biochemistry, sometimes requiring antithyroid drugs.
- **Subclinical thyrotoxicosis**: not usually treated, to avoid fetal hypothyroidism.
- **Antithyroid drugs**: propylthiouracil should be used in the first trimester, with carbimazole substituted in the second and third trimesters.

Hypothyroidism

- **Preterm labour and impaired cognitive development in the offspring**: may be associated with even subclinical hypothyroidism.
- **Levothyroxine replacement therapy dose requirements**: increase by 30–50% from early in pregnancy. Monitoring to maintain TSH results within the trimester-specific reference range is recommended in early pregnancy and at least once in each trimester.

Post-partum thyroiditis

- **Screening**: not recommended for every woman, but thyroid function should be tested 4–6 weeks post-partum in those with a personal history of thyroid disease, goitre or other autoimmune disease including type 1 diabetes, those known to have positive anti-thyroid peroxidase antibodies, or when there is clinical suspicion of thyroid dysfunction.

THE REPRODUCTIVE SYSTEM

Clinical practice in reproductive medicine is shared between several specialties, including gynaecology, urology, paediatrics, psychiatry and endocrinology. The following section is focused on disorders managed by endocrinologists.

Functional anatomy, physiology and investigations

The physiology of male and female reproductive function is illustrated in Figures 20.12 and 20.13 respectively.

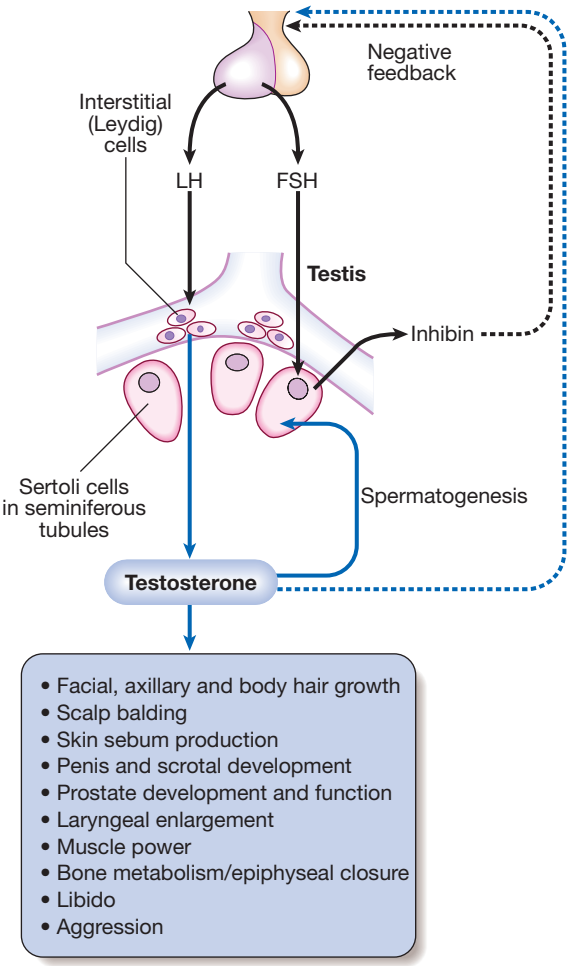

Fig. 20.12 Male reproductive physiology. (FSH = follicle-stimulating hormone; LH = luteinising hormone).

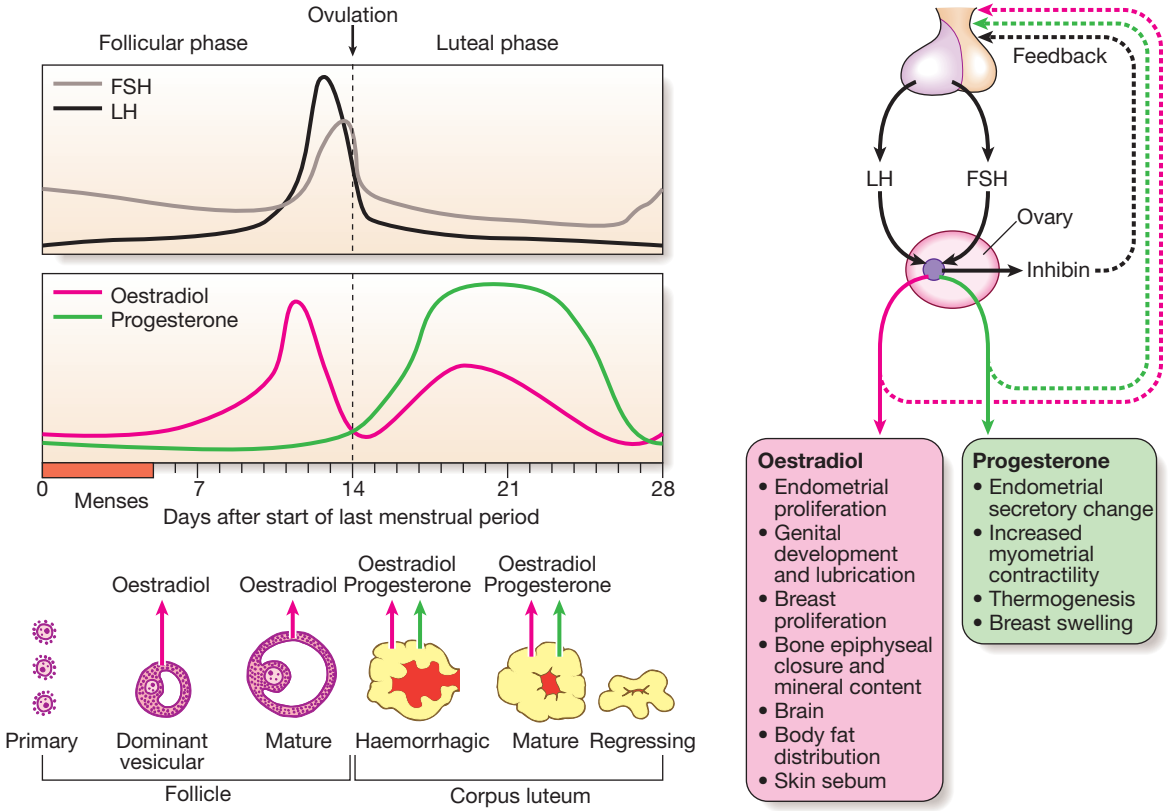

Fig. 20.13 Female reproductive physiology and the normal menstrual cycle.

Pathways for synthesis of sex steroids are shown in Figure 20.18 (p. 772).

The male

In the male, the testis subserves two principal functions: synthesis of testosterone by the interstitial Leydig cells under the control of luteinising hormone (LH), and spermatogenesis by Sertoli cells under the control of follicle-stimulating hormone (FSH) (but also requiring adequate testosterone). Negative feedback suppression of LH is mediated principally by testosterone, while secretion of another hormone by the testis, inhibin, suppresses FSH. The axis can be assessed easily by a random blood sample for testosterone, LH and FSH. Testosterone levels are higher in the morning and therefore, if testosterone is marginally low, sampling should be repeated in the early morning (0900 hrs). Testosterone is largely bound in plasma to sex hormone-binding globulin, and this can also be measured to calculate the 'free androgen index' or the 'bioavailable' testosterone. Testicular function can also be tested by semen analysis.

There is no equivalent of the menopause in men, although testosterone concentrations decline slowly from the fourth decade onwards.

The female

In the female, physiology varies during the normal menstrual cycle. FSH stimulates growth and development of ovarian follicles during the first 14 days after the menses. This leads to a gradual increase in oestradiol production from granulosa cells, which initially suppresses FSH secretion (negative feedback) but then, above a certain level, stimulates an increase in both the frequency and amplitude of gonadotrophin-releasing hormone (GnRH) pulses, resulting in a marked increase in LH secretion (positive feedback). The mid-cycle 'surge' of LH induces ovulation. After release of the ovum, the follicle differentiates into a corpus luteum, which secretes progesterone. Unless pregnancy occurs during the cycle, the corpus luteum regresses and the fall in progesterone levels results in menstrual bleeding. Circulating levels of oestrogen and progesterone in pre-menopausal women are, therefore, critically dependent on the time of the cycle. The most useful 'test' of ovarian function is a careful menstrual history: if menses are regular, measurement of gonadotrophins and oestrogen is not necessary. In addition, ovulation can be confirmed by measuring plasma progesterone levels during the luteal phase ('day 21 progesterone').

Cessation of menstruation (the menopause) occurs at an average age of approximately 50 years in developed countries. In the 5 years before, there is a gradual increase in the number of anovulatory cycles and this is referred to as the climacteric. Oestrogen and inhibin secretion falls and negative feedback results in increased pituitary secretion of LH and FSH (typically to levels above 30 U/L (3.3 µg/L)).

The pathophysiology of male and female reproductive dysfunction is summarised in Box 20.21.

20.21 Classification of diseases of the reproductive system

	Primary	Secondary
Hormone excess	Polycystic ovarian syndrome Granulosa cell tumour Leydig cell tumour Teratoma	Pituitary gonadotrophinoma
Hormone deficiency	Menopause Hypogonadism (see Box 20.22) Turner's syndrome Klinefelter's syndrome	Hypopituitarism Kallmann's syndrome (isolated GnRH deficiency) Severe systemic illness, including anorexia nervosa
Hormone hypersensitivity	Idiopathic hirsutism	
Hormone resistance	Androgen resistance syndromes Complete ('testicular feminisation') Partial (Reifenstein's syndrome) 5α-reductase type 2 deficiency	
Non-functioning tumours	Ovarian cysts Carcinoma Teratoma Seminoma	

20.22 Causes of delayed puberty and hypogonadism

Constitutional delay

Hypogonadotrophic hypogonadism

- Structural hypothalamic/pituitary disease (see Box 20.59, p. 787)
- Functional gonadotrophin deficiency
  - Chronic systemic illness (e.g. asthma, malabsorption, coeliac disease, cystic fibrosis, renal failure)
  - Psychological stress
  - Anorexia nervosa
  - Excessive physical exercise
  - Hyperprolactinaemia
  - Other endocrine disease (e.g. Cushing's syndrome, primary hypothyroidism)
- Isolated gonadotrophin deficiency (Kallmann's syndrome)

Hypergonadotrophic hypogonadism

- Acquired gonadal damage
  - Chemotherapy/radiotherapy to gonads
  - Trauma/surgery to gonads
  - Autoimmune gonadal failure
  - Mumps orchitis
  - Tuberculosis
  - Haemochromatosis
- Developmental/congenital gonadal disorders
  - Steroid biosynthetic defects
  - Anorchidism/cryptorchidism in males
  - Klinefelter's syndrome (47XXY, male phenotype)
  - Turner's syndrome (45XO, female phenotype)

Presenting problems in reproductive disease

Delayed puberty

Puberty is considered to be delayed if the onset of the physical features of sexual maturation has not occurred by a chronological age that is 2.5 standard deviations (SD) above the national average. In the UK, this is by the age of 14 in boys and 13 in girls. Genetic factors have a major influence in determining the timing of the onset of puberty, such that the age of menarche (the onset of menstruation) is often comparable within sibling and mother–daughter pairs and within ethnic groups. However, because there is also a threshold for body weight that acts as a trigger for normal puberty, the onset of puberty can be influenced by other factors including nutritional status and chronic illness (p. 110).

20.23 Delayed puberty

- **Aetiology**: in boys the most common cause is constitutional delay, whereas in girls there is invariably an underlying structural or functional cause.
- **Psychological effects**: whatever the underlying cause, delayed puberty is often associated with substantial psychological distress.
- **Investigations**: a karyotype should be performed in all adolescents with hypergonadotrophic hypogonadism, to exclude Turner's and Klinefelter's syndromes, unless there is an obvious precipitating cause.
- **Medical induction of puberty**: if this is being considered, it needs to be managed carefully and be carried out in a controlled fashion, to avoid premature fusion of the epiphyses.

Clinical assessment

The differential diagnosis is shown in Box 20.22. The key issue is to determine whether the delay in puberty is simply because the 'clock is running slow' (constitutional delay of puberty) or because there is pathology in the hypothalamus/pituitary (hypogonadotrophic hypogonadism) or the gonads (hypergonadotrophic hypogonadism). A general history and physical examination should be performed with particular reference to previous or current medical disorders, social circumstances and family history. Body proportions, sense of smell and pubertal stage should be carefully documented and, in boys, the presence or absence of testes in the scrotum noted. Current weight and height may be plotted on centile charts, along with parental heights. Previous growth measurements in childhood, which can usually be obtained from health records, are extremely useful. Healthy growth usually follows a centile. Usually, children with constitutional delay have always been small, but have maintained a normal growth velocity that is appropriate for bone age. Poor linear growth, with 'crossing of the centiles', is more likely to be associated with acquired disease. Issues that are commonly encountered in the management of adolescents with delayed puberty are summarised in Box 20.23.

Constitutional delay of puberty

This is the most common cause of delayed puberty. Affected children are healthy and have usually been more than 2 SD below the mean height for their age

throughout childhood. There is often a history of delayed puberty in siblings or parents. Since sex steroids are essential for fusion of the epiphyses, 'bone age' can be estimated by X-rays of epiphyses, usually in the wrist and hand; in constitutional delay, bone age is lower than chronological age. Constitutional delay of puberty should be considered as a normal variant, as puberty will commence spontaneously. However, affected children can experience significant psychological distress because of their lack of physical development, particularly when compared with their peers.

Hypogonadotrophic hypogonadism

This may be due to structural, inflammatory or infiltrative disorders of the pituitary and/or hypothalamus (see Box 20.59, p. 787). In such circumstances, other pituitary hormones, such as growth hormone, are also likely to be deficient.

'Functional' gonadotrophin deficiency is caused by a variety of factors, including low body weight, chronic systemic illness (as a consequence of the disease itself or secondary malnutrition), endocrine disorders and profound psychosocial stress.

Isolated gonadotrophin deficiency is usually due to a genetic abnormality that affects the synthesis of either GnRH or gonadotrophins. The most common form is Kallmann's syndrome, in which there is primary GnRH deficiency and, in most affected individuals, agenesis or hypoplasia of the olfactory bulbs, resulting in anosmia or hyposmia. If isolated gonadotrophin deficiency is left untreated, the epiphyses fail to fuse, resulting in tall stature with disproportionately long arms and legs relative to trunk height (eunuchoid habitus).

Cryptorchidism (undescended testes) and gynaecomastia are commonly observed in all forms of hypogonadotrophic hypogonadism.

Hypergonadotrophic hypogonadism

Hypergonadotrophic hypogonadism associated with delayed puberty is usually due to Klinefelter's syndrome in boys and Turner's syndrome in girls (pp. 765 and 766). Other causes of primary gonadal failure are shown in Box 20.22.

Investigations

Key measurements are LH and FSH, testosterone (in boys) and oestradiol (in girls). Chromosome analysis should be performed if gonadotrophin concentrations are elevated. If gonadotrophin concentrations are low, then the differential diagnosis lies between constitutional delay and hypogonadotrophic hypogonadism. A plain X-ray of the wrist and hand may be compared with a set of standard films to obtain a bone age. Full blood count, renal function, liver function, thyroid function and coeliac disease autoantibodies (p. 880) should be measured, but further tests may be unnecessary if the blood tests are normal and the child has all the clinical features of constitutional delay. If hypogonadotrophic hypogonadism is suspected, neuroimaging and further investigations are required (p. 786).

Management

Puberty can be induced using low doses of oral oestrogen in girls (for example, ethinylestradiol 2 µg daily) or testosterone in boys (testosterone gel or depot testosterone esters). Higher doses carry a risk of early fusion of epiphyses. This therapy should be given in a specialist clinic where the progress of puberty and growth can be carefully monitored. In children with constitutional delay, this 'priming' therapy can be discontinued when endogenous puberty is established, usually in less than a year. In children with hypogonadism, the underlying cause should be treated and reversed if possible. If hypogonadism is permanent, sex hormone doses are gradually increased during puberty and full adult replacement doses given when development is complete.

Amenorrhoea

Primary amenorrhoea describes the condition of a female patient who has never menstruated; this usually occurs as a manifestation of delayed puberty but may also be a consequence of anatomical defects of the female reproductive system, such as endometrial hypoplasia or vaginal agenesis. Secondary amenorrhoea describes the cessation of menstruation. The causes of this common presentation are shown in Box 20.24. In non-pregnant women, secondary amenorrhoea is almost invariably a consequence of either ovarian or hypothalamic/pituitary dysfunction. Premature ovarian failure (premature menopause) is defined, arbitrarily, as occurring before 40 years of age. Rarely, endometrial adhesions (Asherman's syndrome) can form after uterine curettage, surgery or infection with tuberculosis or schistosomiasis, preventing endometrial proliferation and shedding.

Clinical assessment

The underlying cause can often be suspected from associated clinical features and the patient's age. Hypothalamic/pituitary disease and premature ovarian failure result in oestrogen deficiency, which causes a variety of symptoms usually associated with the menopause (Box 20.25). A history of galactorrhoea should be sought. Significant weight loss of any cause can cause amenorrhoea by suppression of gonadotrophins. Weight gain may suggest hypothyroidism, Cushing's syndrome or, very rarely, a hypothalamic lesion. Hirsutism, obesity and long-standing irregular periods suggest polycystic ovarian syndrome (PCOS, p. 764). The presence of other autoimmune disease raises the possibility of autoimmune premature ovarian failure.

Investigations

Pregnancy should be excluded in women of reproductive age by measuring urine or serum human chorionic

20.24 Causes of secondary amenorrhoea

Physiological
- Pregnancy
- Menopause

Hypogonadotrophic hypogonadism (see Box 20.22)

Ovarian dysfunction
- Hypergonadotrophic hypogonadism (see Box 20.22)
- Polycystic ovarian syndrome
- Androgen-secreting tumours

Uterine dysfunction
- Asherman's syndrome

20.25 Symptoms of oestrogen deficiency

Vasomotor effects	
• Hot flushes	• Sweating
Psychological	
• Anxiety • Irritability	• Emotional lability

• Dyspareunia • Urgency of micturition	• Vaginal infections

EBM 20.26 Hormone replacement therapy (HRT) in post-menopausal women

'Administering HRT for 5 years to 10 000 women aged 50–79 years prevents 5 hip fractures and 6 cases of colorectal cancer, while inducing 8 extra cases of breast cancer, 8 of pulmonary embolism, 7 of coronary heart disease and 8 of stroke. The risks increase with age.'

- Writing Group for the Women's Health Initiative Investigators. JAMA 2002: 288:321–333.

gonadotrophin (hCG). Serum LH, FSH, oestradiol, prolactin, testosterone, T_4 and TSH should be measured and, in the absence of a menstrual cycle, can be taken at any time. Investigation of hyperprolactinaemia is described on page 791. High concentrations of LH and FSH with low or low-normal oestradiol suggest primary ovarian failure. Ovarian autoantibodies may be positive when there is an underlying autoimmune aetiology, and a karyotype should be performed in younger women to exclude mosaic Turner's syndrome. Elevated LH, prolactin and testosterone levels with normal oestradiol are common in PCOS. Low levels of LH, FSH and oestradiol suggest hypothalamic or pituitary disease, and a pituitary MRI is indicated.

There is some overlap in gonadotrophin and oestrogen concentrations between women with hypogonadotrophic hypogonadism and PCOS. If there is doubt as to the underlying cause of secondary amenorrhoea, then the response to 5 days of treatment with an oral progestogen (e.g. medroxyprogesterone acetate 10 mg twice daily) can be assessed. In women with PCOS, the progestogen will cause maturation of the endometrium and menstruation will occur a few days after the progestogen is stopped. In women with hypogonadotrophic hypogonadism, menstruation does not occur following progestogen withdrawal because the endometrium is atrophic as a result of oestrogen deficiency. If doubt persists in distinguishing oestrogen deficiency from a uterine abnormality, the capacity for menstruation can be tested with 1 month of treatment with cyclical oestrogen and progestogen (usually administered as a combined oral contraceptive pill).

Assessment of bone mineral density by dual energy X-ray absorptiometry (DEXA, p. 1065) may be appropriate in patients with low androgen and oestrogen levels.

Management

Where possible, the underlying cause should be treated. For example, women with functional amenorrhoea due to excessive exercise and low weight should be encouraged to reduce their exercise and regain some weight. The management of structural pituitary and hypothalamic disease is described on page 790 and that of PCOS on page 764.

In oestrogen-deficient women, replacement therapy may be necessary to treat symptoms and/or to prevent osteoporosis. Women who have had a hysterectomy can be treated with oestrogen alone, but those with a uterus should be treated with combined oestrogen/progestogen therapy, since unopposed oestrogen increases the risk of endometrial cancer. Cyclical hormone replacement therapy (HRT) regimens typically involve giving oestrogen on days 1–21 and progestogen on days 14–21 of the cycle and this can be conveniently administered as the oral contraceptive pill. If oestrogenic side-effects (fluid retention, weight gain, hypertension and thrombosis) are a concern, then lower-dose oral or transdermal HRT may be more appropriate.

The timing of the discontinuation of oestrogen replacement therapy is still a matter of debate. In post-menopausal women, HRT has been shown to relieve menopausal symptoms and to prevent osteoporotic fractures but is associated with adverse effects, which are related to the duration of therapy and to the patient's age (Box 20.26). In patients with premature menopause, HRT should be continued up to the age of around 50 years, but only continued beyond this age if there are continued symptoms of oestrogen deficiency on discontinuation.

Management of infertility in oestrogen-deficient women is described on page 760.

Male hypogonadism

The clinical features of both hypo- and hypergonadotrophic hypogonadism include loss of libido, lethargy with muscle weakness, and decreased frequency of shaving. Patients may also present with gynaecomastia, infertility, delayed puberty, osteoporosis or anaemia of chronic disease. The causes of hypogonadism are listed in Box 20.22.

Investigations

Male hypogonadism is confirmed by demonstrating a low serum testosterone level. The distinction between hypo- and hypergonadotrophic hypogonadism is by measurement of random LH and FSH. Patients with hypogonadotrophic hypogonadism should be investigated as described for pituitary disease on page 786. Biochemical hypogonadism is associated with central obesity and the metabolic syndrome (p. 805); postulated mechanisms are complex and include reduction in sex hormone binding globulin by insulin resistance and reduction in GnRH and gonadotrophin secretion by cytokines or oestrogen released by adipose tissue. Testosterone levels also fall gradually with age in men (see Box 20.34, p. 766) and this is associated with gonadotrophin levels that are low or inappropriately within the 'normal' range. There is an increasing trend to measure testosterone in older men, typically as part of an assessment of erectile dysfunction. Patients with hypergonadotrophic hypogonadism should have the testes examined for cryptorchidism or atrophy,

20.27 Options for androgen replacement therapy

Route of administration	Preparation	Dose	Frequency	Comments
Intramuscular	Testosterone enantate	50–250 mg	Every 3–4 wks	Produces peaks and troughs of testosterone levels which are outside the physiological range and may be symptomatic
	Testosterone undecanoate	1000 mg	Every 3 mths	Smoother profile than testosterone enantate, less frequent injections
Subcutaneous	Testosterone pellets	600–800 mg	Every 4–6 mths	Smoother profile than testosterone enantate but implantation causes scarring and infection
Transdermal	Testosterone patch	5–10 mg	Daily	Stable testosterone levels but high incidence of skin hypersensitivity
	Testosterone gel	50–100 mg	Daily	Stable testosterone levels; transfer of gel can occur following skin-to-skin contact with another person
Oral	Testosterone undecanoate	40–120 mg	Twice daily	Very variable testosterone levels; risk of hepatotoxicity

and a karyotype performed (to identify Klinefelter's syndrome).

Management

Testosterone replacement is clearly indicated in younger men with significant hypogonadism to prevent osteoporosis and to restore muscle power and libido. Debate exists as to whether replacement therapy is of benefit in mild hypogonadism associated with ageing and central obesity, particularly in the absence of structural pituitary/hypothalamic disease or other pituitary hormone deficiency. In such instances, a therapeutic trial of testosterone therapy may be considered if symptoms are present, but the benefits of therapy must be carefully weighed against the potential for harm.

Routes of testosterone administration are shown in Box 20.27. First-pass hepatic metabolism of testosterone is highly efficient, so bioavailability of ingested preparations is poor. Doses of systemic testosterone can be titrated against symptoms; circulating testosterone levels may provide only a rough guide to dosage because they may be highly variable (see Box 20.27). Testosterone therapy can aggravate prostatic carcinoma; prostate-specific antigen (PSA) should be measured before commencing testosterone therapy in men older than 50 years and monitored annually thereafter. Haemoglobin concentration should also be monitored in older men, as androgen replacement can cause polycythaemia. Testosterone replacement inhibits spermatogenesis; treatment for fertility is described below.

Infertility

Infertility affects around 1 in 7 couples of reproductive age, often causing psychological distress. The main causes are listed in Box 20.28. In women, it may result from anovulation or abnormalities of the reproductive tract that prevent fertilisation or embryonic implantation, often damaged fallopian tubes from previous infection. In men, infertility may result from impaired sperm quality (for example, reduced motility) or reduced sperm number. Azoospermia or oligospermia is usually idiopathic, but may be a consequence of hypogonadism (see Box 20.22). Microdeletions of the Y chromosome are increasingly recognised as a cause of severely abnormal spermatogenesis. In many couples, more than one factor causing subfertility is present, and in a large proportion no cause can be identified.

20.28 Causes of infertility

Female factor (35–40%)

- Ovulatory dysfunction
  - Polycystic ovarian syndrome
  - Hypogonadotrophic hypogonadism (see Box 20.22)
  - Hypergonadotrophic hypogonadism (see Box 20.22)
- Tubular dysfunction
  - Pelvic inflammatory disease (chlamydia, gonorrhoea)
  - Endometriosis
  - Previous sterilisation
  - Previous pelvic or abdominal surgery
- Cervical and/or uterine dysfunction
  - Congenital abnormalities
  - Fibroids
  - Treatment for cervical carcinoma
  - Asherman's syndrome

Male factor (35–40%)

- Reduced sperm quality or production
  - Y chromosome microdeletions
  - Varicocoele
  - Hypergonadotrophic hypogonadism (see Box 20.22)
  - Hypogonadotrophic hypogonadism (see Box 20.22)
- Tubular dysfunction
  - Varicocoele
  - Congenital abnormality of vas deferens/epididymis
  - Previous sexually transmitted infection (chlamydia, gonorrhoea)
  - Previous vasectomy

Unexplained or mixed factor (20–35%)

Clinical assessment

A history of previous pregnancies, relevant infections and surgery is important in both men and women. A sexual history must be explored sensitively, as some couples have intercourse infrequently or only when they consider the woman to be ovulating, and psychosexual difficulties are common. Irregular and/or infrequent menstrual periods are an indicator of anovulatory cycles in the woman, in which case causes such as PCOS should

be considered. In men, the testes should be examined to confirm that both are in the scrotum and to identify any structural abnormality, such as small size, absent vas deferens or the presence of a varicocoele.

Investigations

Investigations should generally be performed after a couple has failed to conceive despite unprotected intercourse for 12 months, unless there is an obvious abnormality like amenorrhoea. Both partners need to be investigated. The male partner needs a semen analysis to assess sperm count and quality. Home testing for ovulation (by commercial urine dipstick kits, temperature measurement, or assessment of cervical mucus) is not recommended, as the information is often counterbalanced by increased anxiety if interpretation is inconclusive. In women with regular periods, ovulation can be confirmed by an elevated serum progesterone concentration on day 21 of the menstrual cycle. Transvaginal ultrasound can be used to assess uterine and ovarian anatomy. Tubal patency may be examined at laparoscopy or by hysterosalpingography (HSG; a radio-opaque medium is injected into the uterus and should normally outline the fallopian tubes). In vitro assessments of sperm survival in cervical mucus may be done in cases of unexplained infertility but are rarely helpful.

Management

Couples should be advised to have regular sexual intercourse, ideally every 2–3 days throughout the menstrual cycle. It is not uncommon for 'spontaneous' pregnancies to occur in couples undergoing investigations for infertility or with identified causes of male or female subfertility.

In women with anovulatory cycles secondary to PCOS (p. 764), clomifene, which has partial anti-oestrogen action, blocks negative feedback of oestrogen on the hypothalamus/pituitary, causing gonadotrophin secretion and thus ovulation. In women with gonadotrophin deficiency or in whom anti-oestrogen therapy is unsuccessful, ovulation may be induced by direct stimulation of the ovary by daily injection of FSH and an injection of hCG to induce follicular rupture at the appropriate time. In hypothalamic disease, pulsatile GnRH therapy with a portable infusion pump can be used to stimulate pituitary gonadotrophin secretion (note that non-pulsatile administration of GnRH or its analogues paradoxically suppresses LH and FSH secretion). Whatever method of ovulation induction is employed, monitoring of response is essential to avoid multiple ovulation. For clomifene, ultrasound monitoring is recommended for at least the first cycle. During gonadotrophin therapy, closer monitoring of follicular growth by transvaginal ultrasonography and blood oestradiol levels is mandatory. 'Ovarian hyperstimulation syndrome' is characterised by grossly enlarged ovaries and capillary leak with circulatory shock, pleural effusions and ascites. Anovulatory women who fail to respond to ovulation induction or who have primary ovarian failure may wish to consider using donated eggs or embryos, surrogacy and adoption.

Surgery to restore fallopian tube patency can be effective but in vitro fertilisation (IVF) is normally recommended. IVF is widely used for many causes of infertility and in unexplained cases of prolonged (> 3 years) infertility. The success of IVF depends on age, with low success rates in women over 40 years.

Men with hypogonadotrophic hypogonadism who wish fertility are usually given injections of hCG several times a week (recombinant FSH may also be required in men with hypogonadism of pre-pubertal origin); it may take up to 2 years to achieve satisfactory sperm counts. Surgery is rarely an option in primary testicular disease but removal of a varicocoele can improve semen quality. Extraction of sperm from the epididymis for IVF, and intracytoplasmic sperm injection (ICSI, when single spermatozoa are injected into each oöcyte) are being used increasingly in men with oligospermia or poor sperm quality who have primary testicular disease. Azoospermic men may opt to use donated sperm but this may be in short supply.

Gynaecomastia

Gynaecomastia is the presence of glandular breast tissue in males. Normal breast development in women is oestrogen-dependent, while androgens oppose this effect. Gynaecomastia results from an imbalance between androgen and oestrogen activity, which may reflect androgen deficiency or oestrogen excess. Causes are listed in Box 20.29. The most common are physiological: for example, in the newborn baby (due to maternal and placental oestrogens), in pubertal boys (in whom oestradiol concentrations reach adult levels before testosterone) and in elderly men (due to decreasing testosterone concentrations). Prolactin excess alone does not cause gynaecomastia (p. 790).

Clinical assessment

A drug history is important. Gynaecomastia is often asymmetrical and palpation may allow breast tissue to be distinguished from the prominent adipose tissue around the nipple that is often observed in obesity. Features of hypogonadism should be sought (see above) and the testes examined for evidence of cryptorchidism, atrophy or a tumour.

Investigations

If a clinical distinction between gynaecomastia and adipose tissue cannot be made, then ultrasonography or mammography is required. A random blood sample

20.29 Causes of gynaecomastia

Idiopathic

Physiological

Drug-induced
- Cimetidine
- Digoxin
- Anti-androgens (cyproterone acetate, spironolactone)
- Some exogenous anabolic steroids (diethylstilbestrol)
- Cannabis

Hypogonadism (see Box 20.22)

Androgen resistance syndromes

Oestrogen excess
- Liver failure (impaired steroid metabolism)
- Oestrogen-secreting tumour (for example, of testis)
- hCG-secreting tumour (for example, of testis or lung)

should be taken for testosterone, LH, FSH, oestradiol, prolactin and hCG. Elevated oestrogen concentrations are found in testicular tumours and hCG-producing neoplasms.

Management

An adolescent with gynaecomastia who is progressing normally through puberty may be reassured that the gynaecomastia will usually resolve once development is complete. If puberty does not proceed in a harmonious manner, then there may be an underlying abnormality that requires investigation (p. 758). Gynaecomastia may cause significant psychological distress, especially in adolescent boys, and surgical excision may be justified for cosmetic reasons. Androgen replacement will usually improve gynaecomastia in hypogonadal males and any other identifiable underlying cause should be addressed if possible. The anti-oestrogen tamoxifen may also be effective in reducing the size of the breast tissue.

Hirsutism

Hirsutism refers to the excessive growth of thick terminal hair in an androgen-dependent distribution in women (upper lip, chin, chest, back, lower abdomen, thigh, forearm) and is one of the most common presentations of endocrine disease. It should be distinguished from hypertrichosis, which is generalised excessive growth of vellus hair. The aetiology of androgen excess is shown in Box 20.30.

Clinical assessment

The severity of hirsutism is subjective. Some women suffer profound embarrassment from a degree of hair growth which others would not consider remarkable. Important observations are a drug and menstrual history, calculation of body mass index, measurement of blood pressure, and examination for virilisation (clitoromegaly, deep voice, male-pattern balding, breast atrophy) and associated features, including acne vulgaris or Cushing's syndrome (p. 773). Hirsutism of recent onset associated with virilisation is suggestive of an androgen-secreting tumour but this is rare.

Investigations

A random blood sample should be taken for testosterone, prolactin, LH and FSH. If there are clinical features of Cushing's syndrome, further investigations should be performed (p. 774).

If testosterone levels are more than twice the upper limit of normal for females, idiopathic hirsutism and PCOS are less likely, especially if LH and FSH levels are low. Under these circumstances, other causes of androgen excess should be sought. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency is diagnosed by a short ACTH stimulation test with measurement of 17OH-progesterone (p. 782). In patients with androgen-secreting tumours, serum testosterone does not suppress following dexamethasone (either as an overnight or a 48-hour low-dose suppression test) or oestrogen

20.30 Causes of hirsutism

Cause	Clinical features	Investigation findings	Treatment
Idiopathic	Often familial Mediterranean or Asian background	Normal	Cosmetic measures Anti-androgens
Polycystic ovarian syndrome	Obesity Oligomenorrhoea or secondary amenorrhoea Infertility	LH:FSH ratio > 2.5:1 Minor elevation of androgens* Mild hyperprolactinaemia	Weight loss Cosmetic measures Anti-androgens (Metformin, glitazones may be useful)
Congenital adrenal hyperplasia (95% 21-hydroxylase deficiency)	Pigmentation History of salt-wasting in childhood, ambiguous genitalia, or adrenal crisis when stressed Jewish background	Elevated androgens* which suppress with dexamethasone Abnormal rise in 17OH-progesterone with ACTH	Glucocorticoid replacement administered in reverse rhythm to suppress early morning ACTH
Exogenous androgen administration	Athletes Virilisation	Low LH and FSH Analysis of urinary androgens may detect drug of misuse	Stop steroid misuse
Androgen-secreting tumour of ovary or adrenal cortex	Rapid onset Virilisation: clitoromegaly, deep voice, balding, breast atrophy	High androgens* which do not suppress with dexamethasone or oestrogen Low LH and FSH CT or MRI usually demonstrates a tumour	Surgical excision
Cushing's syndrome	Clinical features of Cushing's syndrome (p. 773)	Normal or mild elevation of adrenal androgens* See investigations (p. 774)	Treat the cause (p. 775)

*e.g. Serum testosterone levels in women: < 2 nmol/L (< 58 ng/dL) is normal; 2–5 nmol/L (58–144 ng/dL) is minor elevation; > 5 nmol/L (> 144 ng/dL) is high and requires further investigation.

(30 µg daily for 7 days). The tumour should then be sought by CT or MRI of the adrenals and ovaries.

Management

This depends on the cause (see Box 20.30). Options for the treatment of PCOS and idiopathic hirsutism are similar and are described below.

Polycystic ovarian syndrome

Polycystic ovarian syndrome (PCOS) affects up to 10% of women of reproductive age. It is a heterogenous disorder (Box 20.31), often associated with obesity, for which the primary cause remains uncertain. Genetic factors probably play a role, since PCOS often affects several family members. The severity and clinical features of PCOS vary markedly between individual patients but diagnosis is usually made during the investigation of hirsutism (p. 763) or amenorrhoea/oligomenorrhoea (p. 759). Infertility may also be present (p. 761). There is no universally accepted definition, but it has been recommended that a diagnosis of PCOS requires the presence of two of the following three features:

- menstrual irregularity
- clinical or biochemical androgen excess
- multiple cysts in the ovaries (most readily detected by transvaginal ultrasound; Fig. 20.14).

Women with PCOS are at increased risk of glucose intolerance and some authorities recommend screening for type 2 diabetes and other cardiovascular risk factors associated with the metabolic syndrome (p. 805).

Management

This should be directed at the presenting complaint, but all PCOS patients who are overweight should be encouraged to lose weight, as this can improve several symptoms, including menstrual irregularity, and reduces the risk of type 2 diabetes.

20.31 Features of polycystic ovarian syndrome

Mechanisms*	Manifestations
Pituitary dysfunction	High serum LH High serum prolactin
Anovulatory menstrual cycles	Oligomenorrhoea Secondary amenorrhoea Cystic ovaries Infertility
Androgen excess	Hirsutism Acne
Obesity	Hyperglycaemia Elevated oestrogens
Insulin resistance	Dyslipidaemia Hypertension

*These mechanisms are interrelated; it is not known which, if any, is primary. PCOS probably represents the common end point of several different pathologies.

EBM 20.32 Treatment of infertility in women with PCOS

'In one randomised controlled clinical trial, 626 infertile women with PCOS were randomised to receive clomifene, metformin or combination therapy. After 6 months, the live birth rates were 22.5%, 7.2% and 26.8% respectively. Multiple births occurred in 6% of women receiving clomifene and none of those receiving metformin.'

- RS Legro, et al. New Engl J Med 2008; 356:551–566.

Menstrual irregularity and infertility

Most women with PCOS have oligomenorrhoea, with irregular, heavy menstrual periods. This may not require treatment unless fertility is desired. Metformin (p. 821), by reducing insulin resistance, may restore regular ovulatory cycles in overweight women, although it is less effective than clomifene (p. 762) at restoring fertility as measured by successful pregnancy (Box 20.32). Thiazolidinediones (p. 823) also enhance insulin sensitivity and restore menstrual regularity in PCOS, but are contraindicated in women planning pregnancy.

In women who have very few periods each year or are amenorrhoeic, the high oestrogen concentrations associated with PCOS can cause endometrial hyperplasia. Progestogens can be administered on a cyclical basis to induce regular shedding of the endometrium and a withdrawal bleed, or a progestogen-impregnated intrauterine coil can be fitted.

Hirsutism

For hirsutism, most patients will have used cosmetic measures, such as shaving, bleaching and waxing, before consulting a doctor. Electrolysis and laser treatment are effective for small areas like the upper lip and for chest hair but are expensive. Eflornithine cream inhibits ornithine decarboxylase in hair follicles and may reduce hair growth when applied daily to affected areas of the face.

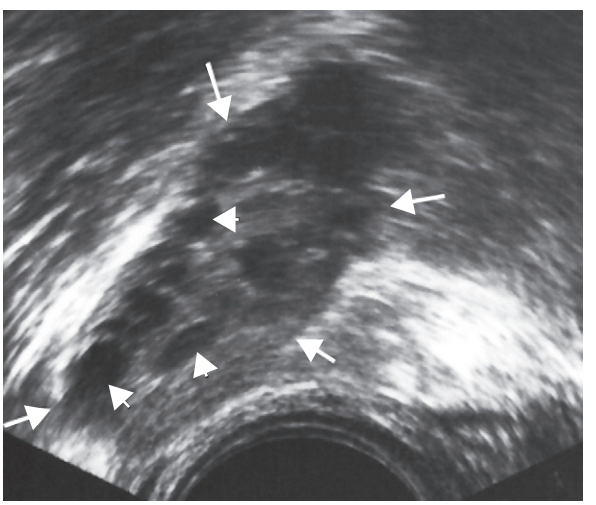

Fig. 20.14 Polycystic ovary. A transvaginal ultrasound scan showing multiple cysts (some indicated by small arrows) in the ovary (highlighted by bigger arrows) of a woman with polycystic ovarian syndrome.

20.33 Anti-androgen therapy

Mechanism of action	Drug	Dose	Hazards
Androgen receptor antagonists	Cyproterone acetate	2, 50 or 100 mg on days 1–11 of 28-day cycle with ethinylestradiol 30 μg on days 1–21	Hepatic dysfunction Feminisation of male fetus Progesterone receptor agonist Dysfunctional uterine bleeding
	Spironolactone	100–200 mg daily	Electrolyte disturbance
	Flutamide	Not recommended	Hepatic dysfunction
5α-reductase inhibitors (prevent conversion of testosterone to active dihydrotestosterone)	Finasteride	5 mg daily	Limited clinical experience; possibly less efficacious than other treatments
Suppress ovarian steroid production and elevate sex hormone-binding globulin	Oestrogen	See combination with cyproterone acetate above *or* Conventional oestrogen-containing contraceptive	Venous thromboembolism Hypertension Weight gain Dyslipidaemia Increased breast and endometrial carcinoma

If conservative measures are unsuccessful, anti-androgen therapy is given (Box 20.33). The life cycle of a hair follicle is at least 3 months and no improvement is likely before this time, when follicles have shed their hair and replacement hair growth has been suppressed. Metformin and thiazolidinediones are less effective at treating hirsutism than at restoring menstrual regularity. Unless weight is lost, hirsutism will return if therapy is discontinued. The patient should know that prolonged exposure to some agents may not be desirable and they should be stopped before pregnancy.

Turner's syndrome

Turner's syndrome affects around 1 in 2500 females. It is classically associated with a 45XO karyotype but other cytogenetic abnormalities may be responsible, including mosaic forms (e.g. 45XO/46XX or 45XO/46XY) and partial deletions of an X chromosome.

Clinical features

These are shown in Figure 20.15.

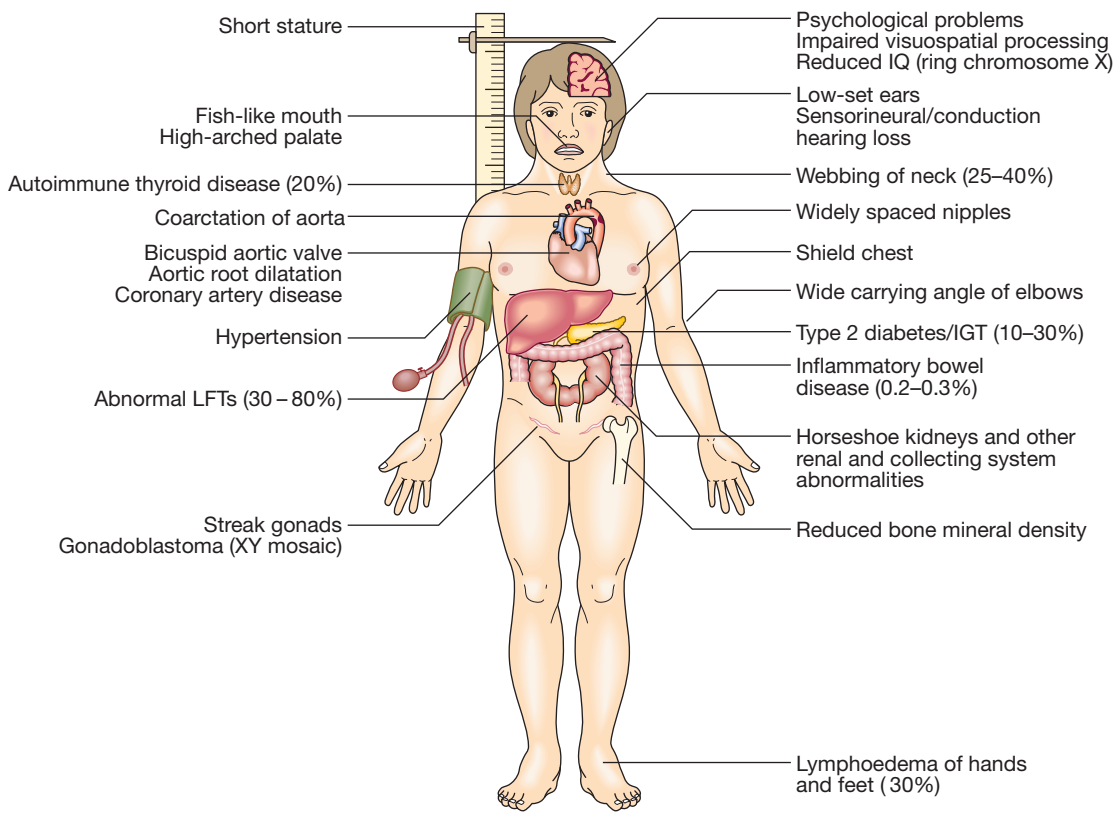

Fig. 20.15 Clinical features of Turner's syndrome (45XO). (IGT = impaired glucose tolerance).

20.34 Gonadal function in old age

- **Post-menopausal osteoporosis**: a major public health issue due to the high incidence of associated fragility fractures, especially of hip.
- **Hormone replacement therapy**: should only be prescribed above the age of 50 for the short-term relief of symptoms of oestrogen deficiency.
- **Sexual activity**: many older people remain sexually active.
- **'Male menopause'**: does not occur, although testosterone concentrations do fall with age. Testosterone therapy in mildly hypogonadal men may be of benefit for body composition, muscle and bone. Large randomised trials are required to determine whether benefits outweigh potentially harmful effects on the prostate and cardiovascular system.
- **Androgens in older women**: hirsutism and balding occur. In the rare patients in whom androgen levels are elevated, this may be pathological, e.g. from an ovarian tumour.

Individuals with Turner's syndrome invariably have short stature from an early age and this is often the initial presenting symptom. It is probably due to haploinsufficiency of the *SHOX* gene, one copy of which is found on both the X and Y chromosomes, which encodes a protein that is predominantly found in bone fibroblasts.

The genital tract and external genitalia in Turner's syndrome are female in character, since this is the default developmental outcome in the absence of testes. Ovarian tissue develops normally until the third month of gestation, but thereafter there is gonadal dysgenesis with accelerated degeneration of oöcytes and increased ovarian stromal fibrosis, resulting in 'streak ovaries'. The inability of ovarian tissue to produce oestrogen results in loss of negative feedback and elevation of FSH and LH concentrations.

There is a wide variation in the spectrum of associated somatic abnormalities. The severity of the phenotype is, in part, related to the underlying cytogenetic abnormality. Mosaic individuals may have only mild short stature and may enter puberty spontaneously before developing gonadal failure.

Diagnosis and management

The diagnosis of Turner's syndrome can be confirmed by karyotype analysis. Short stature, although not directly due to growth hormone deficiency, responds to high doses of growth hormone. Prophylactic gonadectomy is recommended for individuals with 45XO/46XY mosaicism because there is an increased risk of gonadoblastoma. Pubertal development can be induced with oestrogen therapy but causes fusion of the epiphyses and cessation of growth. Therefore, the timing of pubertal induction needs to be carefully planned. Adults with Turner's syndrome require long-term oestrogen replacement therapy and should be monitored periodically for the development of aortic root dilatation, hearing loss and other somatic complications.

Klinefelter's syndrome

Klinefelter's syndrome affects approximately 1 in 1000 males and is usually associated with a 47XXY karyotype. However, other cytogenetic variants may be responsible, especially 46XY/47XXY mosaicism. The principal pathological abnormality is dysgenesis of the seminiferous tubules. This is evident from infancy (and possibly even in utero) and progresses with age. By adolescence, hyalinisation and fibrosis are present within the seminiferous tubules and Leydig cell function is impaired, resulting in hypogonadism.

Clinical features

The diagnosis is typically made in adolescents who have presented with gynaecomastia and failure to progress normally through puberty. Affected individuals usually have small, firm testes. Tall stature is apparent from early childhood, reflecting characteristically long leg length associated with 47XXY, and may be exacerbated by androgen deficiency with lack of epiphyseal closure in puberty. Other clinical features may include learning difficulties and behavioural disorders, as well as an increased risk of breast cancer and type 2 diabetes in later life. The spectrum of clinical features is wide and some individuals, especially those with 46XY/47XXY mosaicism, may pass through puberty normally and be identified only during investigation for infertility.

Diagnosis and management

Klinefelter's syndrome is suggested by the typical phenotype in a patient with hypergonadotrophic hypogonadism and can be confirmed by karyotype analysis. Individuals with clinical and biochemical evidence of androgen deficiency require androgen replacement (see Box 20.27, p. 761).

THE PARATHYROID GLANDS

Parathyroid hormone (PTH) plays a key role in the regulation of calcium and phosphate homeostasis and vitamin D metabolism, as shown in Figure 25.55 (p. 1125). The consequences of altered function of this axis in gut and renal disease are covered in Chapters 22 and 17, respectively. Other metabolic bone diseases are explored in Chapter 25. Here, the investigation of hypercalcaemia and hypocalcaemia and disorders of the parathyroid glands are discussed.

Functional anatomy, physiology and investigations

The four parathyroid glands lie behind the lobes of the thyroid and weigh between 25 and 40 mg. The parathyroid chief cells respond directly to changes in calcium concentrations via a G-protein-coupled cell surface receptor (the calcium-sensing receptor) located on the cell surface (see Fig. 25.55). When serum ionised calcium levels fall, PTH secretion rises. PTH is a single-chain polypeptide of 84 amino acids. It acts on the renal tubules to promote reabsorption of calcium and reduce reabsorption of phosphate, and on the skeleton to increase osteoclastic bone resorption and bone formation. PTH also promotes conversion of 25-hydroxycholecalciferol to the active metabolite 1,25-dihydroxycholecalciferol; the 1,25-dihydroxycholecalciferol, in turn, enhances calcium absorption from the gut.

More than 99% of total body calcium is in bone. Prolonged exposure of bone to high levels of PTH is associated with increased osteoclastic activity and new bone formation, but the net effect is to cause bone loss with mobilisation of calcium into the extracellular fluid. In contrast, pulsatile release of PTH causes net bone gain, an effect that is exploited therapeutically in the treatment of osteoporosis (p. 1124).

The differential diagnosis of disorders of calcium metabolism requires measurement of calcium phosphate, alkaline phosphatase, renal function, PTH and 25(OH)D. Although the parathyroid glands detect and respond to ionised calcium levels, most clinical laboratories only measure total serum calcium levels and about 50% of total calcium is bound to organic ions, such as citrate or phosphate, and to proteins, especially albumin. Accordingly, if the serum albumin level is reduced, total calcium concentrations should be 'corrected' by adjusting the value for calcium upwards by 0.02 mmol/L (0.4 mg/dL) for each 1 g/L reduction in albumin below 40 g/L. If albumin concentrations are significantly low, as in severe acute illness and other chronic illness such as liver cirrhosis, this correction is less accurate and measurement of ionised calcium is needed.

Calcitonin is secreted from the parafollicular C cells of the thyroid gland. Although it is a useful tumour marker in medullary carcinoma of thyroid (p. 755) and can be given therapeutically in Paget's disease of bone (p. 1129), its release from the thyroid is of no clinical relevance to calcium homeostasis in humans.

Disorders of the parathyroid glands are summarised in Box 20.35.

20.35 Classification of diseases of the parathyroid glands

	Primary	Secondary
Hormone excess	Primary hyperparathyroidism Parathyroid adenoma Parathyroid carcinoma[1] Parathyroid hyperplasia[2] Tertiary hyperparathyroidism Following prolonged secondary hyperparathyroidism	Secondary hyperparathyroidism Chronic kidney disease Malabsorption Vitamin D deficiency
Hormone deficiency	Hypoparathyroidism Post-surgical Autoimmune Inherited	
Hormone hypersensitivity	Autosomal dominant hypercalciuric hypocalcaemic (CASR-activating mutation)	
Hormone resistance	Pseudohypoparathyroidism Familial hypocalciuric hypercalcaemia	
Non-functioning tumours	Parathyroid carcinoma[1]	

[1]Parathyroid carcinomas may or may not produce PTH. [2]In multiple endocrine neoplasia (MEN) syndromes (p. 794)
(CASR = calcium-sensing receptor)

Presenting problems in parathyroid disease

Hypercalcaemia

Hypercalcaemia is one of the most common biochemical abnormalities and is often detected during routine biochemical analysis in asymptomatic patients. However, it can present with chronic symptoms, as described below, and occasionally as an acute emergency with severe hypercalcaemia and dehydration.

Causes of hypercalcaemia are listed in Box 20.36. Of these, primary hyperparathyroidism and malignant hypercalcaemia are by far the most common. Familial hypocalciuric hypercalcaemia (FHH) is a rare but important cause that needs differentiation from primary hyperparathyroidism (HPT). Lithium may cause hyperparathyroidism by reducing the sensitivity of the calcium-sensing receptor.

Clinical assessment

Symptoms and signs of hypercalcaemia include polyuria and polydipsia, renal colic, lethargy, anorexia, nausea, dyspepsia and peptic ulceration, constipation, depression, drowsiness and impaired cognition. Patients with malignant hypercalcaemia can have a rapid onset of symptoms and may have clinical features that help to localise the tumour.

The classic symptoms of primary hyperparathyroidism are described by the adage 'bones, stones and abdominal groans', but few patients present in this way nowadays and the disorder is most often picked up as an incidental finding on biochemical testing. About 50% of patients with primary hyperparathyroidism are asymptomatic while others have non-specific symptoms such as fatigue, depression and generalised aches and pains. Some present with renal calculi and it has been estimated that 5% of first stone formers and 15% of recurrent stone formers have primary hyperparathyroidism (p. 769). Hypertension is a common feature of hyperparathyroidism. Parathyroid tumours are almost never palpable.

A family history of hypercalcaemia raises the possibility of FHH or MEN (p. 794).

20.36 Causes of hypercalcaemia

With normal or elevated PTH levels

- Primary or tertiary hyperparathyroidism
- Lithium-induced hyperparathyroidism
- Familial hypocalciuric hypercalcaemia

With low PTH levels

- Malignancy (lung, breast, myeloma, renal, lymphoma, thyroid)
- Elevated 1,25$(OH)_2$ vitamin D (vitamin D intoxication, sarcoidosis, HIV, other granulomatous disease)
- Thyrotoxicosis
- Paget's disease with immobilisation
- Milk-alkali syndrome
- Thiazide diuretics
- Glucocorticoid deficiency

Investigations

The most discriminant investigation is measurement of PTH. If PTH levels are detectable or elevated in the presence of hypercalcaemia, then primary hyperparathyroidism is the most likely diagnosis. High plasma phosphate and alkaline phosphatase accompanied by renal impairment suggest tertiary hyperparathyroidism. Hypercalcaemia may cause nephrocalcinosis and renal tubular impairment, resulting in hyperuricaemia and hyperchloraemia.

Patients with FHH can present with a similar biochemical picture to primary hyperparathyroidism but typically have low urinary calcium excretion (a ratio of urinary calcium clearance to creatinine clearance of < 0.01). The diagnosis of FHH can be confirmed by screening family members for hypercalcaemia and/or a mutation in the gene encoding the calcium-sensing receptor.

If PTH is low and no other cause is apparent, then malignancy with or without bony metastases is likely. PTH-related peptide, which is often responsible for the hypercalcaemia associated with malignancy, is not detected by PTH assays, but can be measured by a specific assay (although this is not usually necessary). Unless the source is obvious, the patient should be screened for malignancy with a chest X-ray, myeloma screen (p. 1046) and CT as appropriate.

Management

Treatment of severe hypercalcaemia and primary hyperparathyroidism is described on pages 273 and 769, respectively. FHH does not require any specific intervention.

Hypocalcaemia

Aetiology

Hypocalcaemia is much less common than hypercalcaemia. The differential diagnosis is shown in Box 20.37.

The most common cause of hypocalcaemia is a low serum albumin with normal ionised calcium concentration. Conversely, ionised calcium may be low in the face of normal total serum calcium in patients with alkalosis: for example, as a result of hyperventilation.

Hypocalcaemia may also develop as a result of magnesium depletion and should be considered in patients with malabsorption, on diuretic or proton pump inhibitor therapy, and/or with a history of alcohol excess. Magnesium deficiency causes hypocalcaemia by impairing the ability of the parathyroid glands to secrete PTH (resulting in PTH concentrations that are low or inappropriately in the reference range) and may also impair the actions of PTH on bone and kidney.

Clinical assessment

Mild hypocalcaemia is often asymptomatic but, with more profound reductions in serum calcium, tetany can occur. This is characterised by muscle spasms due to increased excitability of peripheral nerves.

Children are more liable to develop tetany than adults and present with a characteristic triad of carpopedal spasm, stridor and convulsions, although one or more of these may be found independently of the others. In carpopedal spasm, the hands adopt a characteristic position with flexion of the metacarpophalangeal joints of the fingers and adduction of the thumb ('main d'accoucheur'). Pedal spasm can also occur but is less frequent. Stridor is caused by spasm of the glottis. Adults can also develop carpopedal spasm in association with tingling of the hands and feet and around the mouth, but stridor and fits are rare.

Latent tetany may be detected by eliciting Trousseau's sign; inflation of a sphygmomanometer cuff on the upper arm to more than the systolic blood pressure is followed by carpal spasm within 3 minutes. Less specific is Chvostek's sign, in which tapping over the branches of the facial nerve as they emerge from the parotid gland produces twitching of the facial muscles.

20.37 Differential diagnosis of hypocalcaemia

	Total serum calcium	Ionised serum calcium	Serum phosphate	Serum PTH	Comments
Hypoalbuminaemia	↓	↔	↔	↔	Adjust calcium upwards by 0.02 mmol/L (0.1 mg/dL) for every 1 g/L reduction in albumin below 40 g/L
Alkalosis	↔	↓	↔	↔ or ↑	Ch. 16
Vitamin D deficiency	↓	↓	↓	↑	Ch. 25
Chronic renal failure	↓	↓	↑	↑	Due to impaired vitamin D hydroxylation Serum creatinine ↑
Hypoparathyroidism	↓	↓	↑	↓	See text
Pseudohypoparathyroidism	↓	↓	↑	↑	Characteristic phenotype (see text)
Acute pancreatitis	↓	↓	↔ or ↓	↑	Usually clinically obvious Serum amylase ↑
Hypomagnesaemia	↓	↓	Variable	↓ or ↔	Treatment of hypomagnesaemia may correct hypocalcaemia

(↑ = levels increased; ↓ = levels reduced; ↔ = levels normal)

20.38 Management of severe hypocalcaemia

Immediate management

- 10–20 mL 10% calcium gluconate IV over 10–20 mins
- Continuous IV infusion may be required for several hours (equivalent of 10 mL 10% calcium gluconate/hr)
- Cardiac monitoring is recommended

If associated hypomagnesaemia

- 50 mmol magnesium chloride IV over 24 hours
- Most parenteral magnesium will be excreted in the urine, so further doses may be required to replenish body stores

Hypocalcaemia can cause papilloedema and prolongation of the ECG QT interval, which may predispose to ventricular arrhythmias. Prolonged hypocalcaemia and hyperphosphataemia (as in hypoparathyroidism) may cause calcification of the basal ganglia, grand mal epilepsy, psychosis and cataracts. Hypocalcaemia associated with hypophosphataemia, as in vitamin D deficiency, causes rickets in children and osteomalacia in adults (p. 1125).

Management

Emergency management of hypocalcaemia associated with tetany is described in Box 20.38. Treatment of chronic hypocalcaemia is described on page 770.

Primary hyperparathyroidism

Primary hyperparathyroidism is caused by autonomous secretion of PTH, usually by a single parathyroid adenoma, which can vary in diameter from a few millimetres to several centimetres. It should be distinguished from secondary hyperparathyroidism, in which there is a physiological increase in PTH secretion to compensate for prolonged hypocalcaemia (such as in vitamin D deficiency, p. 1126), and from tertiary hyperparathyroidism, in which continuous stimulation of the parathyroids over a prolonged period of time results in adenoma formation and autonomous PTH secretion (Box 20.39). This is most commonly seen in individuals with advanced chronic kidney disease (p. 483).

The prevalence of primary hyperparathyroidism is about 1 in 800 and it is 2–3 times more common in women than men; 90% of patients are over 50 years of age. It also occurs in the familial MEN syndromes (p. 795), in which case hyperplasia or multiple adenomas of all four parathyroid glands are more likely than a solitary adenoma.

Clinical and radiological features

The clinical presentation of primary hyperparathyroidism is described on page 769. Parathyroid bone disease is now rare due to earlier diagnosis and treatment. Osteitis fibrosa results from increased bone resorption by osteoclasts with fibrous replacement in the lacunae. This may present as bone pain and tenderness, fracture and deformity. Chondrocalcinosis can occur due to deposition of calcium pyrophosphate crystals within articular cartilage. It typically affects the menisci at the knees and can result in secondary degenerative arthritis or predispose to attacks of acute pseudogout

20.39 Hyperparathyroidism

Type	Serum calcium	PTH
Primary Single adenoma (90%) Multiple adenomas (4%) Nodular hyperplasia (5%) Carcinoma (1%)	Raised	Not suppressed
Secondary Chronic renal failure Malabsorption Osteomalacia and rickets	Low	Raised
Tertiary	Raised	Not suppressed

(p. 1090). Skeletal X-rays are usually normal in mild primary hyperparathyroidism, but in patients with advanced disease characteristic changes are observed. In the early stages there is demineralisation, with subperiosteal erosions and terminal resorption in the phalanges. A 'pepper-pot' appearance may be seen on lateral X-rays of the skull. Reduced bone mineral density, resulting in either osteopenia or osteoporosis, is now the most common skeletal manifestation of hyperparathyroidism. This is usually not evident radiographically and requires assessment by DEXA (p. 1065).

In nephrocalcinosis, scattered opacities may be visible within the renal outline. There may be soft tissue calcification in arterial walls and hands and in the cornea.

Investigations

The diagnosis can be confirmed by finding a raised PTH level in the presence of hypercalcaemia, provided that FHH is excluded (p. 770). Parathyroid scanning by ^{99m}Tc-sestamibi scintigraphy (Fig. 20.16) and/or ultrasound examination can be performed prior to surgery, in an attempt to localise an adenoma and allow a targeted resection. However, negative imaging does not exclude the diagnosis.

Management

The treatment of choice for primary hyperparathyroidism is surgery, with excision of a solitary parathyroid adenoma or hyperplastic glands. Experienced surgeons will identify solitary tumours in more than 90% of cases. Patients with parathyroid bone disease run a significant risk of developing hypocalcaemia postoperatively, but the risk of this can be reduced by correcting vitamin D deficiency pre-operatively.

Surgery is usually indicated for individuals aged less than 50 years, with clear-cut symptoms or documented complications (such as peptic ulceration, renal stones, renal impairment or osteoporosis), and (in asymptomatic patients) significant hypercalcaemia (corrected serum calcium > 2.85 mmol/L (> 11.4 mg/dL)). Patients who are treated conservatively without surgery should have calcium biochemistry and renal function checked annually and bone density monitored periodically. They should be encouraged to maintain a high oral fluid intake to avoid renal stones.

Occasionally, primary hyperparathyroidism presents with severe life-threatening hypercalcaemia. This is often due to dehydration and should be managed medically with intravenous fluids and bisphosphonates, as

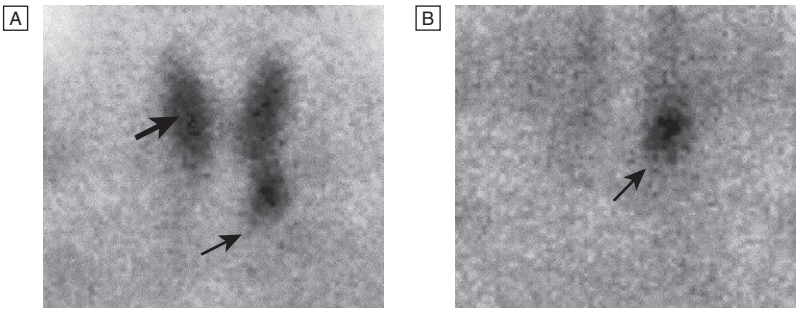

Fig. 20.16 ^{99m}**Tc-sestamibi scan of a patient with primary hyperparathyroidism secondary to a parathyroid adenoma.** A After 1 hour, there is uptake in the thyroid gland (thick arrow) and the enlarged left inferior parathyroid gland (thin arrow). B After 3 hours, uptake is evident only in the parathyroid.

described on page 273. If this is not effective, then urgent parathyroidectomy should be considered.

Cinacalcet is a calcimimetic which enhances the sensitivity of the calcium-sensing receptor, so reducing PTH levels, and is licensed for tertiary hyperparathyroidism and as a treatment for patients with primary hyperparathyroidism who are unwilling to have surgery or are medically unfit.

Familial hypocalciuric hypercalcaemia

This autosomal dominant disorder is caused by an inactivating mutation in one of the alleles of the calcium-sensing receptor gene, which reduces the ability of the parathyroid gland to 'sense' ionised calcium concentrations. As a result, higher than normal calcium levels are required to suppress PTH secretion. The typical presentation is with mild hypercalcaemia with PTH concentrations that are 'inappropriately' at the upper end of the reference range or are slightly elevated. Calcium-sensing receptors in the renal tubules are also affected and this leads to increased renal tubular reabsorption of calcium and hypocalciuria. The hypercalcaemia of FHH is always asymptomatic and complications do not occur. The main risk of FHH is of the patient being subjected to an unnecessary (and ineffective) parathyroidectomy if misdiagnosed as having primary hyperparathyroidism. Testing of family members for hypercalcaemia is helpful in confirming the diagnosis and it is also possible to perform genetic testing. No treatment is necessary.

Hypoparathyroidism

The most common cause of hypoparathyroidism is damage to the parathyroid glands (or their blood supply) during thyroid surgery; post-operative hypocalcaemia develops in 5.5% of patients overall but 9% of patients undergoing total thyroidectomy. Rarely, hypoparathyroidism can occur as a result of infiltration of the glands with iron in haemochromatosis (p. 972) or copper in Wilson's disease (p. 973).

There are a number of rare congenital or inherited forms of hypoparathyroidism. One form is associated with autoimmune polyendocrine syndrome type 1 (p. 795) and another with DiGeorge syndrome (p. 56). Autosomal dominant hypoparathyroidism (ADH) is the mirror image of familial hypocalciuric hypercalcaemia (see above), in that an activating mutation in the calcium-sensing receptor reduces PTH levels, resulting in hypocalcaemia and hypercalciuria.

20.40 The parathyroid glands in old age

- **Osteoporosis**: always exclude osteomalacia and hyperparathyroidism by checking vitamin D and calcium concentrations.
- **Primary hyperparathyroidism**: more common with ageing. Older people can often be observed without surgical intervention.
- **Hypercalcaemia**: may cause confusion.
- **Vitamin D deficiency**: common because of poor diet and limited exposure to the sun.

Pseudohypoparathyroidism

In this disorder, the individual is functionally hypoparathyroid but, instead of PTH deficiency, there is tissue resistance to the effects of PTH, such that PTH concentrations are markedly elevated. The PTH receptor itself is normal but the downstream signalling pathways are defective due to mutations that affect *GNAS1*, which encodes the Gsα protein, a molecule involved in signal transduction downstream of the PTH receptor and other G-protein-coupled receptors. There are several subtypes but the most common (pseudohypoparathyroidism type 1a) is characterised by hypocalcaemia and hyperphosphataemia, in association with short stature, short fourth metacarpals and metatarsals, rounded face, obesity and subcutaneous calcification; these features are collectively referred to as Albright's hereditary osteodystrophy (AHO). Type 1a pseudohypoparathyroidism occurs only when the *GNAS1* mutation is inherited on the maternal chromosome.

The term pseudopseudohypoparathyroidism is used to describe patients who have clinical features of AHO but normal serum calcium and PTH concentrations; it occurs when the *GNAS1* mutation is inherited on the paternal chromosome. The inheritance of these disorders is an example of genetic imprinting (p. 52). The difference in clinical features occurs as a result of the fact that renal cells exclusively express the maternal *GNAS1* allele, whereas both maternal and paternal alleles are expressed in other cell types; this explains why maternal inheritance is associated with hypocalcaemia and resistance to PTH (which regulates serum calcium and phosphate levels largely by an effect on the renal tubule), and why paternal inheritance is associated with skeletal and other abnormalities in the absence of hypocalcaemia and raised PTH values.

Management of hypoparathyroidism

Persistent hypoparathyroidism and pseudohypoparathyroidism are treated with oral calcium salts and

vitamin D analogues, either 1α-hydroxycholecalciferol (alfacalcidol) or 1,25-dihydroxycholecalciferol (calcitriol). This therapy needs careful monitoring because of the risks of iatrogenic hypercalcaemia, hypercalciuria and nephrocalcinosis. Recombinant PTH is available as subcutaneous injection therapy for osteoporosis (p. 1120) and, although not currently licensed, has been used in hypoparathyroidism (but not in pseudohypoparathyroidism). It is much more expensive than calcium and vitamin D analogue therapy but has the advantage that it is less likely to cause hypercalciuria. There is no specific treatment for AHO other than to try to maintain calcium levels within the reference range using active vitamin D metabolites.

THE ADRENAL GLANDS

The adrenals comprise several separate endocrine glands within a single anatomical structure. The adrenal medulla is an extension of the sympathetic nervous system which secretes catecholamines into capillaries rather than synapses. Most of the adrenal cortex is made up of cells which secrete cortisol and adrenal androgens, and form part of the hypothalamic–pituitary–adrenal (HPA) axis. The small outer glomerulosa of the cortex secretes aldosterone under the control of the renin–angiotensin system. These functions are important in the integrated control of cardiovascular, metabolic and immune responses to stress.

There is increasing evidence that subtle alterations in adrenal function contribute to the pathogenesis of common diseases such as hypertension, obesity and type 2 diabetes mellitus. However, classical syndromes of adrenal hormone deficiency and excess are relatively rare.

Functional anatomy and physiology

Adrenal anatomy and function are shown in Figure 20.17. Histologically, the cortex is divided into three zones, but these function as two units (zona glomerulosa and zonae fasciculata/reticularis) which produce

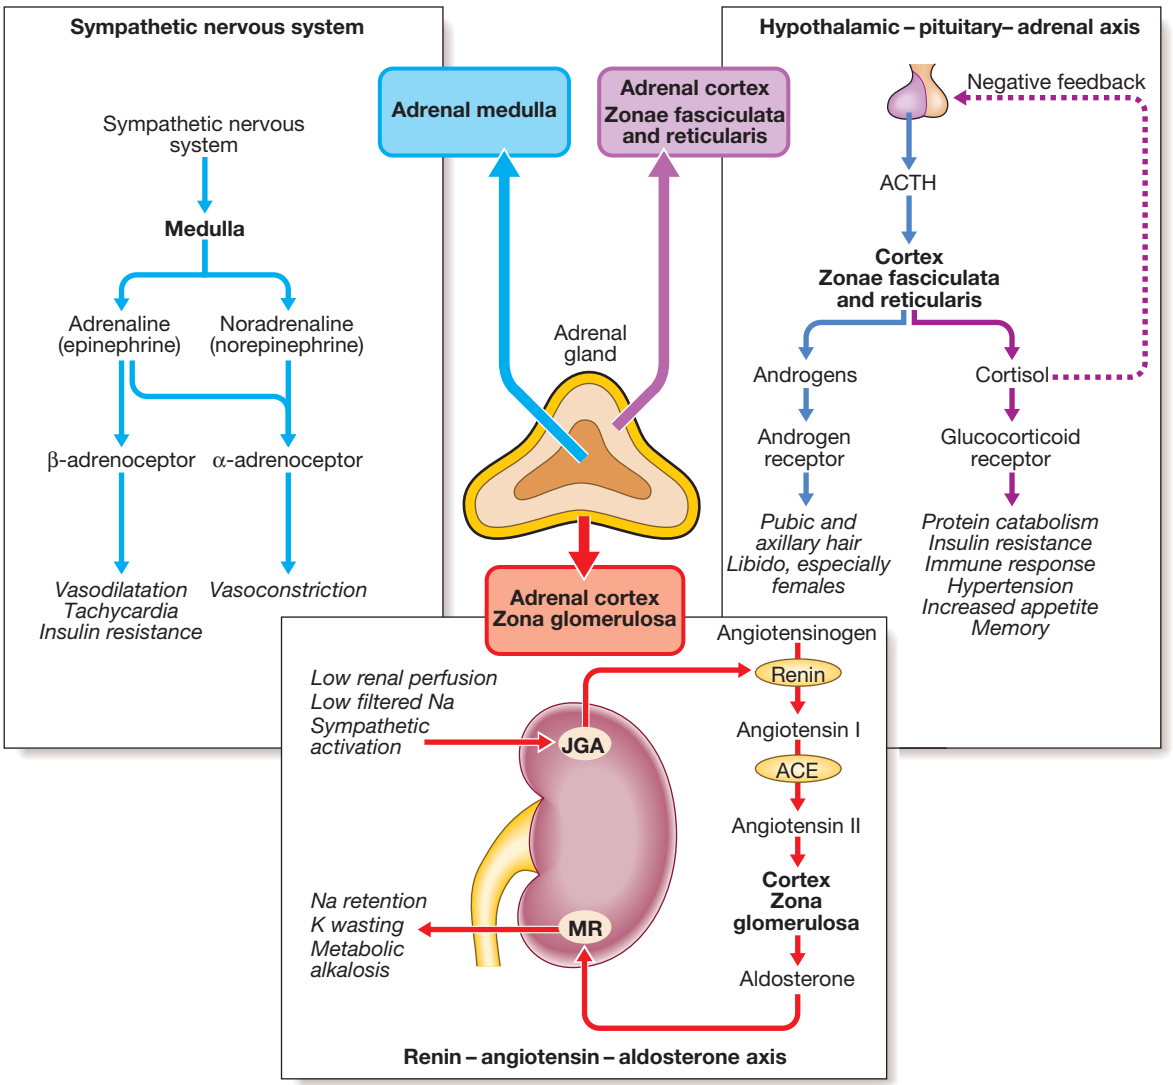

Fig. 20.17 Structure and function of the adrenal glands. (ACE = angiotensin-converting enzyme; ACTH = adrenocorticotrophic hormone; JGA = juxtaglomerular apparatus; MR = mineralocorticoid receptor).

20.41 Classification of diseases of the adrenal glands

	Primary	Secondary
Hormone excess	Non-ACTH-dependent Cushing's syndrome Primary hyperaldosteronism Phaeochromocytoma	ACTH-dependent Cushing's syndrome Secondary hyperaldosteronism
Hormone deficiency	Addison's disease Congenital adrenal hyperplasia	Hypopituitarism
Hormone hypersensitivity	11 β-hydroxysteroid dehydrogenase type 2 deficiency Liddle's syndrome	
Hormone resistance	Pseudohypoaldosteronism Glucocorticoid resistance syndrome	
Non-functioning tumours	Adenoma Carcinoma (usually functioning) Metastatic tumours	

corticosteroids in response to humoral stimuli. Pathways for the biosynthesis of corticosteroids are shown in Figure 20.18. Investigation of adrenal function is described under specific diseases below. The different types of adrenal disease are shown in Box 20.41.

Glucocorticoids

Cortisol is the major glucocorticoid in humans. Levels are highest in the morning on waking and lowest in the middle of the night. Cortisol rises dramatically during stress, including any illness. This elevation protects key metabolic functions (such as the maintenance of cerebral glucose supply during starvation) and inhibits potentially damaging inflammatory responses to infection and injury. The clinical importance of cortisol deficiency is, therefore, most obvious at times of stress.

More than 95% of circulating cortisol is bound to protein, principally cortisol-binding globulin, which is increased by oestrogens. It is the free fraction that is biologically active. Cortisol regulates cell function by binding to glucocorticoid receptors that regulate the transcription of many genes. Cortisol can also activate mineralocorticoid receptors, but it does not normally do so because most cells containing mineralocorticoid receptors also express an enzyme called 11 β-hydroxysteroid dehydrogenase type 2 (11 β-HSD2), which inactivates cortisol by converting it to cortisone. Inhibitors of 11 β-HSD2 (such as liquorice) or mutations in the gene that encodes 11 β-HSD2 cause cortisol to act as a mineralocorticoid, resulting in sodium retention and hypertension (see Box 20.50, p. 780).

Mineralocorticoids

Aldosterone is the most important mineralocorticoid. It binds to mineralocorticoid receptors in the kidney and causes sodium retention and increased excretion of potassium and protons (Ch. 16). The principal stimulus to aldosterone secretion is angiotensin II, a peptide produced by activation of the renin–angiotensin system (see Fig. 20.17). Renin activity in the juxtaglomerular apparatus of the kidney is stimulated by low perfusion pressure in the afferent arteriole, low sodium filtration leading to low sodium concentrations at the macula densa, or increased sympathetic nerve activity. As a result, renin activity is increased in hypovolaemia and renal artery stenosis, and is approximately doubled when standing up from a recumbent position.

Catecholamines

In humans, only a small proportion of circulating noradrenaline (norepinephrine) is derived from the adrenal medulla; much more is released from sympathetic nerve endings. Conversion of noradrenaline to adrenaline (epinephrine) is catalysed by catechol-o-methyltransferase (COMT), which is induced by glucocorticoids. Blood flow in the adrenal is centripetal, so that the medulla is bathed in high concentrations of cortisol and is the major source of circulating adrenaline. However, after surgical removal of the adrenal medullae, there appear to be no clinical consequences attributable to deficiency of circulating catecholamines.

Adrenal androgens

Adrenal androgens are secreted in response to ACTH and are the most abundant steroids in the blood stream. They are probably important in the initiation of puberty (adrenarche). The adrenals are also the major source of androgens in adult females and may be important in female libido.

Presenting problems in adrenal disease

Cushing's syndrome

Cushing's syndrome is caused by excessive activation of glucocorticoid receptors. It is most commonly iatrogenic, due to prolonged administration of synthetic glucocorticoids such as prednisolone. Endogenous Cushing's syndrome is uncommon but is due to chronic over-production of cortisol by the adrenal glands, either as the result of an adrenal tumour or because of excessive production of ACTH by a pituitary tumour or ectopic ACTH production by other tumours.

Aetiology

The causes are shown in Box 20.42. Amongst endogenous causes, pituitary-dependent cortisol excess (by convention, called Cushing's disease) accounts for approximately 80% of cases. Both Cushing's disease and cortisol-secreting adrenal tumours are four times more common in women than men. In contrast, ectopic ACTH syndrome (often due to a small-cell carcinoma of the bronchus) is more common in men.

Clinical assessment

The diverse manifestations of glucocorticoid excess are shown in Figure 20.19. Many of these are not specific to Cushing's syndrome and, because spontaneous Cushing's syndrome is rare, the positive predictive

20.42 Classification of endogenous Cushing's syndrome

ACTH-dependent – 80%

- Pituitary adenoma secreting ACTH (Cushing's disease) – 70%
- Ectopic ACTH syndrome (bronchial carcinoid, small-cell lung carcinoma, other neuro-endocrine tumour) – 10%

Non-ACTH-dependent – 20%

- Adrenal adenoma – 15%
- Adrenal carcinoma – 5%
- ACTH-independent macronodular hyperplasia; primary pigmented nodular adrenal disease; McCune–Albright syndrome (together < 1%)

Hypercortisolism due to other causes (also referred to as pseudo-Cushing's syndrome)

- Alcohol excess (biochemical and clinical features)
- Major depressive illness (biochemical features only, some clinical overlap)
- Primary obesity (mild biochemical features, some clinical overlap)

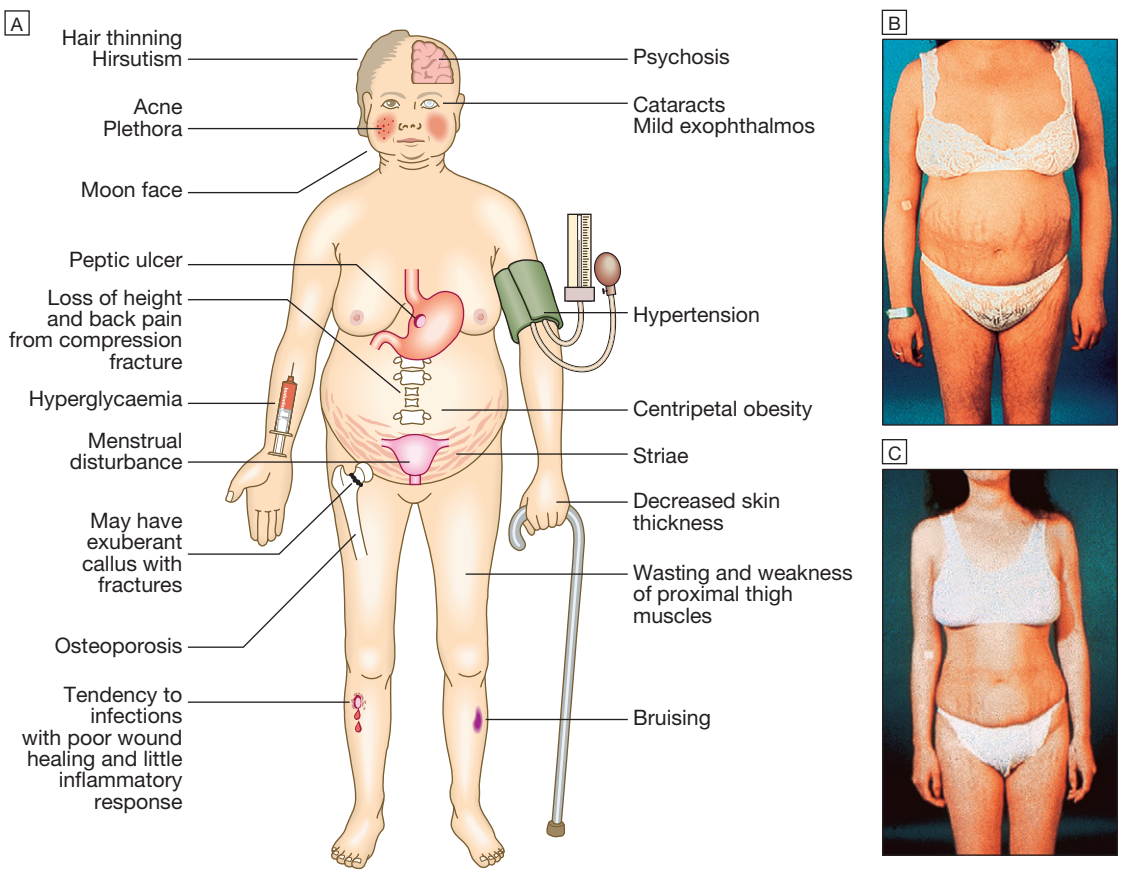

Fig. 20.19 Cushing's syndrome. A Clinical features common to all causes. B A patient with Cushing's disease before treatment. C The same patient 1 year after the successful removal of an ACTH-secreting pituitary microadenoma by trans-sphenoidal surgery.

value of any single clinical feature alone is low. Moreover, some common disorders can be confused with Cushing's syndrome because they are associated with alterations in cortisol secretion: for example, obesity and depression (see Box 20.42). Features which favour Cushing's syndrome in an obese patient are bruising, myopathy and thin skin. Any clinical suspicion of cortisol excess is best resolved by further investigation.

It is vital to exclude iatrogenic causes in all patients with Cushing's syndrome since even inhaled or topical glucocorticoids can induce the syndrome in susceptible individuals. A careful drug history must therefore be taken before embarking on complex investigations.

Some clinical features are more common in ectopic ACTH syndrome. Whilst ACTH-secreting pituitary tumours retain some negative feedback sensitivity to cortisol, this is absent in tumours that produce ectopic ACTH, typically resulting in higher levels of both ACTH and cortisol than are observed in pituitary-driven disease. The high ACTH levels are associated with marked pigmentation because of binding to melanocortin 1 receptors on melanocytes in the skin. The high cortisol levels also overcome the capacity of 11 β-HSD2 to inactivate cortisol in the kidney (p. 772), causing hypokalaemic alkalosis which aggravates myopathy and hyperglycaemia (by inhibiting insulin secretion). When the tumour that is secreting ACTH is malignant, then the onset is usually rapid and may be associated with cachexia. For these reasons, the classical features of Cushing's syndrome are less common in ectopic ACTH syndrome; if present, they suggest that a less aggressive tumour, such as a bronchial carcinoid, is responsible.

In Cushing's disease, the pituitary tumour is usually a microadenoma (< 10 mm in diameter); hence other features of a pituitary macroadenoma (hypopituitarism, visual failure or disconnection hyperprolactinaemia, p. 787) are rare.

Investigations

The large number of tests available for Cushing's syndrome reflects the fact that each one has limited specificity and sensitivity in isolation. Accordingly, several tests are usually combined to establish the diagnosis. Testing for Cushing's syndrome should be avoided under conditions of stress, such as an acute illness, because this activates the HPA axis, causing potentially spurious results. The diagnosis of Cushing's is a two-step process:

1. to establish whether the patient has Cushing's syndrome (Fig. 20.20)
2. to define its cause (Fig. 20.21).

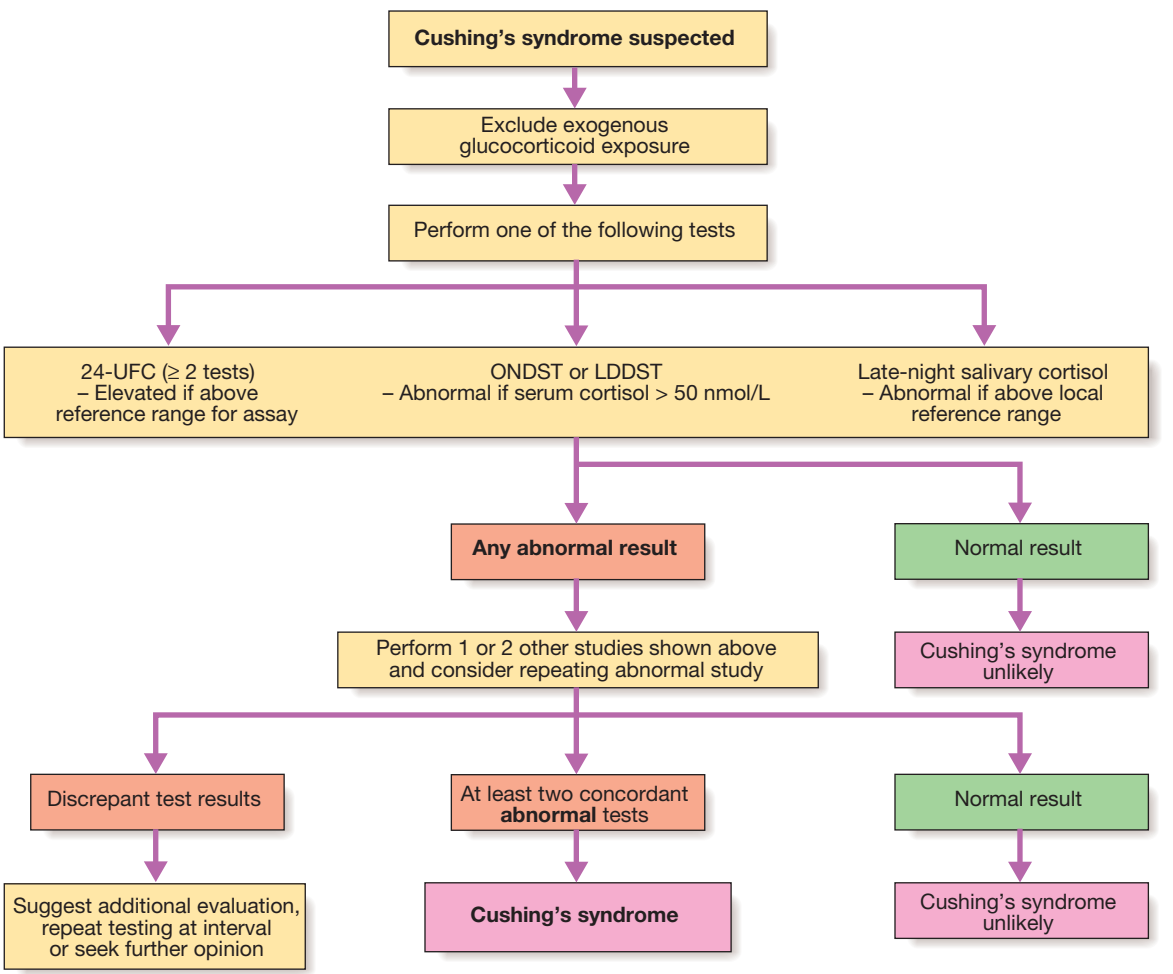

Fig. 20.20 Sequence of investigations in suspected spontaneous Cushing's syndrome. A serum cortisol of 50 nmol/L is equivalent to 1.81 μg/dL. (LDDST = low-dose dexamethasone suppression test; ONDST = overnight dexamethasone suppression test; UFC = urinary free cortisol)

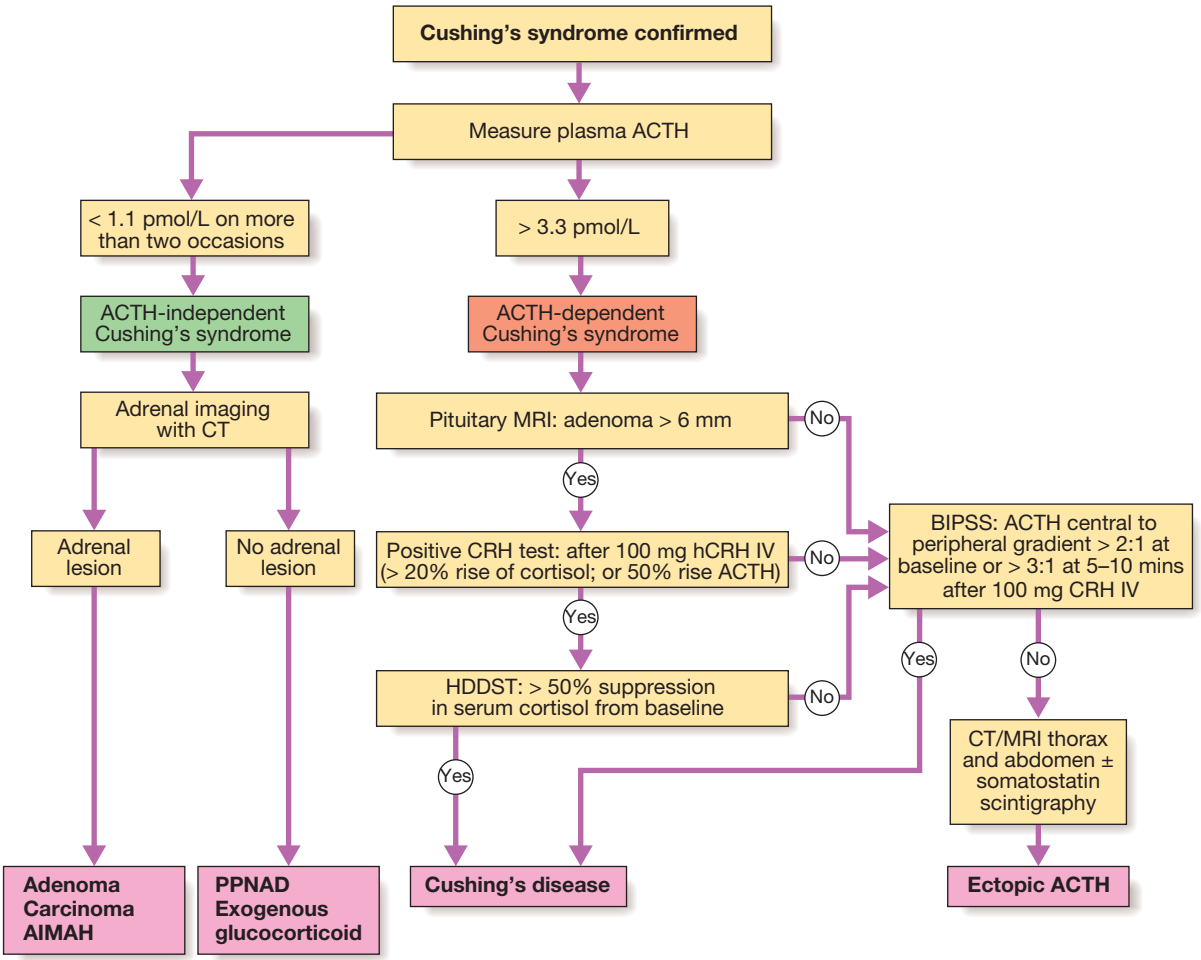

Fig. 20.21 Determining the cause of confirmed Cushing's syndrome. To convert pmol/L to ng/L, multiply by 4.541. (ACTH = adrenocorticotrophic hormone; AIMAH = ACTH-independent macronodular adrenal hyperplasia; BIPSS = bilateral inferior petrosal sinus sampling; CRH = corticotrophin-releasing hormone; HDDST = high-dose dexamethasone suppression test; PPNAD = primary pigmented nodular adrenal disease)

Some additional tests are useful in all cases of Cushing's syndrome, including plasma electrolytes, glucose, glycosylated haemoglobin and bone mineral density measurement.

Establishing the presence of Cushing's syndrome

Cushing's syndrome is confirmed by using two of three main tests:

1. failure to suppress serum cortisol with low doses of oral dexamethasone
2. loss of the normal circadian rhythm of cortisol, with inappropriately elevated late-night serum or salivary cortisol
3. increased 24-hour urine free cortisol (see Fig. 20.20).

Dexamethasone is used for suppression testing because it does not cross-react in radioimmunoassays for cortisol. An overnight dexamethasone suppression test (ONDST) involves administration of 1 mg dexamethasone at 2300 hrs and measuring serum cortisol at 0900 hrs the following day. In a low-dose dexamethasone suppression test (LDDST), serum cortisol is measured following administration of 0.5 mg dexamethasone 4 times daily for 48 hours. It is important for any oestrogens to be stopped for 6 weeks prior to investigation to allow corticosteroid-binding globulin (CBG) levels to return to normal and to avoid false-positive responses, as most cortisol assays measure total cortisol, including that bound to CBG. Cyclicity of cortisol secretion is a feature of all types of Cushing's syndrome and, if very variable, can confuse diagnosis. Use of multiple salivary cortisol samples over weeks or months can be of use in diagnosis, but an elevated salivary cortisol alone should not be taken as proof of diagnosis. In iatrogenic Cushing's syndrome, cortisol levels are low unless the patient is taking a corticosteroid (such as prednisolone) that cross-reacts in immunoassays with cortisol.

Determining the underlying cause

Once the presence of Cushing's syndrome is confirmed, measurement of plasma ACTH is the key to establishing the differential diagnosis. In the presence of excess cortisol secretion, an undetectable ACTH (below 1.1 pmol/L (5 pg/mL)) indicates an adrenal cause, while ACTH levels greater than 3.3 pmol/L (15 pg/mL) suggest a pituitary cause or ectopic ACTH. ACTH

levels between these values represent a 'grey area', and further evaluation by a specialist is required. Tests to discriminate pituitary from ectopic sources of ACTH rely on the fact that pituitary tumours, but not ectopic tumours, retain some features of normal regulation of ACTH secretion. Thus, in pituitary-dependent Cushing's disease, ACTH secretion is suppressed by high-dose dexamethasone and ACTH is stimulated by corticotrophin-releasing hormone (CRH). In a high-dose dexamethasone suppression test (HDDST), serum cortisol is measured before and after administration of 2 mg of dexamethasone 4 times daily for 48 hours.

Techniques for localisation of tumours secreting ACTH or cortisol are listed in Figure 20.21. MRI detects around 60% of pituitary microadenomas secreting ACTH. If available, bilateral inferior petrosal sinus sampling (BIPSS) with measurement of ACTH is the best means of confirming Cushing's disease, unless MRI shows a tumour bigger than 6 mm. CT or MRI detects most adrenal tumours; adrenal carcinomas are usually large (> 5 cm) and have other features of malignancy (p. 779).

Management

Untreated severe Cushing's syndrome has a 50% 5-year mortality. Most patients are treated surgically, but medical therapy may be given in severe cases for a few weeks prior to operation to improve the clinical state. A number of drugs are used to inhibit corticosteroid biosynthesis, including metyrapone and ketoconazole. The dose of these agents is best titrated against serum cortisol levels or 24-hour urine free cortisol.

Cushing's disease

Trans-sphenoidal surgery carried out by an experienced surgeon with selective removal of the adenoma is the treatment of choice, with approximately 70% of patients going into immediate remission. Around 20% of patients suffer a recurrence, often years later, emphasising the need for life-long follow-up.

Laparoscopic bilateral adrenalectomy performed by an expert surgeon effectively cures ACTH-dependent Cushing's syndrome, but in patients with pituitary-dependent Cushing's syndrome, this can result in Nelson's syndrome, with an invasive pituitary macroadenoma and very high ACTH levels causing pigmentation. The risk of Nelson's syndrome may be reduced by pituitary irradiation.

Adrenal tumours

Laparoscopic adrenal surgery is the treatment of choice for adrenal adenomas. Surgery offers the only prospect of cure for adrenocortical carcinomas, but in general, prognosis is poor with high rates of recurrence, even in patients with localised disease at presentation. Radiotherapy to the tumour bed reduces the risk of local recurrence, and systemic therapy consists of the adrenolytic drug mitotane and chemotherapy, but responses are often poor.

Ectopic ACTH syndrome

Localised tumours, such as bronchial carcinoid, should be removed surgically. In patients with incurable malignancy, it is important to reduce the severity of the Cushing's syndrome using medical therapy (see above) or, if appropriate, bilateral adrenalectomy.

Therapeutic use of glucocorticoids

The remarkable anti-inflammatory properties of glucocorticoids have led to their use in a wide variety of clinical conditions but the hazards are significant. Equivalent doses of commonly used glucocorticoids are listed in Box 20.43. Topical preparations (dermal, rectal and inhaled) can also be absorbed into the systemic circulation, and although this rarely occurs to a sufficient degree to produce clinical features of Cushing's syndrome, it can result in significant suppression of endogenous ACTH and cortisol secretion. Severe Cushing's syndrome can result if there is concomitant administration of inhaled glucocorticoids and inhibitors of the liver enzyme CYP450 3A4, such as the antiretroviral drug ritonavir (p. 407).

Adverse effects of glucocorticoids

The clinical features of glucocorticoid excess are illustrated in Figure 20.19. Adverse effects are related to dose, duration of therapy, and pre-existing conditions that might be worsened by corticosteroid therapy, such as diabetes mellitus or osteoporosis. Osteoporosis is a particularly important problem because, for a given bone mineral density, the fracture risk is greater in glucocorticoid-treated patients than in post-menopausal osteoporosis. Therefore, when systemic glucocorticoids are prescribed and the anticipated duration of steroid therapy is more than 3 months, bone-protective therapy should be considered, as detailed on page 1102. Rapid changes in glucocorticoid levels can also lead to marked mood disturbances, including depression, mania and insomnia.

The anti-inflammatory effect of glucocorticoids may mask signs of disease. For example, perforation of a viscus may be masked and the patient may show no febrile response to an infection. Although there is debate about whether or not corticosteroids increase the risk of peptic ulcer when used alone, they act synergistically with NSAIDs, including aspirin, to increase the risk of serious gastrointestinal adverse effects. Latent tuberculosis may be re-activated and patients on corticosteroids should be advised to avoid contact with varicella zoster virus if they are not immune.

Management of glucocorticoid withdrawal

All glucocorticoid therapy, even if inhaled or applied topically, can suppress the HPA axis. In practice, this is only likely to result in a crisis due to adrenal insufficiency on withdrawal of treatment if glucocorticoids have been administered orally or systemically for longer than 3 weeks, if repeated courses have been prescribed within the previous year, or if the dose is higher than the equivalent of 7.5 mg prednisolone per day. In these circumstances, the drug, when it is no longer required for the underlying condition, must be withdrawn slowly at a rate dictated by the duration of treatment. If

20.43 Approximate equivalent doses of glucocorticoids

- Hydrocortisone: 20 mg
- Cortisone acetate: 25 mg
- Prednisolone: 5 mg
- Dexamethasone: 0.5 mg

20.44 Advice to patients on glucocorticoid replacement therapy

Intercurrent stress

- Febrile illness: double dose of hydrocortisone

Surgery

- Minor operation: hydrocortisone 100 mg IM with pre-medication
- Major operation: hydrocortisone 100 mg 4 times daily for 24 hrs, then 50 mg IM 4 times daily until ready to take tablets

Vomiting

- Patients must have parenteral hydrocortisone if unable to take it by mouth

Steroid card

- Patient should carry this at all times; it should give information regarding diagnosis, steroid, dose and doctor

Bracelet and emergency pack

- Patients should be encouraged to buy one of these and have it engraved with the diagnosis, current treatment and a reference number for a central database
- Patients should be given a hydrocortisone emergency pack and trained in the self-administration of hydrocortisone 100 mg IM; they should be advised to take the pack on holidays/trips abroad

glucocorticoid therapy has been prolonged, then it may take many months for the HPA axis to recover. All patients must be advised to avoid sudden drug withdrawal. They should be issued with a steroid card and/or wear an engraved bracelet (Box 20.44).

Recovery of the HPA axis is aided if there is no exogenous glucocorticoid present during the nocturnal surge in ACTH secretion. This can be achieved by giving glucocorticoid in the morning. Giving ACTH to stimulate adrenal recovery is of no value, as the pituitary remains suppressed.

In patients who have received glucocorticoids for longer than a few weeks, it is often valuable to confirm that the HPA axis is recovering during glucocorticoid withdrawal. Once the dose of glucocorticoid is reduced to a minimum (e.g. 4 mg prednisolone or 0.5 mg dexamethasone per day), then measure plasma cortisol at 0900 hrs before the next dose. If this is detectable, then perform an ACTH stimulation test (see Box 20.47) to confirm that glucocorticoids can be withdrawn completely. Even once glucocorticoids have been successfully withdrawn, short-term replacement therapy is often advised during significant intercurrent illness occurring in subsequent months, as the HPA axis may not be able to respond fully to severe stress.

Adrenal insufficiency

Adrenal insufficiency results from inadequate secretion of cortisol and/or aldosterone. It is potentially fatal and notoriously variable in its presentation. A high index of suspicion is therefore required in patients with unexplained fatigue, hyponatraemia or hypotension. Causes are shown in Box 20.45. The most common is ACTH deficiency (secondary adrenocortical failure), usually because of inappropriate withdrawal of chronic glucocorticoid therapy or a pituitary tumour (p. 789).

20.45 Causes of adrenocortical insufficiency

Secondary (↓ACTH)

- Withdrawal of suppressive glucocorticoid therapy
- Hypothalamic or pituitary disease

Primary (↑ACTH)

Addison's disease

Common causes

- Autoimmune
  - Sporadic
  - Polyglandular syndromes (p. 795)
- Tuberculosis
- HIV/AIDS
- Metastatic carcinoma
- Bilateral adrenalectomy

Rare causes

- Lymphoma
- Intra-adrenal haemorrhage (Waterhouse–Friedrichsen syndrome following meningococcal septicaemia)
- Amyloidosis
- Haemochromatosis

Corticosteroid biosynthetic enzyme defects

- Congenital adrenal hyperplasias
- Drugs
  - Metyrapone, ketoconazole, etomidate

Congenital adrenal hyperplasias and Addison's disease (primary adrenocortical failure) are rare causes.

Clinical assessment

The clinical features of adrenal insufficiency are shown in Box 20.46. In Addison's disease, either glucocorticoid or mineralocorticoid deficiency may come first, but eventually all patients fail to secrete both classes of corticosteroid.

Patients may present with chronic features and/or in acute circulatory shock. With a chronic presentation, initial symptoms are often misdiagnosed as chronic fatigue syndrome or depression. Adrenocortical insufficiency should also be considered in patients with hyponatraemia, even in the absence of symptoms (p. 437).

Features of an acute adrenal crisis include circulatory shock with severe hypotension, hyponatraemia, hyperkalaemia and, in some instances, hypoglycaemia and hypercalcaemia. Muscle cramps, nausea, vomiting, diarrhoea and unexplained fever may be present. The crisis is often precipitated by intercurrent disease, surgery or infection.

Vitiligo occurs in 10–20% of patients with autoimmune Addison's disease (p. 734).

Investigations

Treatment should not be delayed to wait for results in patients with suspected acute adrenal crisis. Here, a random blood sample should be stored for subsequent measurement of cortisol and, if the patient's clinical condition permits, it may be appropriate to spend 30 minutes performing a short ACTH stimulation test (Box 20.47) before administering hydrocortisone. Investigations should be performed before treatment is given in patients who present with features suggestive of chronic adrenal insufficiency.

Assessment of glucocorticoids

Random plasma cortisol is usually low in patients with adrenal insufficiency but it may be within the reference

20.46 Clinical and biochemical features of adrenal insufficiency

20.47 How and when to do an ACTH stimulation test

Use

- Diagnosis of primary or secondary adrenal insufficiency
- Assessment of HPA axis in patients taking suppressive glucocorticoid therapy
- Relies on ACTH-dependent adrenal atrophy in secondary adrenal insufficiency, so may not detect acute ACTH deficiency (for example, in pituitary apoplexy, p. 789)

Dose

- 250 µg $ACTH_{1–24}$ (Synacthen) by IM injection at any time of day

Blood samples

- 0 and 30 mins for plasma cortisol
- 0 mins also for ACTH (on ice) if Addison's disease is being considered (patient not known to have pituitary disease or to be taking exogenous glucocorticoids)

Results

- Normal subjects: plasma cortisol > 500 nmol/L (~18 µg/dL)* either at baseline or at 30 mins
- Incremental change in cortisol is not a criterion

*The exact cortisol concentration depends on the cortisol assay being used.

range, yet inappropriately low, for a seriously ill patient. Random measurement of plasma cortisol cannot therefore be used to confirm or refute the diagnosis, unless the value is above 500 nmol/L (> 18 µg/dL), which effectively excludes adrenal insufficiency.

More useful is the short ACTH stimulation test (also called the tetracosactrin or short Synacthen test) described in Box 20.47. Cortisol levels fail to increase in response to exogenous ACTH in patients with primary or secondary adrenal insufficiency. These can be distinguished by measurement of ACTH (which is low in ACTH deficiency and high in Addison's disease).

Assessment of mineralocorticoids

Mineralocorticoid secretion in patients with suspected Addison's disease cannot be adequately assessed by electrolyte measurements since hyponatraemia occurs in both aldosterone and cortisol deficiency (see Box 20.46 and p. 437). Hyperkalaemia is common, but not universal, in aldosterone deficiency. Plasma renin and aldosterone should be measured in the supine position. In mineralocorticoid deficiency, plasma renin activity is high, with plasma aldosterone being either low or in the lower part of the reference range.

Assessment of adrenal androgens

This is not necessary in men because testosterone from the testes is the principal androgen. In women, dehydroepiandrosterone (DHEA) and androstenedione may be measured in a random specimen of blood, though levels are highest in the morning.

Other tests to establish the cause

Patients with unexplained secondary adrenocortical insufficiency should be investigated as described on page 786. In patients with elevated ACTH, further tests are required to establish the cause of Addison's disease. Adrenal autoantibodies are frequently positive in autoimmune adrenal failure. If antibody tests are negative, imaging of the adrenal glands with CT or MRI is indicated. Tuberculosis causes adrenal calcification, visible on plain X-ray or ultrasound scan. An HIV test should be performed if risk factors for infection are present (p. 391). Adrenal metastases are a rare cause of adrenal insufficiency. Patients with evidence of autoimmune adrenal failure should be screened for other organ-specific autoimmune diseases, such as thyroid disease, pernicious anaemia and type 1 diabetes.

Management

Patients with adrenocortical insufficiency always need glucocorticoid replacement therapy and usually, but

20.48 Management of adrenal crisis

Correct volume depletion

- IV saline as required to normalise blood pressure and pulse
- In severe hyponatraemia (< 125 mmol/L) avoid increases of plasma Na > 10 mmol/L/day to prevent pontine demyelination (p. 437)
- Fludrocortisone is not required during the acute phase of treatment

Replace glucocorticoids

- IV hydrocortisone succinate 100 mg stat, and 100 mg 4 times daily for first 12–24 hours
- Continue parenteral hydrocortisone (50–100 mg IM 4 times daily) until patient is well enough for reliable oral therapy

Correct other metabolic abnormalities

- Acute hypoglycaemia: IV 10% glucose
- Hyperkalaemia: should respond to volume replacement but occasionally requires specific therapy (see Box 16.17, p. 443)

Identify and treat underlying cause

- Consider acute precipitant, such as infection
- Consider adrenal or pituitary pathology (see Box 20.45)

20.49 Glucocorticoids in old age

- **Adrenocortical insufficiency**: often insidious and difficult to spot.
- **Glucocorticoid therapy**: especially hazardous in older people, who are already relatively immunocompromised and susceptible to osteoporosis, diabetes, hypertension and other complications.
- **'Physiological' glucocorticoid replacement therapy**: increased risk of adrenal crisis because compliance may be poor and there is a greater incidence of intercurrent illness. Patient and carer education, with regular reinforcement of the principles described in Box 20.44, is crucial.

not always, mineralocorticoid therapy. There is some evidence that adrenal androgen replacement may also be beneficial in women. Other treatments depend on the underlying cause. The emergency management of adrenal crisis is described in Box 20.48.

Glucocorticoid replacement

Adrenal replacement therapy consists of oral hydrocortisone (cortisol) 15–20 mg daily in divided doses, typically 10 mg on waking and 5 mg at around 1500 hrs. These are physiological replacement doses which should not cause Cushingoid side-effects. The dose may need to be adjusted for the individual patient but this is subjective. Excess weight gain usually indicates over-replacement, whilst persistent lethargy or hyperpigmentation may be due to an inadequate dose or lack of absorption. Measurement of plasma cortisol levels is not usually helpful. Advice to patients dependent on glucocorticoid replacement is given in Box 20.44.

Mineralocorticoid replacement

Fludrocortisone (9α-fluoro-hydrocortisone) is administered at the usual dose of 0.05–0.15 mg daily, and adequacy of replacement may be assessed by measurement of blood pressure, plasma electrolytes and plasma renin.

Androgen replacement

Androgen replacement with DHEA (50 mg/day) is occasionally given to women with primary adrenal insufficiency who have symptoms of reduced libido and fatigue, but the evidence in support of this is not robust and treatment may be associated with side-effects such as acne and hirsutism.

Incidental adrenal mass

It is not uncommon for a mass in the adrenal gland to be identified on a CT or MRI scan of the abdomen that has been performed for another indication. Such lesions are known as adrenal 'incidentalomas'. They are present in up to 10% of adults and the prevalence increases with age.

Eighty-five per cent of adrenal incidentalomas are non-functioning adrenal adenomas. The remainder includes functional tumours of the adrenal cortex (secreting cortisol, aldosterone or androgens), phaeochromocytomas, primary and secondary carcinomas, hamartomas and other rare disorders, including granulomatous infiltrations.

Clinical assessment and investigations

There are two key questions to be resolved: is the lesion secreting hormones, and is it benign or malignant?

Patients with an adrenal incidentaloma are usually asymptomatic. However, clinical signs and symptoms of excess glucocorticoids (p. 772), mineralocorticoids (see below), catecholamines (p. 781) and, in women, androgens (p. 763) should be sought. Investigations should include a dexamethasone suppression test, urine or plasma metanephrines and, in virilised women, measurement of serum testosterone, DHEA and androstenedione. Patients with hypertension should be investigated for mineralocorticoid excess, as described below.

CT and MRI are equally effective in assessing the malignant potential of an adrenal mass, using the following parameters:

- *Size.* The larger the lesion, the greater the malignant potential. Around 90% of adrenocortical carcinomas are over 4 cm in diameter, but specificity is poor since only approximately 25% of such lesions are malignant.
- *Configuration.* Homogeneous and smooth lesions are more likely to be benign. The presence of metastatic lesions elsewhere increases the risk of malignancy, but as many as two-thirds of adrenal incidentalomas in patients with cancer are benign.
- *Presence of lipid.* Adenomas are usually lipid-rich, resulting in an attenuation of below 10 Hounsfield Units (HU) on an unenhanced CT, and in signal dropout on chemical shift MRI.
- *Enhancement.* Benign lesions demonstrate rapid washout of contrast, whereas malignant lesions tend to retain contrast.

Histology in a sample obtained by CT-guided biopsy is rarely indicated, and is not useful in distinguishing an adrenal adenoma from an adrenal carcinoma. Biopsy is

occasionally helpful in confirming adrenal metastases from other cancers, but should be avoided if either phaeochromocytoma or primary adrenal cancer is suspected in order to avoid precipitation of a hypertensive crisis or seeding of tumour cells, respectively.

Management

Functional lesions and tumours of more than 4 cm in diameter should be considered for removal by adrenal surgery. In patients with radiologically benign, non-functioning lesions of less than 4 cm in diameter, surgery is only required if serial imaging suggests tumour growth. Optimal management of patients with low-grade cortisol secretion, as demonstrated by the dexamethasone suppression test, remains to be established.

Primary hyperaldosteronism

Estimates of the prevalence of primary hyperaldosteronism vary according to the screening tests employed, but it may occur in as many as 10% of people with hypertension. Indications to test for mineralocorticoid excess in hypertensive patients include hypokalaemia (including hypokalaemia induced by thiazide diuretics), poor control of blood pressure with conventional therapy, a family history of early-onset hypertension, or presentation at a young age.

Causes of excessive activation of mineralocorticoid receptors are shown in Box 20.50. It is important to differentiate primary hyperaldosteronism, caused by an intrinsic abnormality of the adrenal glands resulting in aldosterone excess, from secondary hyperaldosteronism, which is usually a consequence of enhanced activity of renin in response to inadequate renal perfusion and hypotension. Most individuals with primary hyperaldosteronism have bilateral adrenal hyperplasia (idiopathic hyperaldosteronism), while only a minority have an aldosterone-producing adenoma (APA; Conn's syndrome). Glucocorticoid-suppressible hyperaldosteronism is a rare autosomal dominant condition in which aldosterone is secreted 'ectopically' from the adrenal fasciculata/reticularis in response to ACTH. Rarely, the mineralocorticoid receptor pathway in the distal nephron is activated, even though aldosterone concentrations are low.

20.50 Causes of mineralocorticoid excess

With renin high and aldosterone high (secondary hyperaldosteronism)

- Inadequate renal perfusion (diuretic therapy, cardiac failure, liver failure, nephrotic syndrome, renal artery stenosis)
- Renin-secreting renal tumour (very rare)

With renin low and aldosterone high (primary hyperaldosteronism)

- Adrenal adenoma secreting aldosterone (Conn's syndrome)
- Idiopathic bilateral adrenal hyperplasia
- Glucocorticoid-suppressible hyperaldosteronism (rare)

With renin low and aldosterone low (non-aldosterone-dependent activation of mineralocorticoid pathway)

- Ectopic ACTH syndrome
- Liquorice misuse (inhibition of 11 β-HSD2)
- Liddle's syndrome
- 11-deoxycorticosterone-secreting adrenal tumour
- Rare forms of congenital adrenal hyperplasia and 11 β-HSD2 deficiency

Clinical features

Individuals with primary hyperaldosteronism are usually asymptomatic but may have features of sodium retention or potassium loss. Sodium retention may cause oedema, while hypokalaemia may cause muscle weakness (or even paralysis, especially in Chinese), polyuria (secondary to renal tubular damage, which produces nephrogenic diabetes insipidus) and occasionally tetany (because of associated metabolic alkalosis and low ionised calcium). Blood pressure is elevated but accelerated phase hypertension is rare.

Investigations

Biochemical

Routine blood tests may show a hypokalaemic alkalosis. Sodium is usually at the upper end of the reference range in primary hyperaldosteronism, but is characteristically low in secondary hyperaldosteronism (because low plasma volume stimulates antidiuretic hormone (ADH) release and high angiotensin II levels stimulate thirst). The key measurements are plasma renin and aldosterone (see Box 20.50), and in many centres, the aldosterone:renin ratio (ARR) is employed as a screening test for primary hyperaldosteronism in hypertensive patients. Almost all antihypertensive drugs interfere with this ratio (β-blockers inhibit whilst thiazide diuretics stimulate renin secretion). Thus, individuals with an elevated ARR require further testing after stopping antihypertensive drugs for at least 2 weeks. If necessary, antihypertensive agents that have minimal effects on the renin–angiotensin system, such as calcium antagonists and α-blockers, may be substituted. Oral potassium supplementation may also be required, as hypokalaemia itself suppresses renin activity. If, on repeat testing, plasma renin is low and aldosterone concentrations are elevated, then further investigation under specialist supervision may include suppression tests (sodium loading) and/or stimulation tests (captopril or furosemide administration) to differentiate angiotensin II-dependent aldosterone secretion in idiopathic hyperplasia from autonomous aldosterone secretion typical of an APA.

Imaging and localisation

Imaging with CT or MRI will identify most APAs (Fig. 20.22), but it is important to recognise the risk of false-positives (non-functioning adrenal adenomas are common) and false-negatives (imaging may have insufficient resolution to identify adenomas with diameter of less than 0.5 cm). If the imaging is inconclusive and there is an intention to proceed with surgery on the basis of strong biochemical evidence of an APA, then adrenal vein catheterisation with measurement of aldosterone (and cortisol to confirm positioning of the catheters) is required. In some centres, this is performed even in the presence of a unilateral 'adenoma', to avoid inadvertent removal of an incidental non-functioning adenoma contralateral to the inapparent cause of aldosterone excess.

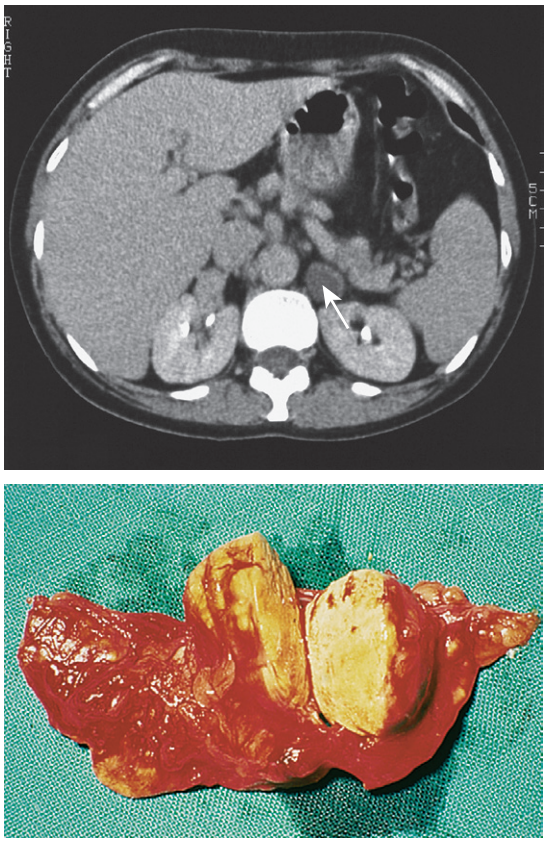

Fig. 20.22 Aldosterone-producing adenoma causing Conn's syndrome. A CT scan of left adrenal adenoma (arrow). B The tumour is 'canary yellow' because of intracellular lipid accumulation.

Management

Mineralocorticoid receptor antagonists (spironolactone and eplerenone) are valuable in treating both hypokalaemia and hypertension in all forms of mineralocorticoid excess. Up to 20% of males develop gynaecomastia on spironolactone. Amiloride (10–40 mg/day), which blocks the epithelial sodium channel regulated by aldosterone, is an alternative.

In patients with an APA, medical therapy is usually given for a few weeks to normalise whole-body electrolyte balance before unilateral adrenalectomy. Laparoscopic surgery cures the biochemical abnormality but, depending on the pre-operative duration, hypertension remains in as many as 70% of cases, probably because of irreversible damage to the systemic microcirculation.

Phaeochromocytoma and paraganglioma

These are rare neuro-endocrine tumours that may secrete catecholamines (adrenaline/epinephrine, noradrenaline/norepinephrine). Approximately 80% of these tumours occur in the adrenal medulla (phaeochromocytomas), while 20% arise elsewhere in the body in sympathetic ganglia (paragangliomas). Most are benign but approximately 15% show malignant features. Around 30% are associated with inherited disorders, including neurofibromatosis (p. 1215), von Hippel–Lindau syndrome (p. 1216) and MEN 2 (p. 795). Paragangliomas are particularly associated with mutations in the succinate dehydrogenase B, C and D genes.

20.51 Clinical features of phaeochromocytoma

- Hypertension (usually paroxysmal; often postural drop of blood pressure)
- Paroxysms of:
  - Pallor (occasionally flushing)
  - Palpitations, sweating
  - Headache
  - Anxiety (angor animi)
- Abdominal pain, vomiting
- Constipation
- Weight loss
- Glucose intolerance

Clinical features

These depend on the pattern of catecholamine secretion and are listed in Box 20.51.

Some patients present with hypertension, although it has been estimated that phaeochromocytoma accounts for less than 0.1% of cases of hypertension. The presentation may be with a complication of hypertension, such as stroke, myocardial infarction, left ventricular failure, hypertensive retinopathy or accelerated phase hypertension. The apparent paradox of postural hypotension between episodes is explained by 'pressure natriuresis' during hypertensive episodes so that intravascular volume is reduced. There may also be features of the familial syndromes associated with phaeochromocytoma. Paragangliomas are often non-functioning.

Investigations

Excessive secretion of catecholamines can be confirmed by measuring metabolites in plasma and/or urine (metanephrine and normetanephrine). There is a high 'false-positive' rate, as misleading metanephrine concentrations may be seen in stressed patients (during acute illness, following vigorous exercise or severe pain) and following ingestion of some drugs such as tricyclic antidepressants. For this reason, a repeat sample should usually be requested if elevated levels are found, although, as a rule, the higher the concentration of metanephrines, the more likely is the diagnosis of phaeochromocytoma/paraganglioma. Serum chromogranin A is often elevated and may be a useful tumour marker in patients with non-secretory tumours and/or metastatic disease. Genetic testing should be considered in individuals with other features of a genetic syndrome, with a family history of phaeochromocytoma/paraganglioma, and in those presenting under the age of 50 years.

Localisation

Phaeochromocytomas are usually identified by abdominal CT or MRI (Fig. 20.23). Localisation of paragangliomas may be more difficult. Scintigraphy using meta-iodobenzyl guanidine (MIBG) can be useful, particularly if combined with CT. ^{18}F-deoxyglucose PET is especially useful for detection of malignant disease and for confirming an imaging abnormality as a paraganglioma in an individual with underlying risk due to genetic mutation.

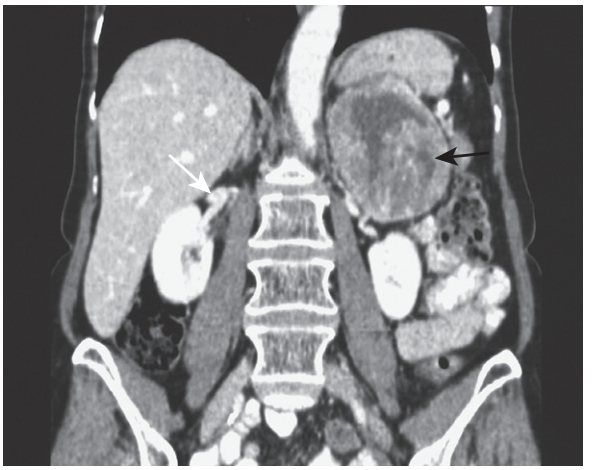

Fig. 20.23 CT scan of abdomen showing large left adrenal phaeochromocytoma. The normal right adrenal (white arrow) contrasts with the large heterogeneous phaeochromocytoma arising from the left adrenal gland (black arrow).

Management

Medical therapy is required to prepare the patient for surgery, preferably for a minimum of 6 weeks to allow restoration of normal plasma volume. The most useful drug in the face of very high circulating catecholamines is the α-blocker phenoxybenzamine (10–20 mg orally 3–4 times daily) because it is a non-competitive antagonist, unlike prazosin or doxazosin. If α-blockade produces a marked tachycardia, then a β-blocker such as propranolol can be added. On no account should a β-blocker be given before an α-blocker, as this may cause a paradoxical rise in blood pressure due to unopposed α-mediated vasoconstriction.

During surgery, sodium nitroprusside and the short-acting α-antagonist phentolamine are useful in controlling hypertensive episodes, which may result from anaesthetic induction or tumour mobilisation. Post-operative hypotension may occur and require volume expansion and, very occasionally, noradrenaline (norepinephrine) infusion, but is uncommon if the patient has been prepared with phenoxybenzamine.

Metastatic tumours may behave in an aggressive or a very indolent fashion. Management options include debulking surgery, radionuclide therapy with ^{131}I-MIBG, chemotherapy and (chemo)embolisation of hepatic metastases; some may respond to tyrosine kinase and angiogenesis inhibitors.

Congenital adrenal hyperplasia

Pathophysiology and clinical features

Inherited defects in enzymes of the cortisol biosynthetic pathway (see Fig. 20.18, p. 772) result in insufficiency of hormones downstream of the block, with impaired negative feedback and increased ACTH secretion. ACTH then stimulates the production of steroids upstream of the enzyme block. This produces adrenal hyperplasia and a combination of clinical features that depend on the severity and site of the defect in biosynthesis. All of these enzyme abnormalities are inherited as autosomal recessive traits.

The most common enzyme defect is 21-hydroxylase deficiency. This results in impaired synthesis of cortisol and aldosterone and accumulation of 17OH-progesterone, which is then diverted to form adrenal androgens. In about one-third of cases, this defect is severe and presents in infancy with features of glucocorticoid and mineralocorticoid deficiency (see Box 20.46, p. 778) and androgen excess, such as ambiguous genitalia in girls. In the other two-thirds, mineralocorticoid secretion is adequate but there may be features of cortisol insufficiency and/or ACTH and androgen excess, including precocious pseudo-puberty, which is distinguished from 'true' precocious puberty by low gonadotrophins. Sometimes the mildest enzyme defects are not apparent until adult life, when females may present with amenorrhoea and/or hirsutism (p. 763). This is called 'non-classical' or 'late-onset' congenital adrenal hyperplasia.

Defects of all the other enzymes in Figure 20.18 (p. 772) are rare. Both 17-hydroxylase and 11 β-hydroxylase deficiency may produce hypertension due to excess production of 11-deoxycorticosterone, which has mineralocorticoid activity.

Investigations

Circulating 17OH-progesterone levels are raised in 21-hydroxylase deficiency, but this may only be demonstrated after ACTH administration in late-onset cases. To avoid salt-wasting crises in infancy, 17OH-progesterone can be routinely measured in heelprick blood spot samples taken from all infants in the first week of life. Assessment is otherwise as described for adrenal insufficiency on page 778.

In siblings of affected children, antenatal genetic diagnosis can be made by amniocentesis or chorionic villus sampling. This allows prevention of virilisation of affected female fetuses by administration of dexamethasone to the mother to suppress ACTH levels.

Management

The aim is to replace deficient corticosteroids and to suppress ACTH-driven adrenal androgen production. A careful balance is required between adequate suppression of adrenal androgen excess and excessive glucocorticoid replacement resulting in features of Cushing's syndrome. In children, growth velocity is an important measurement, since either under- or over-replacement with glucocorticoids suppresses growth. In adults, there is no uniformly agreed adrenal replacement regime, and clinical features (menstrual cycle, hirsutism, weight gain, blood pressure) and biochemical profiles (plasma renin, 17OH-progesterone and testosterone levels) provide a guide.

Women with late-onset 21-hydroxylase deficiency may not require corticosteroid replacement. If hirsutism is the main problem, anti-androgen therapy may be just as effective (p. 764).

THE ENDOCRINE PANCREAS AND GASTROINTESTINAL TRACT

A series of hormones are secreted from cells distributed throughout the gastrointestinal tract and pancreas. Functional anatomy and physiology are

20.52 Classification of endocrine diseases of the pancreas and gastrointestinal tract

	Primary	Secondary
Hormone excess	Insulinoma Gastrinoma (Zollinger–Ellison syndrome) Carcinoid syndrome (secretion of 5-HT) Glucagonoma VIPoma Somatostatinoma	Hypergastrinaemia of achlorhydria Hyperinsulinaemia after bariatric surgery
Hormone deficiency	Diabetes mellitus	
Hormone resistance	Insulin resistance syndromes (e.g. type 2 diabetes mellitus, lipodystrophy, leprechaunism)	
Non-functioning tumours	Pancreatic carcinoma Pancreatic neuro-endocrine tumour	

described in Chapters 21 and 22. Diseases associated with abnormalities of these hormones are listed in Box 20.52. Most are rare, with the exception of diabetes mellitus (Ch. 21).

Presenting problems in endocrine pancreas disease

Spontaneous hypoglycaemia

Hypoglycaemia most commonly occurs as a side-effect of treatment with insulin or sulphonylurea drugs in people with diabetes mellitus. In non-diabetic individuals, symptomatic hypoglycaemia is rare, but it is not uncommon to detect venous blood glucose concentrations below 3.0 mmol/L in asymptomatic patients. For this reason, and because the symptoms of hypoglycaemia are non-specific, a hypoglycaemic disorder should only be diagnosed if all three conditions of Whipple's triad are met (Fig. 20.24). There is no specific blood glucose concentration at which spontaneous hypoglycaemia can be said to occur, although the lower the blood glucose concentration, the more likely it is to have pathological significance.

Clinical assessment

The clinical features of hypoglycaemia are described in the section on insulin-induced hypoglycaemia on page 814. Individuals with chronic spontaneous hypoglycaemia often have attenuated autonomic responses and 'hypoglycaemia unawareness', and may present with a wide variety of features of neuro-glycopenia, including odd behaviour and convulsions. The symptoms are usually episodic and relieved by consumption of carbohydrate. Symptoms occurring while fasting (such as before breakfast) or following exercise are much more likely to be representative of pathological hypoglycaemia than those which develop after food (post-prandial or 'reactive' symptoms). Hypoglycaemia should be considered in all comatose patients, even if there is an apparently obvious cause, such as hemiplegic stroke or alcohol intoxication.

Investigations

Does the patient have a hypoglycaemic disorder?

Patients who present acutely with confusion, coma or convulsions should be tested for hypoglycaemia at the bedside with a capillary blood sample and an automated meter. While this is sufficient to exclude hypoglycaemia, blood glucose meters are relatively inaccurate in the hypoglycaemic range and the diagnosis should always be confirmed by a laboratory-based glucose measurement. At the same time, a sample should be taken for later measurement, if necessary, of alcohol, insulin, C-peptide, cortisol and sulphonylurea levels. Taking these samples during an acute presentation

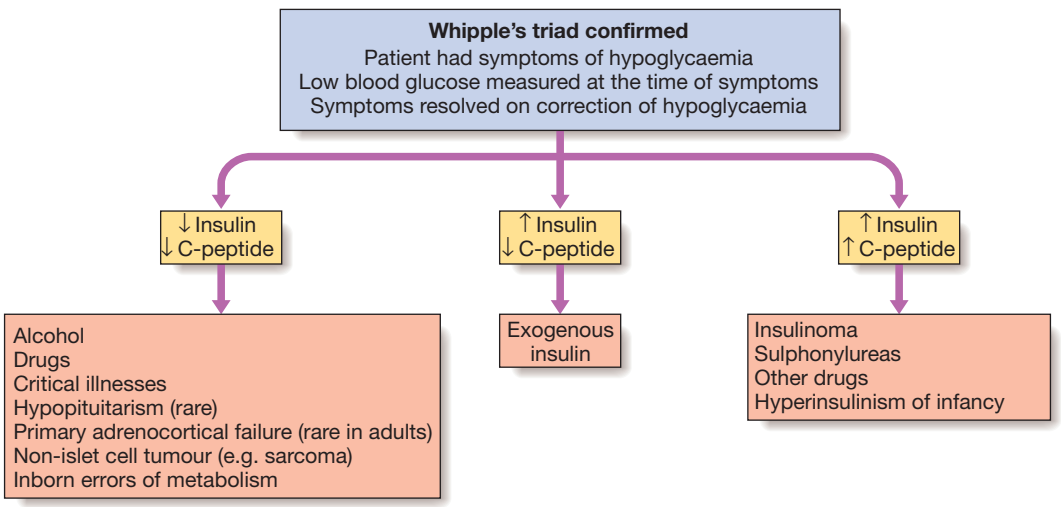

Fig. 20.24 Differential diagnosis of spontaneous hypoglycaemia. Measurement of insulin and C-peptide concentrations during an episode is helpful in determining the underlying cause.

prevents subsequent unnecessary dynamic tests and is of medico-legal importance in cases where poisoning is suspected.

Patients who attend the outpatient clinic with episodic symptoms suggestive of hypoglycaemia present a more challenging problem. The main diagnostic test is the prolonged (72-hour) fast. If symptoms of hypoglycaemia develop during the fast, then blood samples should be taken to confirm hypoglycaemia and for later measurement of insulin and C-peptide. Hypoglycaemia is then corrected with oral or intravenous glucose and Whipple's triad completed by confirmation of the resolution of symptoms. The absence of clinical and biochemical evidence of hypoglycaemia during a prolonged fast effectively excludes the diagnosis of a hypoglycaemic disorder.

What is the cause of the hypoglycaemia?

In the acute setting, the underlying diagnosis is often obvious. In non-diabetic individuals, alcohol excess is the most common cause of hypoglycaemia in the UK, but other drugs – for example, salicylates, quinine and pentamidine – may also be implicated. Hypoglycaemia is one of many metabolic derangements which occur in patients with hepatic failure, renal failure, sepsis or malaria.

Hypoglycaemia in the absence of insulin, or any insulin-like factor, in the blood indicates impaired gluconeogenesis and/or availability of glucose from glycogen in the liver. Hypoglycaemia associated with high insulin and low C-peptide concentrations is indicative of administration of exogenous insulin, either factitiously or feloniously. Adults with high insulin and C-peptide concentrations during an episode of hypoglycaemia are most likely to have an insulinoma, but sulphonylurea ingestion should also be considered (particularly in individuals with access to such medication, such as health-care professionals or family members of someone with type 2 diabetes). Suppressed plasma β-hydroxybutyrate helps confirm inappropriate insulin secretion during fasting. Usually, insulinomas in the pancreas are small (< 5 mm diameter) but can be identified by CT, MRI or ultrasound (endoscopic or laparoscopic). Imaging should include the liver since around 10% of insulinomas are malignant. Rarely, large non-pancreatic tumours, such as sarcomas, may cause recurrent hypoglycaemia because of their ability to produce excess pro-insulin-like growth factor-2 (pro-IGF-2).

Management

Treatment of acute hypoglycaemia should be initiated as soon as laboratory blood samples have been taken, and should *not* be deferred until formal laboratory confirmation has been obtained. Intravenous dextrose (5% or 10%) is effective in the short term in the obtunded patient, and should be followed on recovery with oral unrefined carbohydrate (starch). Continuous dextrose infusion may be necessary, especially in sulphonylurea poisoning. Intramuscular glucagon (1 mg) stimulates hepatic glucose release, but is ineffective in patients with depleted glycogen reserves, such as in alcohol excess or liver disease.

Chronic recurrent hypoglycaemia in insulin-secreting tumours can be treated by regular consumption of oral carbohydrate combined with agents that inhibit insulin secretion (diazoxide or somatostatin analogues). Insulinomas are resected when benign, providing the individual is fit enough to undergo surgery. Metastatic malignant insulinomas are incurable and are managed along the same lines as other metastatic neuro-endocrine tumours (see below).

20.53 Spontaneous hypoglycaemia in old age

- **Presentation**: may present with focal neurological abnormality. Blood glucose should be checked in all patients with acute neurological symptoms and signs, especially stroke, as these will reverse with early treatment of hypoglycaemia.

Gastroenteropancreatic neuro-endocrine tumours

Neuro-endocrine tumours (NETs) are a heterogeneous group derived from neuro-endocrine cells in many organs, including the gastrointestinal tract, lung, adrenals (phaeochromocytoma, p. 781) and thyroid (medullary carcinoma, p. 755). Most NETs occur sporadically, but a proportion are associated with genetic cancer syndromes, such as MEN 1, MEN 2 and neurofibromatosis type 1 (pp. 795 and 1215). NETs may secrete hormones into the circulation.

Gastroenteropancreatic NETs arise in organs that are derived embryologically from the gastrointestinal tract. Most commonly, they occur in the small bowel but they can also arise elsewhere in the bowel, pancreas, thymus and bronchi. The term 'carcinoid' is often used when referring to non-pancreatic gastroenteropancreatic NETs because, when initially described, they were thought to behave in an indolent fashion compared with conventional cancers. It is now recognised that there is a wide spectrum of malignant potential for all NETs; some are benign (most insulinomas and appendiceal carcinoid tumours), while others have an aggressive clinical course with widespread metastases (small-cell carcinoma of the lung). The majority of gastroenteropancreatic NETs behave in an intermediate manner, with relatively slow growth but a propensity to invade and metastasise to remote organs, especially the liver.

Clinical features

Patients with gastroenteropancreatic NETs often have a history of abdominal pain over many years prior to diagnosis and usually present with local mass effects, such as small-bowel obstruction, appendicitis, and pain from hepatic metastases. Thymic and bronchial carcinoids occasionally present with ectopic ACTH syndrome (p. 774). Pancreatic NETs can also cause hormone excess (Box 20.54) but most are non-functional. The classic 'carcinoid syndrome' (Box 20.55) occurs when vasoactive hormones reach the systemic circulation. In the case of gastrointestinal carcinoids, this invariably means that the tumour has metastasised to the liver or there are peritoneal deposits, which allow secreted hormones to gain access to the systemic circulation; hormones secreted by the primary tumour into the portal vein are metabolised and inactivated in the liver.

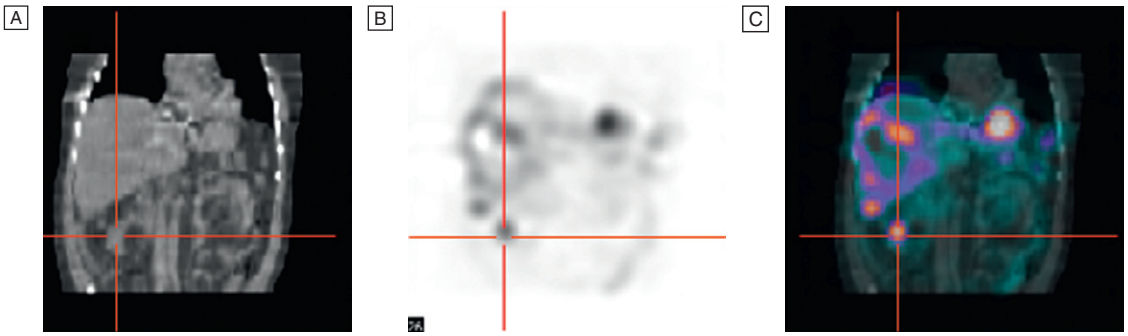

Fig. 20.25 Octreotide scintigraphy in a metastatic neuro-endocrine tumour. A Coronal CT scan showing hepatomegaly and a mass inferior to the liver (at the intersection of the horizontal and vertical red lines). B Octreotide scintogram showing patches of increased uptake in the upper abdomen. C When the octreotide and CT scans are superimposed, it shows that the areas of increased uptake are in hepatic metastases and in the tissue mass, which may be lymph nodes or a primary tumour.

20.54 Pancreatic neuro-endocrine tumours

Tumour	Hormone	Effects
Gastrinoma	Gastrin	Peptic ulcer and steatorrhoea (Zollinger–Ellison syndrome)
Insulinoma	Insulin	Recurrent hypoglycaemia (see above)
VIPoma	Vasoactive intestinal peptide (VIP)	Watery diarrhoea and hypokalaemia
Glucagonoma	Glucagon	Diabetes mellitus, necrolytic migratory erythema
Somatostatinoma	Somatostatin	Diabetes mellitus and steatorrhoea

20.55 Clinical features of the carcinoid syndrome

- Episodic flushing, wheezing and diarrhoea
- Facial telangiectasia
- Cardiac involvement (tricuspid regurgitation, pulmonary stenosis, right ventricular endocardial plaques) leading to heart failure

Investigations

A combination of imaging with ultrasound, CT, MRI and/or radio-labelled somatostatin analogue (Fig. 20.25) will usually identify the primary tumour and allow staging, which is crucial for determining prognosis. Biopsy of the primary tumour or a metastatic deposit is required to confirm the histological type. NETs demonstrate immunohistochemical staining for the proteins chromogranin A and synaptophysin, and the histological grade may also provide prognostic information.

Carcinoid syndrome is confirmed by measuring elevated concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, in a 24-hour urine collection. False-positives can occur, particularly if the individual has been eating certain foods, such as avocado and pineapple. Plasma chromogranin A can be measured in a fasting blood sample, along with the hormones listed in Box 20.54. All of these can be useful as tumour markers.

Management

Treatment of solitary tumours is by surgical resection. If metastatic or multifocal primary disease is present, then surgery is usually not indicated, unless there is a complication such as gastrointestinal obstruction. Diazoxide can reduce insulin secretion in insulinomas, and high doses of proton pump inhibitors suppress acid production in gastrinomas. Somatostatin analogues are effective in reducing the symptoms of carcinoid syndrome and of excess glucagon and vasoactive intestinal peptide (VIP) production. The slow-growing nature of NETs means that conventional cancer therapies, such as chemotherapy and radiotherapy, have limited efficacy. Other treatments, such as interferon, targeted radionuclide therapy with ^{131}I-MIBG and radio-labelled somatostatin analogues (which may be taken up by NET metastases), and resection/embolisation of hepatic metastases, may have a role in the palliation of symptoms but there is little evidence that they prolong life. The tyrosine kinase inhibitor sunitinib and the mammalian target of rapamycin (mTOR) inhibitor everolimus have shown benefit in progressive pancreatic NETS (Box 20.56), and should be considered as part of standard therapy.

THE HYPOTHALAMUS AND THE PITUITARY GLAND

Diseases of the hypothalamus and pituitary have an annual incidence of approximately 3:100 000 and a

prevalence of 30–40 per 100 000. The pituitary plays a central role in several major endocrine axes, so that investigation and treatment invariably involve several other endocrine glands.

Functional anatomy, physiology and investigations

The anatomical relationships of the pituitary are shown in Figure 20.26 and its numerous functions are shown in Figure 20.2 (p. 737). The pituitary gland is enclosed in the sella turcica and bridged over by a fold of dura mater called the diaphragma sellae, with the sphenoidal air sinuses below and the optic chiasm above. The cavernous sinuses are lateral to the pituitary fossa and contain the 3rd, 4th and 6th cranial nerves and the internal carotid arteries. The gland is composed of two lobes, anterior and posterior, and is connected to the hypothalamus by the infundibular stalk, which has portal vessels carrying blood from the median eminence of the hypothalamus to the anterior lobe and nerve fibres to the posterior lobe.

Diseases of the hypothalamus and pituitary are classified in Box 20.57. By far the most common disorder is an adenoma of the anterior pituitary gland.

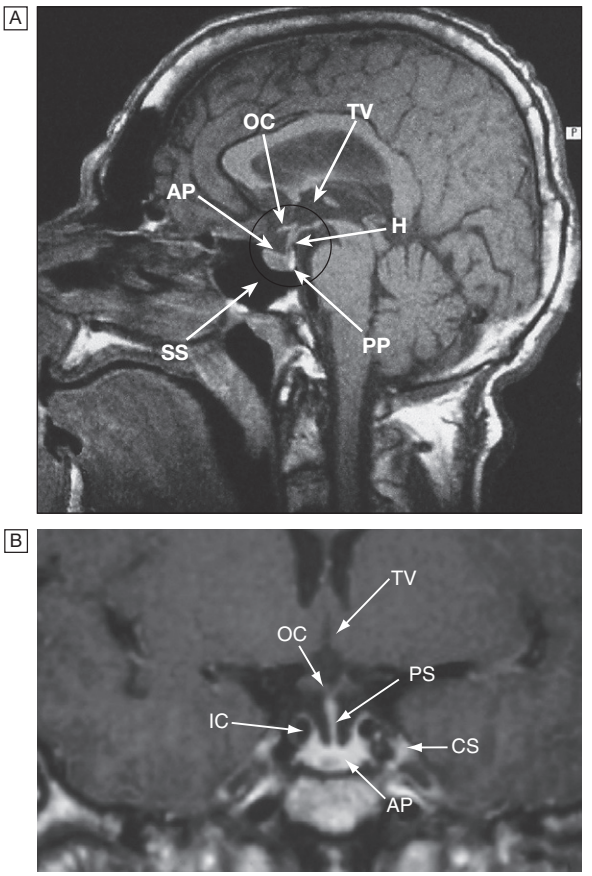

Fig. 20.26 Anatomical relationships of the normal pituitary gland and hypothalamus. See also Figure 20.2 (p. 737). A Sagittal MRI. B Coronal MRI. (AP = anterior pituitary; CS = cavernous sinus; H = hypothalamus; IC = internal carotid artery; OC = optic chiasm; PP = posterior pituitary; PS = pituitary stalk; SS = sphenoid sinus; TV = third ventricle)

20.57 Classification of diseases of the pituitary and hypothalamus

	Primary	Secondary
Non-functioning tumours	Pituitary adenoma Craniopharyngioma Metastatic tumours	
Hormone excess		
Anterior pituitary	Prolactinoma Acromegaly Cushing's disease Rare TSH-, LH-and FSH-secreting adenomas	Disconnection hyperprolactinaemia
Hypothalamus and posterior pituitary	Syndrome of inappropriate antidiuretic hormone (SIADH; p. 438)	
Hormone deficiency		
Anterior pituitary Hypothalamus and posterior pituitary	Hypopituitarism Cranial diabetes insipidus	GnRH deficiency (Kallmann's syndrome)
Hormone resistance	Growth hormone resistance (Laron dwarfism) Nephrogenic diabetes insipidus	

Investigation of patients with pituitary disease

Although pituitary disease presents with diverse clinical manifestations (see below), the approach to investigation is similar in all cases (Box 20.58).

The approach to testing for hormone deficiency is outlined in Box 20.58. Details are given in the sections on individual glands elsewhere in this chapter. Tests for hormone excess vary according to the hormone in question. For example, prolactin is not secreted in pulsatile fashion, although it rises with significant psychological stress. Assuming that the patient was not distressed by venepuncture, a random measurement of serum prolactin is sufficient to diagnose hyperprolactinaemia. In contrast, growth hormone is secreted in a pulsatile fashion. A high random level does not confirm acromegaly; the diagnosis is only confirmed by failure of growth hormone to be suppressed during an oral glucose tolerance test, and a high serum insulin-like growth factor-1 (IGF-1). Similarly, in suspected ACTH-dependent Cushing's disease (p. 773), random measurement of plasma cortisol is unreliable and the diagnosis is usually made by a dexamethasone suppression test.

The most common local complication of a large pituitary tumour is compression of the optic pathway. The resulting visual field defect can be documented using a Goldman's perimetry chart.

MRI reveals 'abnormalities' of the pituitary gland in as many as 10% of 'healthy' middle-aged people. It should therefore be performed only if there is a clear biochemical abnormality or in a patient who presents with clinical features of pituitary tumour (see below). A pituitary tumour may be classified as either a macroadenoma (> 10 mm diameter) or a microadenoma (< 10 mm diameter).

20.58 How to investigate patients with suspected pituitary hypothalamic disease

Identify pituitary hormone deficiency

ACTH deficiency
- Short ACTH stimulation test (see Box 20.47, p. 778)
- Insulin tolerance test (see Box 20.61, p. 788): only if uncertainty in interpretation of short ACTH stimulation test (e.g. acute presentation)

LH/FSH deficiency
- In the male, measure random serum testosterone, LH and FSH
- In the pre-menopausal female, ask if menses are regular
- In the post-menopausal female, measure random serum LH and FSH (which would normally be > 30 mU/L)

TSH deficiency
- Measure random serum T_4
- Note that TSH is often detectable in secondary hypothyroidism

Growth hormone deficiency

Only investigate if growth hormone replacement therapy is being contemplated; p. 789
- Measure immediately after exercise
- Consider other stimulatory tests (see Box 20.60)

Cranial diabetes insipidus

Only investigate if patient complains of polyuria/polydipsia, which may be masked by ACTH or TSH deficiency
- Exclude other causes of polyuria with blood glucose, potassium and calcium measurements
- Water deprivation test (see Box 20.66, p. 795) or 5% saline infusion test

Identify hormone excess
- Measure random serum prolactin
- Investigate for acromegaly (glucose tolerance test) or Cushing's syndrome (p. 774) if there are clinical features

Establish the anatomy and diagnosis
- Consider visual field testing
- Image the pituitary and hypothalamus by MRI or CT

Surgical biopsy is usually only performed as part of a therapeutic operation. Conventional histology identifies tumours as chromophobe (usually non-functioning), acidophil (typically prolactin- or growth hormone-secreting) or basophil (typically ACTH-secreting); immunohistochemistry may confirm their secretory capacity but is poorly predictive of growth potential of the tumour.

Presenting problems in hypothalamic and pituitary disease

The clinical features of pituitary disease are shown in Figure 20.27 overleaf. Younger women with pituitary disease most commonly present with secondary amenorrhoea (p. 759) or galactorrhoea (in hyperprolactinaemia). Post-menopausal women and men of any age are less likely to report symptoms of hypogonadism and so are more likely to present late with larger tumours causing visual field defects. Nowadays, many patients present with the incidental finding of a pituitary tumour on a CT or MRI scan.

Hypopituitarism

Hypopituitarism describes combined deficiency of any of the anterior pituitary hormones. The clinical presentation is variable and depends on the underlying lesion and the pattern of resulting hormone deficiency. The most common cause is a pituitary macroadenoma but other causes are listed in Box 20.59.

Clinical assessment

The presentation is highly variable. For example, following radiotherapy to the pituitary region, there is a characteristic sequence of loss of pituitary hormone secretion. Growth hormone secretion is often the earliest to be lost. In adults, this produces lethargy, muscle weakness and increased fat mass but these features are not obvious in isolation. Next, gonadotrophin (LH and FSH) secretion becomes impaired with, in the male, loss of libido and, in the female, oligomenorrhoea or amenorrhoea. Later, in the male there may be gynaecomastia and decreased frequency of shaving. In both sexes, axillary and pubic hair eventually become sparse or even absent and the skin becomes characteristically finer and wrinkled. Chronic anaemia may also occur. The next hormone to be lost is usually ACTH, resulting in symptoms of cortisol insufficiency (including postural hypotension and

20.59 Causes of anterior pituitary hormone deficiency

Structural
- Primary pituitary tumour
  - Adenoma*
  - Carcinoma (exceptionally rare)
- Craniopharyngioma*
- Meningioma*
- Secondary tumour (including leukaemia and lymphoma)
- Chordoma
- Germinoma (pinealoma)
- Arachnoid cyst
- Rathke's cleft cyst
- Haemorrhage (apoplexy)

Inflammatory/infiltrative
- Sarcoidosis
- Infections, e.g. pituitary abscess, tuberculosis, syphilis, encephalitis
- Lymphocytic hypophysitis
- Haemochromatosis
- Langerhans cell histiocytosis

Congenital deficiencies
- GnRH (Kallmann's syndrome)* – gonadotrophin-releasing hormone
- GHRH* – growth hormone-releasing hormone
- TRH – thyrotrophin-releasing hormone
- CRH – corticotrophin-releasing hormone

Functional*
- Chronic systemic illness
- Anorexia nervosa
- Excessive exercise

Other
- Head injury*
- (Para)sellar surgery*
- (Para)sellar radiotherapy*
- Post-partum necrosis (Sheehan's syndrome)
- Opiate analgesia

*The most common causes of pituitary hormone deficiency.

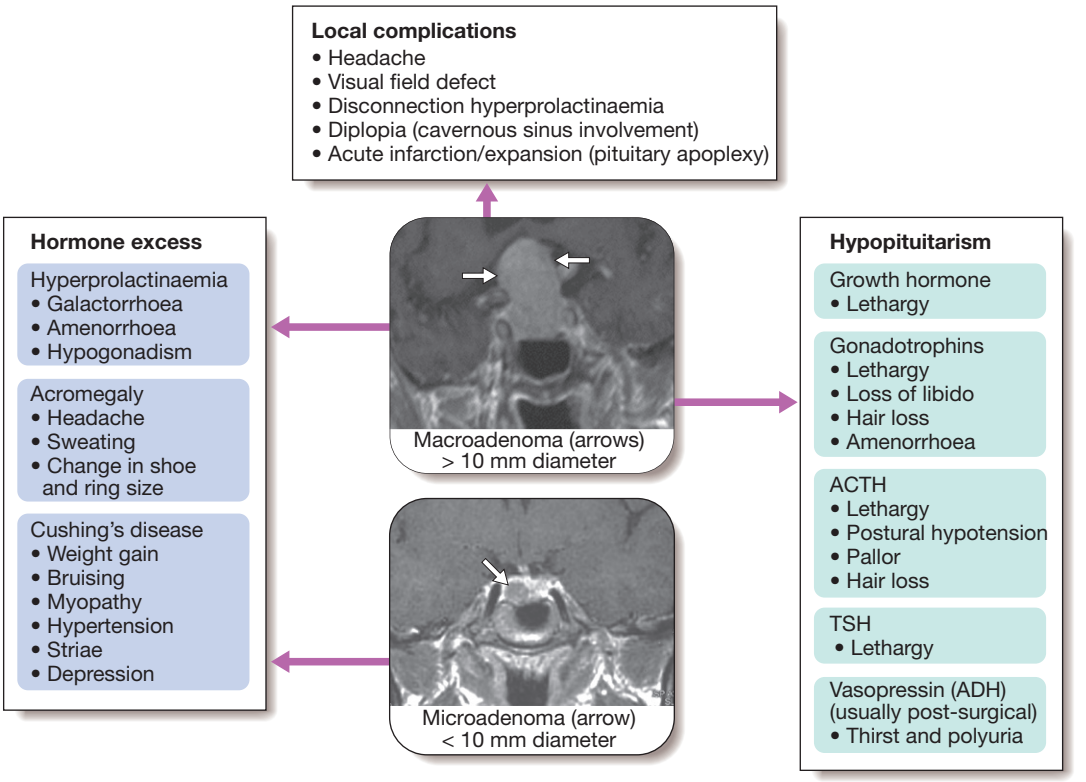

Fig. 20.27 Common symptoms and signs to consider in a patient with suspected pituitary disease.

a *dilutional* hyponatraemia). In contrast to primary adrenal insufficiency (p. 777), angiotensin II-dependent zona glomerulosa function is not lost and hence aldosterone secretion maintains normal plasma potassium. In contrast to the pigmentation of Addison's disease due to high levels of circulating ACTH acting on the skin melanocytes, a striking degree of pallor is usually present. Finally, TSH secretion is lost with consequent secondary hypothyroidism. This contributes further to apathy and cold intolerance. In contrast to primary hypothyroidism, frank myxoedema is rare, presumably because the thyroid retains some autonomous function. The onset of all of the above symptoms is notoriously insidious. However, patients sometimes present acutely unwell with glucocorticoid deficiency. This may be precipitated by a mild infection or injury, or may occur secondary to pituitary apoplexy (p. 789).

Other features of pituitary disease may be present (see Fig. 20.27).

Investigations

The strategy for investigation of pituitary disease is described in Box 20.58. In acutely unwell patients, the priority is to diagnose and treat cortisol deficiency (p. 776). Other tests can be undertaken later. Specific dynamic tests for diagnosing hormone deficiency are described in Boxes 20.47 (p. 778) and 20.60. More specialised biochemical tests, such as insulin tolerance tests (Box 20.61), GnRH and TRH tests, are rarely required. All patients with biochemical evidence of pituitary hormone deficiency should have an MRI or CT scan to identify pituitary or hypothalamic tumours. If a tumour is not identified, then further investigations are indicated to exclude infectious or infiltrative causes.

20.60 Tests of growth hormone secretion

GH levels are commonly undetectable, so a choice from the range of 'stimulation' tests is required:
- Insulin-induced hypoglycaemia
- Arginine (may be combined with GHRH)
- Glucagon
- Clonidine

Management

Treatment of acutely ill patients is similar to that described for adrenocortical insufficiency on page 778, except that sodium depletion is not an important component to correct. Chronic hormone replacement therapies are described below. Once the cause of hypopituitarism is established, specific treatment – of a pituitary macroadenoma, for example (see below) – may be required.

Cortisol replacement

Hydrocortisone should be given if there is ACTH deficiency. Suitable doses are described in the section on adrenal disease on page 779. Mineralocorticoid replacement is not required.

Thyroid hormone replacement

Levothyroxine 50–150 µg once daily should be given as described on page 743. Unlike in primary

20.61 How and when to do an insulin tolerance test

Use

- Assessment of the HPA axis
- Assessment of growth hormone deficiency
- Indicated when there is doubt after the other tests in Box 20.58
- Usually performed in specialist centres, especially in children
- IV glucose and hydrocortisone must be available for resuscitation

Contraindications

- Ischaemic heart disease
- Epilepsy
- Severe hypopituitarism (0800 hrs plasma cortisol < 180 nmol/L (6.6 µg/dL))

Dose

- 0.15 U/kg body weight soluble insulin IV

Aim

- To produce adequate hypoglycaemia (tachycardia and sweating with blood glucose < 2.2 mmol/L (40 mg/dL))

Blood samples

- 0, 30, 45, 60, 90, 120 mins for blood glucose, plasma cortisol and growth hormone

Results

- Normal subjects: GH > 6.7 µg/L (20 mU/L)*
- Normal subjects: cortisol > 550 nmol/L (~20.2 µg/dL)*

*The precise cut-off figure for a satisfactory cortisol and GH response depends on the assay used and so varies between centres.

hypothyroidism, measuring TSH is not helpful in adjusting the replacement dose because patients with hypopituitarism often secrete glycoproteins which are measured in the TSH assays but are not bioactive. The aim is to maintain serum T_4 in the upper part of the reference range. It is dangerous to give thyroid replacement in adrenal insufficiency without first giving glucocorticoid therapy, since this may precipitate adrenal crisis.

Sex hormone replacement

This is indicated if there is gonadotrophin deficiency in women under the age of 50 and in men to restore normal sexual function and to prevent osteoporosis (p. 1120).

Growth hormone replacement

Growth hormone (GH) is administered by daily subcutaneous self-injection to children and adolescents with GH deficiency and, until recently, was discontinued once the epiphyses had fused. However, although hypopituitary adults receiving 'full' replacement with hydrocortisone, levothyroxine and sex steroids are usually much improved by these therapies, some individuals remain lethargic and unwell compared with a healthy population. Some of these patients feel better, and have objective improvements in their fat:muscle mass ratios and other metabolic parameters, if they are also given GH replacement. Treatment with GH may also help young adults to achieve a higher peak bone mineral density. The principal side-effect is sodium retention, manifest as peripheral oedema or carpal tunnel syndrome. For this reason, GH replacement should be started at a low dose, with monitoring of the response by measurement of serum IGF-1.

Pituitary tumour

Pituitary tumours produce a variety of mass effects, depending on their size and location, but also present as incidental findings on CT or MRI, or with hypopituitarism, as described above. A wide variety of disorders can present as mass lesions in or around the pituitary gland (see Box 20.59). Most intrasellar tumours are pituitary macroadenomas (most commonly non-functioning adenomas, see Fig. 20.27), whereas suprasellar masses may be craniopharyngiomas (see Fig. 20.30, p. 794). The most common cause of a parasellar mass is a meningioma.

Clinical assessment

Clinical features are shown in Figure 20.27. A common but non-specific presentation is with headache, which may be the consequence of stretching of the diaphragma sellae. Although the classical abnormalities associated with compression of the optic chiasm are bitemporal hemianopia (see Fig. 20.28) or upper quadrantanopia, any type of visual field defect can result from suprasellar extension of a tumour because it may compress the optic nerve (unilateral loss of acuity or scotoma) or the optic tract (homonymous hemianopia). Optic atrophy may be apparent on ophthalmoscopy. Lateral extension of a sellar mass into the cavernous sinus with subsequent compression of the 3rd, 4th or 6th cranial nerve may cause diplopia and strabismus, but in anterior pituitary tumours this is an unusual presentation.

Occasionally, pituitary tumours infarct or there is bleeding into cystic lesions. This is termed 'pituitary apoplexy' and may result in sudden expansion with local compression symptoms and acute-onset hypopituitarism. Non-haemorrhagic infarction can also occur in a normal pituitary gland; predisposing factors include catastrophic obstetric haemorrhage (Sheehan's syndrome), diabetes mellitus and raised intracranial pressure.

Investigations

Patients suspected of having a pituitary tumour should undergo MRI or CT. Whilst some lesions have distinctive neuro-radiological features, the definitive diagnosis is made on histology after surgery. All patients with (para)sellar space-occupying lesions should have pituitary function assessed as described in Box 20.58 (p. 787).

Management

Modalities of treatment of common pituitary and hypothalamic tumours are shown in Box 20.62. Associated hypopituitarism should be treated as described above.

Urgent treatment is required if there is evidence of pressure on visual pathways. The chances of recovery of a visual field defect are proportional to the duration of symptoms, with full recovery unlikely if the defect has been present for longer than 4 months. In the presence of a sellar mass lesion, it is crucial that serum prolactin is measured before emergency surgery is performed. If the prolactin is over 5000 mU/L, then the lesion is likely to be a macroprolactinoma and to respond

20.62 Therapeutic modalities for hypothalamic and pituitary tumours

	Surgery	Radiotherapy	Medical	Comment
Non-functioning pituitary macroadenoma	1st line	2nd line	–	
Prolactinoma	2nd line	2nd line	1st line Dopamine agonists	Dopamine agonists usually cause macroadenomas to shrink
Acromegaly	1st line	2nd line	2nd line Somatostatin analogues Dopamine agonists GH receptor antagonists	Medical therapy does not reliably cause macroadenomas to shrink Radiotherapy and medical therapy are used in combination for inoperable tumours
Cushing's disease	1st line	2nd line	–	Radiotherapy may be more effective in children than in adults and appears to cause less hypopituitarism in the long-term
Craniopharyngioma	1st line	2nd line	–	

to a dopamine agonist with shrinkage of the lesion, making surgery unnecessary (see Fig. 20.28).

Most operations on the pituitary are performed using the trans-sphenoidal approach via the nostrils, while transfrontal surgery via a craniotomy is reserved for suprasellar tumours. It is uncommon to be able to resect lateral extensions into the cavernous sinuses. All operations on the pituitary carry a risk of damaging normal endocrine function; this risk increases with the size of the primary lesion.

Pituitary function (see Box 20.58, p. 787) should be retested 4–6 weeks following surgery, primarily to detect the development of any new hormone deficits. Rarely, the surgical treatment of a sellar lesion can result in recovery of hormone secretion that was deficient pre-operatively.

Following surgery, usually after 3–6 months, imaging should be repeated and, if there is a significant residual mass and the histology confirms an anterior pituitary tumour, external radiotherapy may be given to reduce the risk of recurrence. Radiotherapy is not useful in patients requiring urgent therapy because it takes many months or years to be effective and there is a risk of acute swelling of the mass. Fractionated radiotherapy carries a life-long risk of hypopituitarism (50–70% in the first 10 years) and annual pituitary function tests are obligatory. There is also concern that radiotherapy might impair cognitive function, cause vascular changes and even induce primary brain tumours, but these side-effects have not been quantified reliably and are likely to be rare. Stereotactic radiosurgery, best delivered by the 'gamma knife', allows specific targeting of residual disease in a more focused fashion.

Non-functioning tumours should be followed up by repeated imaging at intervals that depend on the size of the lesion and on whether or not radiotherapy has been administered. For smaller lesions that are not causing mass effects, therapeutic surgery may not be indicated and the lesion may simply be monitored by serial neuroimaging without a clear-cut diagnosis having been established.

Hyperprolactinaemia/galactorrhoea

Hyperprolactinaemia is a common abnormality which usually presents with hypogonadism and/or galactorrhoea (lactation in the absence of breastfeeding). Since prolactin stimulates milk secretion but not breast development, galactorrhoea rarely occurs in men and only does so if gynaecomastia has been induced by hypogonadism (p. 760). The differential diagnosis of hyperprolactinaemia is shown in Box 20.63. Many drugs, especially dopamine antagonists, elevate prolactin concentrations. Pituitary tumours can cause hyperprolactinaemia by directly secreting prolactin (prolactinomas, see below), or by compressing the infundibular stalk

20.63 Causes of hyperprolactinaemia

Physiological

- Stress (e.g. post-seizure)
- Pregnancy
- Lactation
- Nipple stimulation
- Sleep
- Coitus
- Exercise
- Baby crying

Drug-induced

Dopamine antagonists

- Antipsychotics (phenothiazines and butyrophenones)
- Antidepressants
- Antiemetics (e.g. metoclopramide, domperidone)

Dopamine-depleting drugs

- Reserpine
- Methyldopa

Oestrogens

- Oral contraceptive pill

Pathological

Common

- Disconnection hyperprolactinaemia (e.g. non-functioning pituitary macroadenoma)
- Prolactinoma (usually microadenoma)
- Primary hypothyroidism
- Polycystic ovarian syndrome
- Macroprolactinaemia

Uncommon

- Pituitary tumour secreting prolactin and growth hormone
- Hypothalamic disease
- Renal failure

Rare

- Chest wall reflex (e.g. post-herpes zoster)

and thus interrupting the tonic inhibitory effect of hypothalamic dopamine on prolactin secretion ('disconnection' hyperprolactinaemia).

Prolactin usually circulates as a free (monomeric) hormone in plasma, but in some individuals prolactin becomes bound to an IgG antibody. This complex is known as macroprolactin and such patients have macroprolactinaemia (not to be confused with macro-prolactinoma, a prolactin-secreting pituitary tumour of more than 1 cm in diameter). Since macroprolactin cannot cross blood-vessel walls to reach prolactin receptors in target tissues, it is of no pathological significance. Some commercial prolactin assays do not distinguish prolactin from macroprolactin and so macroprolactinaemia is a cause of spurious hyperprolactinaemia. Identification of macroprolactin requires gel filtration chromatography or polyethylene glycol precipitation techniques, and one of these tests should be performed in all patients with hyperprolactinaemia if the prolactin assay is known to cross-react.

Clinical assessment

In women, in addition to galactorrhoea, hypogonadism associated with hyperprolactinaemia causes secondary amenorrhoea and anovulation with infertility (p. 759). Important points in the history include drug use, recent pregnancy and menstrual history. The quantity of milk produced is variable, and it may be observed only by manual expression. In men there is decreased libido, reduced shaving frequency and lethargy (p. 760). Unilateral galactorrhoea may be confused with nipple discharge, and breast examination to exclude malignancy or fibrocystic disease is important. Further assessment should address the features in Figure 20.27 (p. 788).

Investigations

Pregnancy should first be excluded before further investigations are performed in women of child-bearing potential. The upper limit of normal for many assays of serum prolactin is approximately 500 mU/L (14 ng/mL). In non-pregnant and non-lactating patients, monomeric prolactin concentrations of 500–1000 mU/L are likely to be induced by stress or drugs, and a repeat measurement is indicated. Levels between 1000 and 5000 mU/L are likely to be due to either drugs, or a microprolactinoma or 'disconnection' hyperprolactinaemia. Levels above 5000 mU/L are highly suggestive of a macroprolactinoma.

Patients with prolactin excess should have tests of gonadal function (p. 757), and T_4 and TSH should be measured to exclude primary hypothyroidism causing TRH-induced prolactin excess. Unless the prolactin falls after withdrawal of relevant drug therapy, a serum prolactin consistently above the reference range is an indication for MRI or CT scan of the hypothalamus and pituitary. Patients with a macroadenoma also need tests for hypopituitarism (see Box 20.58).

Management

If possible, the underlying cause should be corrected (for example, cessation of offending drugs and giving levothyroxine replacement in primary hypothyroidism). If dopamine antagonists are the cause, then dopamine agonist therapy is contraindicated, and if gonadal dysfunction is the primary concern, sex steroid replacement therapy may be indicated. Troublesome physiological galactorrhoea can also be treated with dopamine agonists (see Box 20.64). Management of prolactinomas is described below.

Prolactinoma

Most prolactinomas in pre-menopausal women are microadenomas because the symptoms of prolactin excess usually result in early presentation. Prolactin-secreting cells of the anterior pituitary share a common lineage with GH-secreting cells, so occasionally prolactinomas can secrete excess GH and cause acromegaly. In prolactinomas there is a relationship between prolactin concentration and tumour size: the higher the level, the bigger the tumour. Some macroprolactinomas can elevate prolactin concentrations above 100 000 mU/L. The investigation of prolactinomas is the same as for other pituitary tumours (see above).

Management

As shown in Box 20.62, several therapeutic modalities can be employed in the management of prolactinomas.

Medical

Dopamine agonist drugs are first-line therapy for the majority of patients (Box 20.64). They usually reduce

20.64 Dopamine agonist therapy: drugs used to treat prolactinomas

	Oral dose*	Advantages	Disadvantages
Bromocriptine	2.5–15 mg/day 2–3 times daily	Available for parenteral use Short half-life; useful in treating infertility Proven long-term efficacy	Ergotamine-like side-effects (nausea, headache, postural hypotension, constipation) Frequent dosing so poor compliance Rare reports of fibrotic reactions in various tissues
Cabergoline	250–1000 µg/week 2 doses/week	Long-acting, so missed doses less important Reported to have fewer ergotamine-like side-effects	Limited data on safety in pregnancy Associated with cardiac valvular fibrosis in Parkinson's disease
Quinagolide	50–150 µg/day Once daily	A non-ergot with few side-effects in patients intolerant of the above	Untested in pregnancy

*Tolerance develops for the side-effects. All of these agents, especially bromocriptine, must be introduced at low dose and increased slowly. If several doses of bromocriptine are missed, the process must start again.

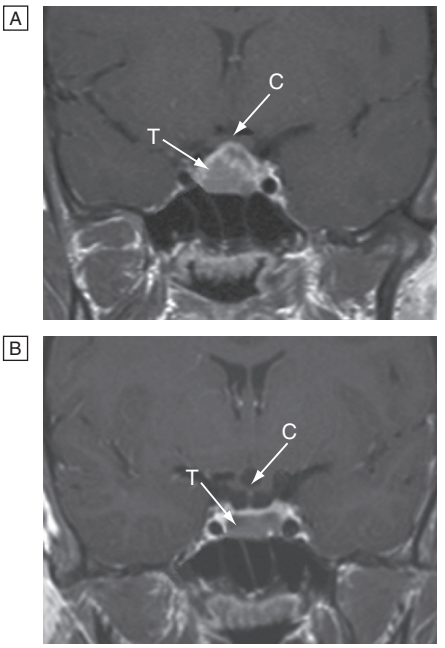

Fig. 20.28 Shrinkage of a macroprolactinoma following treatment with a dopamine agonist. A MRI scan showing a pituitary macroadenoma (T) compressing the optic chiasm (C). B MRI scan of the same tumour following treatment with a dopamine agonist. The macroadenoma, which was a prolactinoma, has decreased in size substantially and is no longer compressing the optic chiasm.

serum prolactin concentrations and cause significant tumour shrinkage after several months of therapy (Fig. 20.28), but visual field defects, if present, may improve within days of first administration. It is possible to withdraw dopamine agonist therapy without recurrence of hyperprolactinaemia after a few years of treatment in some patients with a microadenoma. Also, after the menopause, suppression of prolactin is only required in microadenomas if galactorrhoea is troublesome, since hypogonadism is then physiological and tumour growth unlikely. In patients with macroadenomas, drugs can only be withdrawn after curative surgery or radiotherapy and under close supervision.

Ergot-derived dopamine agonists (bromocriptine and cabergoline) can bind to 5-HT_{2B} receptors in the heart and elsewhere and have been associated with fibrotic reactions, particularly tricuspid valve regurgitation, when used in high doses in patients with Parkinson's disease. At the relatively low doses used in prolactinomas most data suggest that systematic screening for cardiac fibrosis is unnecessary, but if dopamine agonist therapy is prolonged, periodic screening by echocardiography or use of non-ergot agents (quinagolide) may be indicated.

Surgery and radiotherapy

Surgical decompression is usually only necessary when a macroprolactinoma has failed to shrink sufficiently with dopamine agonist therapy, and this may be because the tumour has a significant cystic component. Surgery may also be performed in patients who are intolerant of dopamine agonists. Microadenomas can be removed selectively by trans-sphenoidal surgery with a cure rate of about 80% but recurrence is not unusual; the cure rate for surgery in macroadenomas is substantially lower.

External irradiation may be required for some macroadenomas to prevent regrowth if dopamine agonists are stopped.

Pregnancy

Hyperprolactinaemia often presents with infertility, so dopamine agonist therapy may be followed by pregnancy. Patients with microadenomas should be advised to withdraw dopamine agonist therapy as soon as pregnancy is confirmed. In contrast, macroprolactinomas may enlarge rapidly under oestrogen stimulation and these patients should continue dopamine agonist therapy and need measurement of prolactin levels and visual fields during pregnancy. All patients should be advised to report headache or visual disturbance promptly.

Acromegaly

Acromegaly is caused by growth hormone (GH) secretion from a pituitary tumour, usually a macroadenoma, and carries an approximate two-fold excess mortality when untreated.

Clinical features

If GH hypersecretion occurs before puberty, then the presentation is with gigantism. More commonly, GH excess occurs in adult life and presents with acromegaly. If hypersecretion starts in adolescence and persists into adult life, then the two conditions may be combined. The clinical features are shown in Figure 20.29. The most common complaints are headache and sweating. Additional features include those of any pituitary tumour (see Fig. 20.27, p. 788).

Investigations

The clinical diagnosis must be confirmed by measuring GH levels during an oral glucose tolerance test and measuring serum IGF-1. In normal subjects, plasma GH suppresses to below 0.5 μg/L (approximately 2 mU/L). In acromegaly, GH does not suppress and in about 30% of patients there is a paradoxical rise; IGF-1 is also elevated. The rest of pituitary function should be investigated as described in Box 20.58 (p. 787). Prolactin concentrations are elevated in about 30% of patients due to co-secretion of prolactin from the tumour. Additional tests in acromegaly may include screening for colonic neoplasms with colonoscopy.

Management

The main aims are to improve symptoms and to normalise serum GH and IGF-1 to reduce morbidity and mortality. Treatment is summarised in Box 20.62.

Surgical

Trans-sphenoidal surgery is usually the first line of treatment and may result in cure of GH excess, especially in patients with microadenomas. More often, surgery serves to debulk the tumour and further second-line therapy is required, according to post-operative imaging and glucose tolerance test results.

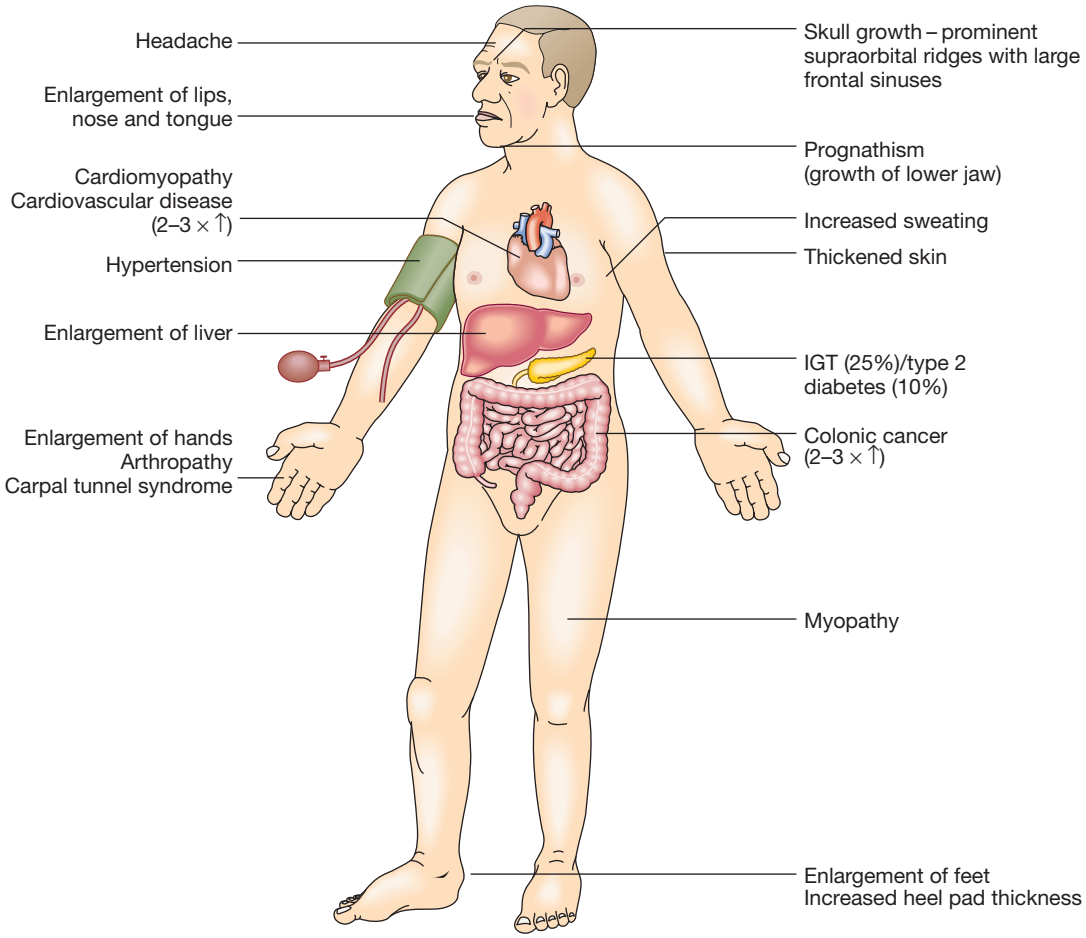

Fig. 20.29 Clinical features of acromegaly. (IGT = impaired glucose tolerance)

Radiotherapy

External radiotherapy is usually employed as second-line treatment if acromegaly persists after surgery, to stop tumour growth and lower GH levels. However, GH levels fall slowly (over many years) and there is a risk of hypopituitarism.

Medical

If acromegaly persists after surgery, medical therapy is usually employed to lower GH levels to below 1.5 µg/L (below approximately 5 mU/L) and to normalise IGF-1 concentrations. Medical therapy may be discontinued after several years in patients who have received radiotherapy. Somatostatin analogues (such as octreotide or lanreotide) can be administered as slow-release injections every few weeks. Somatostatin analogues can also be used as primary therapy for acromegaly either as an alternative or in advance of surgery, given evidence that they can induce modest tumour shrinkage in some patients. Dopamine agonists are less effective at lowering GH but may sometimes be helpful, especially with associated prolactin excess. Pegvisomant is a peptide GH receptor antagonist administered by daily self-injection and may be indicated in some patients whose GH and IGF-1 concentrations fail to suppress sufficiently following somatostatin analogue therapy.

Craniopharyngioma

Craniopharyngiomas are benign tumours that develop in cell rests of Rathke's pouch, and may be located within the sella turcica, or commonly in the suprasellar space. They are often cystic, with a solid component that may or may not be calcified (Fig. 20.30). In young people, they are diagnosed more commonly than pituitary adenomas. They may present with pressure effects on adjacent structures, hypopituitarism and/or cranial diabetes insipidus. Other clinical features directly related to hypothalamic damage may also occur. These include hyperphagia and obesity, loss of the sensation of thirst and disturbance of temperature regulation.

Craniopharyngiomas can be treated by the transsphenoidal route but surgery may also involve a craniotomy, with a relatively high risk of hypothalamic damage and other complications. If the tumour has a large cystic component, it may be safer to place in the cyst cavity a drain which is attached to a subcutaneous access device, rather than attempt a resection. Whatever form it takes, surgery is unlikely to be curative and radiotherapy is usually given to reduce the risk of relapse. Unfortunately, craniopharyngiomas often recur, requiring repeated surgery. They often cause considerable morbidity, usually from hypothalamic obesity, water balance problems and/or visual failure.

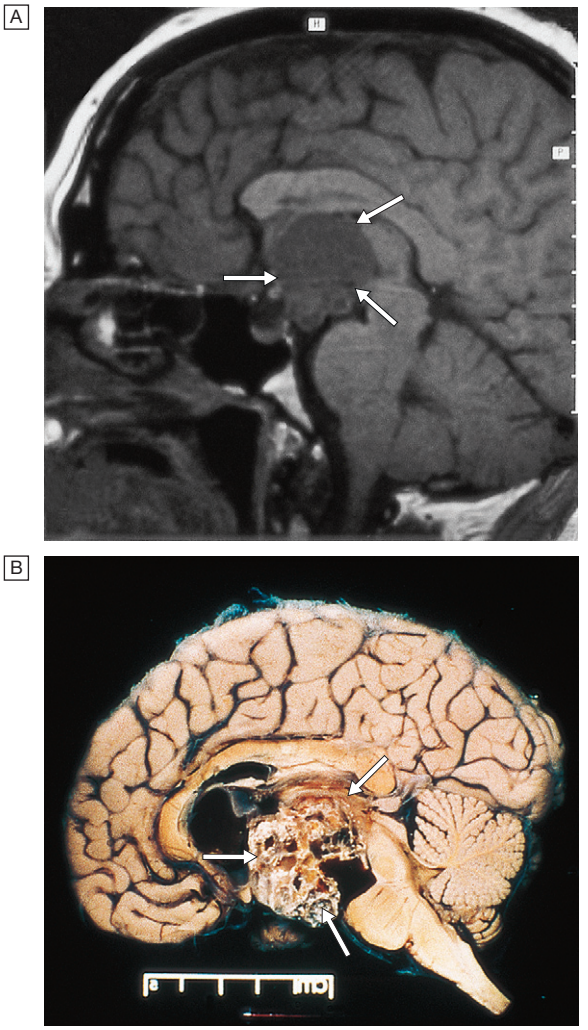

Fig. 20.30 Craniopharyngioma. A This developmental tumour characteristically presents in younger patients; it is often cystic and calcified, as shown in this MRI scan (arrows). B Pathology specimen.

Diabetes insipidus

This uncommon disorder is characterised by the persistent excretion of excessive quantities of dilute urine and by thirst. It is classified into two types:

- cranial diabetes insipidus, in which there is deficient production of ADH by the hypothalamus
- nephrogenic diabetes insipidus, in which the renal tubules are unresponsive to ADH.

The underlying causes are listed in Box 20.65.

Clinical features

The most marked symptoms are polyuria and polydipsia. The patient may pass 5–20 L or more of urine in 24 hours. This is of low specific gravity and osmolality. If the patient has an intact thirst mechanism, is conscious and has access to oral fluids, then he or she can maintain adequate fluid intake. However, in an unconscious patient or a patient with damage to the hypothalamic thirst centre, diabetes insipidus is potentially lethal. If there is associated cortisol deficiency, then diabetes insipidus may not be manifest until glucocorticoid replacement therapy is given. The most common differential diagnosis is primary polydipsia, caused by drinking excessive amounts of fluid in the absence of a defect in ADH or thirst control.

20.65 Causes of diabetes insipidus

Cranial

Structural hypothalamic or high stalk lesion
- See Box 20.59

Idiopathic

Genetic defect
- Dominant (*AVP* gene mutation)
- Recessive (DIDMOAD syndrome – association of diabetes insipidus with diabetes mellitus, optic atrophy, deafness)

Nephrogenic

Genetic defect
- V2 receptor mutation
- Aquaporin-2 mutation
- Cystinosis

Metabolic abnormality
- Hypokalaemia
- Hypercalcaemia

Drug therapy
- Lithium
- Demeclocycline

Poisoning
- Heavy metals

Chronic kidney disease
- Polycystic kidney disease
- Sickle-cell anaemia
- Infiltrative disease

Investigations

Diabetes insipidus can be confirmed if serum ADH is undetectable (although the assay for this is not widely available) or the urine is not maximally concentrated (i.e. is below 600 mOsm/kg) in the presence of increased plasma osmolality (i.e. greater than 300 mOsm/kg). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The water deprivation test described in Box 20.66 is widely used, but an alternative is to infuse hypertonic (5%) saline and measure ADH secretion in response to increasing plasma osmolality. Thirst can also be assessed during these tests on a visual analogue scale. Anterior pituitary function and suprasellar anatomy should be assessed in patients with cranial diabetes insipidus (see Box 20.58, p. 787).

In primary polydipsia, the urine may be excessively dilute because of chronic diuresis, which 'washes out' the solute gradient across the loop of Henle, but plasma osmolality is low rather than high. DDAVP (see below) should not be administered to patients with primary polydipsia, since it will prevent excretion of water and there is a risk of severe water intoxication if the patient continues to drink fluid to excess.

In nephrogenic diabetes insipidus, appropriate further tests include plasma electrolytes, calcium and investigation of the renal tract (Chs 16 and 17).

Management

Treatment of cranial diabetes insipidus is with desamino-des-aspartate-arginine vasopressin (desmopressin, DDAVP), an analogue of ADH which has a

20.66 How and when to do a water deprivation test

Use

- To establish a diagnosis of diabetes insipidus and to differentiate cranial from nephrogenic causes

Protocol

- No coffee, tea or smoking on the test day
- Free fluids until 0730 hrs on the morning of the test, but discourage patients from 'stocking up' with extra fluid in anticipation of fluid deprivation
- No fluids from 0730 hrs
- Attend at 0830 hrs for body weight, plasma and urine osmolality
- Record body weight, urine volume, urine and plasma osmolality and thirst score on a visual analogue scale every 2 hrs for up to 8 hrs
- Stop the test if the patient loses 3% of body weight
- If plasma osmolality reaches > 300 mOsm/kg and urine osmolality < 600 mOsm/kg, then administer DDAVP (see text) 2 μg IM

Interpretation

- Diabetes insipidus is confirmed by a plasma osmolality > 300 mOsm/kg with a urine osmolality < 600 mOsm/kg
- Cranial diabetes insipidus is confirmed if urine osmolality rises by at least 50% after DDAVP
- Nephrogenic diabetes insipidus is confirmed if DDAVP does not concentrate the urine
- Primary polydipsia is suggested by low plasma osmolality at the start of the test

longer half-life. DDAVP is usually administered intranasally. An oral formulation is also available but bioavailability is low and rather unpredictable. In sick patients, DDAVP should be given by intramuscular injection. The dose of DDAVP should be adjusted on the basis of serum sodium concentrations and/or osmolality. The principal hazard is excessive treatment, resulting in water intoxication and hyponatraemia. Conversely, inadequate treatment results in thirst and polyuria. The ideal dose prevents nocturia but allows a degree of polyuria from time to time before the next dose (e.g. DDAVP nasal dose 5 μg in the morning and 10 μg at night).

The polyuria in nephrogenic diabetes insipidus is improved by thiazide diuretics (e.g. bendroflumethiazide 5–10 mg/day), amiloride (5–10 mg/day) and NSAIDs (e.g. indometacin 15 mg 3 times daily), although the last of these carries a risk of reducing glomerular filtration rate.

20.67 The pituitary and hypothalamus in old age

- **Late presentation**: often with large tumours causing visual disturbance, because early symptoms such as amenorrhoea and sexual dysfunction do not occur or are not recognised.
- **Coincidentally discovered pituitary tumours**: may not require surgical intervention if the visual apparatus is not involved, because of slow growth. Radiotherapy alone is sometimes employed simply to prevent further growth.
- **Hyperprolactinaemia**: less impact in post-menopausal women who are already 'physiologically' hypogonadal. Macroprolactinomas, however, require treatment because of their potential to cause mass effects.

DISORDERS AFFECTING MULTIPLE ENDOCRINE GLANDS

Multiple endocrine neoplasia

Multiple endocrine neoplasias (MEN) are rare autosomal dominant syndromes characterised by hyperplasia and formation of adenomas or malignant tumours in multiple glands. They fall into two groups, as shown in Box 20.68. Some other genetic diseases also have an increased risk of endocrine tumours; for example, phaeochromocytoma is associated with von Hippel–Lindau syndrome (p. 1216) and neurofibromatosis type 1 (p. 1215).

20.68 Multiple endocrine neoplasia (MEN) syndromes

MEN 1 (Wermer's syndrome)

- Primary hyperparathyroidism
- Pituitary tumours
- Pancreatic neuro-endocrine tumours (insulinoma, gastrinoma)

MEN 2 (Sipple's syndrome)

- Primary hyperparathyroidism
- Medullary carcinoma of thyroid
- Phaeochromocytoma

In addition, in MEN 2b syndrome, there are phenotypic changes (including marfanoid habitus, skeletal abnormalities, abnormal dental enamel, multiple mucosal neuromas)

The MEN syndromes should be considered in all patients with two or more endocrine tumours and in patients with solitary tumours who report other endocrine tumours in their family. Inactivating mutations in *MENIN*, a tumour suppressor gene on chromosome 11, cause MEN 1, whereas MEN 2 is caused by gain-of-function mutations in the *RET* proto-oncogene on chromosome 10. These cause constitutive activation of the membrane-associated tyrosine kinase RET, which controls the development of cells that migrate from the neural crest. In contrast, loss-of-function mutations of the RET kinase cause Hirschsprung's disease (p. 917). Genetic testing can be performed on relatives of affected individuals, after appropriate counselling (p. 67).

Individuals who carry mutations associated with MEN should be entered into a surveillance programme. In MEN 1, this typically involves annual history, examination and measurements of serum calcium, gastrointestinal hormones (see Box 20.54, p. 785) and prolactin; MRI of the pituitary and pancreas is performed at less frequent intervals. In individuals with MEN 2, annual history, examination and measurement of serum calcium and urinary catecholamine metabolites should be performed. Because the penetrance of medullary carcinoma of the thyroid is 100% in individuals with a *RET* mutation, prophylactic thyroidectomy should be performed in early childhood.

Autoimmune polyendocrine syndromes

Two distinct autoimmune polyendocrine syndromes are known: APS types 1 and 2.

20.69 Autoimmune polyendocrine syndromes (APS)*

Type 1 (APECED)	
• Addison's disease	• Chronic mucocutaneous candidiasis
• Hypoparathyroidism	• Nail dystrophy
• Type 1 diabetes	• Dental enamel hypoplasia
• Primary hypothyroidism	

Type 2 (Schmidt's syndrome)	
• Addison's disease	• Type 1 diabetes
• Primary hypothyroidism	• Vitiligo
• Graves' disease	• Coeliac disease
• Pernicious anaemia	• Myasthenia gravis
• Primary hypogonadism	

*In both types of APS, the precise pattern of disease varies between affected individuals.

The most common is APS type 2 (Schmidt's syndrome), which typically presents in women between the ages of 20 and 60. It is usually defined as the occurrence in the same individual of two or more autoimmune endocrine disorders, some of which are listed in Box 20.69. The mode of inheritance is autosomal dominant with incomplete penetrance and there is a strong association with HLA-DR3 and CTLA-4.

Much less common is APS type 1, which is also termed autoimmune poly-endocrinopathy-candidiasis-ectodermal dystrophy (APECED). This is inherited in an autosomal recessive fashion and is caused by loss-of-function mutations in the autoimmune regulator gene *AIRE*, which is responsible for the presentation of self-antigens to thymocytes in utero. This is essential for the deletion of thymocyte clones that react against self-antigens and hence for the development of immune tolerance (Ch. 4). The most common clinical features are described in Box 20.69, although the pattern of presentation is variable and other autoimmune disorders are often observed.

Late effects of childhood cancer therapy

Prolonged survival is increasingly common following successful treatment of cancers in children and adolescents. The therapies used to treat these diseases, including radiotherapy and chemotherapy, may cause long-term endocrine dysfunction. In many circumstances this is predictable, such as cytotoxic chemotherapy causing future infertility and pubertal delay (especially in boys), cranial irradiation causing long-term pituitary dysfunction, and radiotherapy to the neck causing hypothyroidism and thyroid cancer. Increasing recognition of these issues has resulted in active monitoring programmes for survivors of childhood cancer, who are best seen in specialist 'late effects' multidisciplinary clinics where teams include endocrinologists, oncologists, reproductive medicine specialists, psychologists and nurse specialists.

CLINICAL EXAMINATION OF THE PATIENT WITH DIABETES

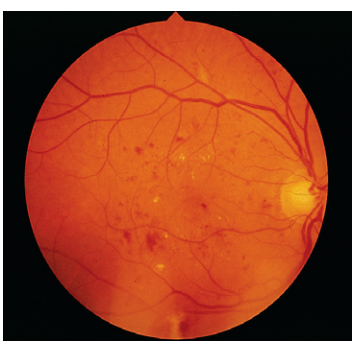
Inset (*Acanthosis nigricans*) From Shotliff. In: Lim 2007 – see p. 836.

Diabetes can affect every system in the body. In routine clinical practice, examination of the patient with diabetes is focused on 1 hands, 3 blood pressure, 4 and 5 axillae and neck, 7 eyes, 8 insulin injection sites and 11 feet.

7 Examination of the eyes

Visual acuity

- Distance vision using Snellen chart at 6 metres
- Near vision using standard reading chart



Visual acuity can alter reversibly with acute hyperglycaemia due to osmotic changes affecting the lens. Most patients with retinopathy do not have altered visual acuity, except after a vitreous haemorrhage or in some cases of maculopathy.

Lens opacification

- Look for the red reflex using the ophthalmoscope held 30 cm from the eye

Fundal examination

- Either use a three-field retinal camera or dilate pupils with a mydriatic (e.g. tropicamide) and examine with ophthalmoscope in a darkened room
- Note features of diabetic retinopathy (p. 828), including photocoagulation scars from previous laser treatment

Background retinopathy.

Proliferative retinopathy.

1 Examination of the hands

Several abnormalities are more common in diabetes:

- Limited joint mobility ('cheiroarthropathy') causes painless stiffness. The inability to extend (to 180°) the metacarpophalangeal or interphalangeal joints of at least one finger bilaterally can be demonstrated in the 'prayer sign'
- Dupuytren's contracture (p. 1134) causes nodules or thickening of the skin and knuckle pads
- Carpal tunnel syndrome (p. 1224) presents with wrist pain radiating into the hand
- Trigger finger (flexor tenosynovitis)
- Muscle-wasting/sensory changes may be present in peripheral sensorimotor neuropathy, although this is more common in the lower limbs

8 Insulin injection sites

Main areas used

- Anterior abdominal wall
- Upper thighs/buttocks
- Upper outer arms

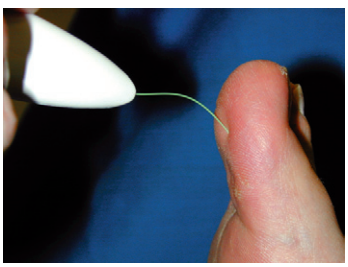
Inspection

- Bruising
- Subcutaneous fat deposition (lipohypertrophy)
- Subcutaneous fat loss (lipoatrophy; associated with injection of unpurified animal insulins – now rare)
- Erythema, infection (rare)

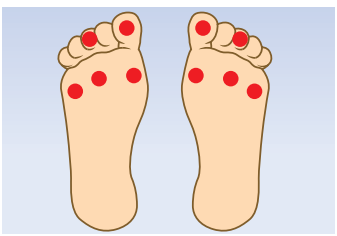
Lipohypertrophy of the upper arm.

11 Examination of the feet

Inspection



- Look for evidence of callus formation on weight-bearing areas, clawing of the toes (in neuropathy), loss of the plantar arch, discoloration of the skin (ischaemia), localised infection and ulcers
- Deformity may be present, especially in Charcot neuroarthropathy
- Fungal infection may affect skin between toes, and nails



Circulation

- Peripheral pulses, skin temperature and capillary refill may be abnormal

Sensation

- Abnormal in stocking distribution in typical peripheral sensorimotor neuropathy
- Testing light touch with monofilaments is sufficient for risk assessment; test other sensation modalities (vibration, pain, proprioception) only when neuropathy is being evaluated

Monofilaments. The monofilament is applied gently until slightly deformed at 5 points on each foot. Callus should be avoided as sensation is reduced. If the patient feels fewer than 8 out of 10 touches, the risk of foot ulceration is increased 5–10-fold.

Reflexes

- Loss of ankle reflexes in typical sensorimotor neuropathy
- Test plantar and ankle reflexes

Diabetes mellitus is a clinical syndrome characterised by an increase in plasma blood glucose (hyperglycaemia). Diabetes has many causes (see Box 21.5, p. 807) but is most commonly due to type 1 or type 2 diabetes. Type 1 diabetes is caused by autoimmune destruction of insulin-producing cells (β cells) in the pancreas, resulting in absolute insulin deficiency, whereas type 2 diabetes is characterised by resistance to the action of insulin and an inability to produce sufficient insulin to overcome this 'insulin resistance'. Hyperglycaemia results in both acute and long-term problems. Acutely, high glucose and lack of insulin can result in marked symptoms, metabolic decompensation and hospitalisation. Chronic hyperglycaemia is responsible for diabetes-specific 'microvascular' complications affecting the eyes (retinopathy), kidneys (nephropathy) and feet (neuropathy).

There is a continuous distribution of blood glucose in the population, with no clear division between people with normal and abnormal values. The diagnostic criteria for diabetes (a fasting plasma glucose ≥ 7.0 mmol/L (126 mg/dL) or glucose 2 hours after an oral glucose challenge ≥ 11.1 mmol/L (200 mg/dL); see p. 807) have been selected to identify those who have a degree of hyperglycaemia which, if untreated, carries a significant risk of microvascular disease, and in particular diabetic retinopathy. Less severe hyperglycaemia is called 'impaired glucose tolerance'. This is not associated with a substantial risk of microvascular disease, but is connected with an increased risk of large vessel disease (e.g. atheroma leading to myocardial infarction) and with a greater risk of developing diabetes in future.

The incidence of diabetes is rising. Globally, it is estimated that 366 million people had diabetes in 2011 (approximately 8.3% of the world population, or 3 new cases every 10 seconds), and this figure is expected to reach 552 million by 2030. This global pandemic principally involves type 2 diabetes, the prevalence of which varies considerably around the world (Fig. 21.1), being associated with differences in genetic as well as environmental factors such as greater longevity, obesity, unsatisfactory diet, sedentary lifestyle, increasing urbanisation and economic development. A pronounced rise in the prevalence of type 2 diabetes occurs in migrant populations to industrialised countries, as in Asian and Afro-Caribbean immigrants to the UK or USA. Type 2 diabetes is now being observed in children and adolescents, particularly in some ethnic groups, such as Hispanics and Afro-Americans.

The incidence of type 1 diabetes is also increasing, such that between 1960 and 1996, 3% more children were diagnosed worldwide each year. Type 1 diabetes is generally more common in countries closer to the polar regions. Finland, for instance, has the highest rate of type 1 diagnosis per year at around 40 per 100 000 of the population, whereas in China the incidence is only 0.1 per 100 000 of the population. Type 1 diabetes is most common in Caucasians and more people are diagnosed in the winter months.

Diabetes is a major burden upon health-care facilities in all countries. Globally, diabetes caused 4.6 million deaths in 2011, and health-care expenditure attributed to diabetes was estimated to be at least US$465 billion, or 11% of total health-care expenditure.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Normal glucose and fat metabolism

Blood glucose is tightly regulated and maintained within a narrow range. This is essential for ensuring a continuous supply of glucose to the central nervous system. The brain has little capacity to store energy in the form of glycogen or triglyceride and the blood–brain barrier is largely impermeable to fatty acids, so the brain depends on the liver for a constant supply of glucose for oxidation and hence generation of adenosine triphosphate (ATP). Glucose homeostasis is achieved through the coordinated actions of multiple organs, but mainly reflects a balance between the entry of glucose into the circulation from the liver, supplemented by intestinal

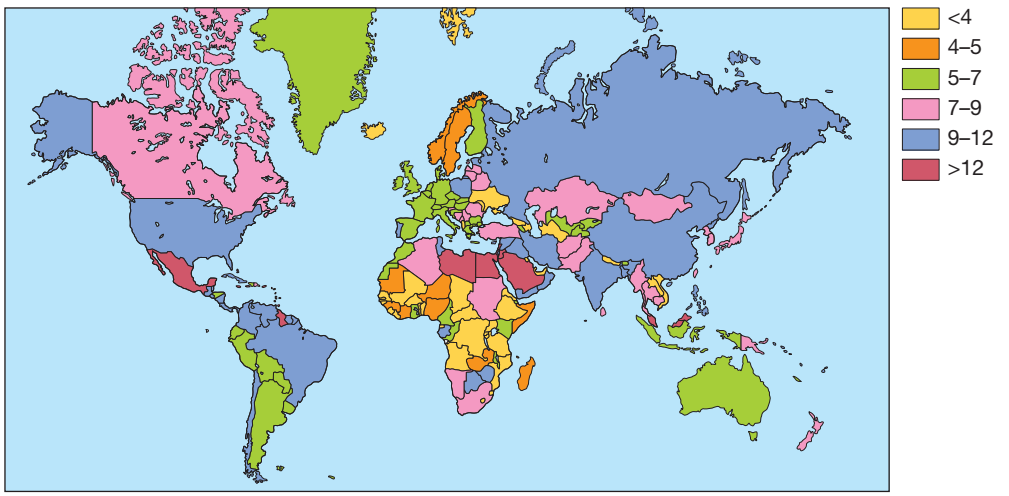


Fig. 21.1 Prevalence (%) of diabetes in those aged 20–79 years, 2011, based on estimates from the International Diabetes Federation.

absorption of glucose after meals, and the uptake of glucose by peripheral tissues, particularly skeletal muscle and brain.

After ingestion of a meal containing carbohydrate, normal blood glucose levels are maintained by:

- suppression of hepatic glucose production
- stimulation of hepatic glucose uptake
- stimulation of glucose uptake by peripheral tissues (Fig. 21.2).

Insulin, the primary regulator of glucose metabolism and storage (Box 21.1), is secreted from pancreatic β cells into the portal circulation in response to a rise in blood glucose (Fig. 21.3). A number of other factors released from the gut following food intake can augment insulin release, including amino acids and hormones such as glucagon-like peptide 1 (GLP-1) and gastrointestinal peptide (GIP). As a result, insulin release is greater when glucose is administered by mouth than when the same rise in plasma glucose is achieved by intravenous glucose infusion, a phenomenon termed the 'incretin' effect (see Fig. 21.3). The post-prandial rise in portal vein insulin and glucose, together with a fall in portal

Protein synthesis	

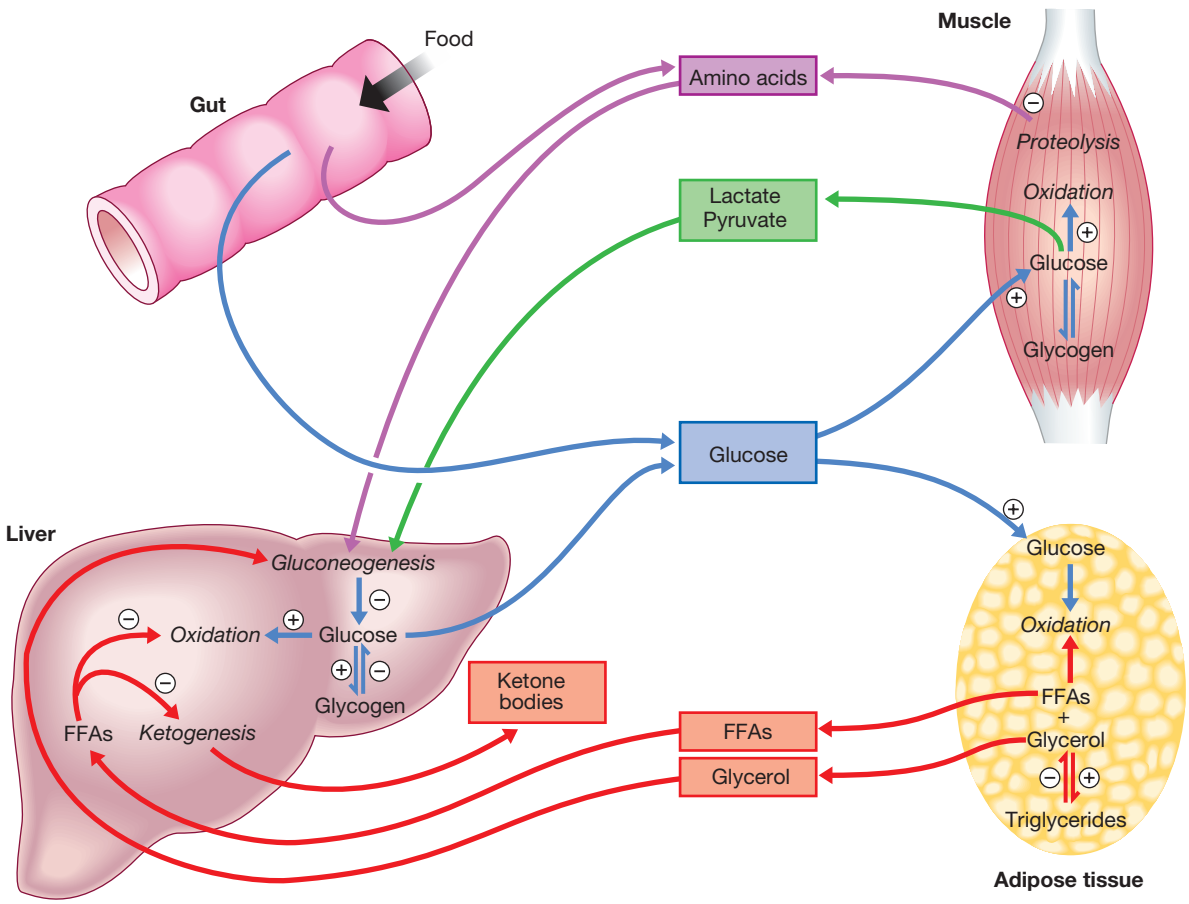

Fig. 21.2 Major metabolic pathways of fuel metabolism and the actions of insulin. ⊕ indicates stimulation and ⊖ indicates suppression by insulin. In response to a rise in blood glucose, e.g. after a meal, insulin is released, suppressing gluconeogenesis and promoting glycogen synthesis and storage. Insulin promotes the peripheral uptake of glucose, particularly in skeletal muscle, and encourages storage (as muscle glycogen). It also promotes protein synthesis and lipogenesis, and suppresses lipolysis. The release of intermediate metabolites, including amino acids (glutamine, alanine), 3-carbon intermediates in oxidation (lactate, pyruvate) and free fatty acids (FFAs), is controlled by insulin. In the absence of insulin, e.g. during fasting, these processes are reversed and favour gluconeogenesis in liver from glycogen, glycerol, amino acids and other 3-carbon precursors.

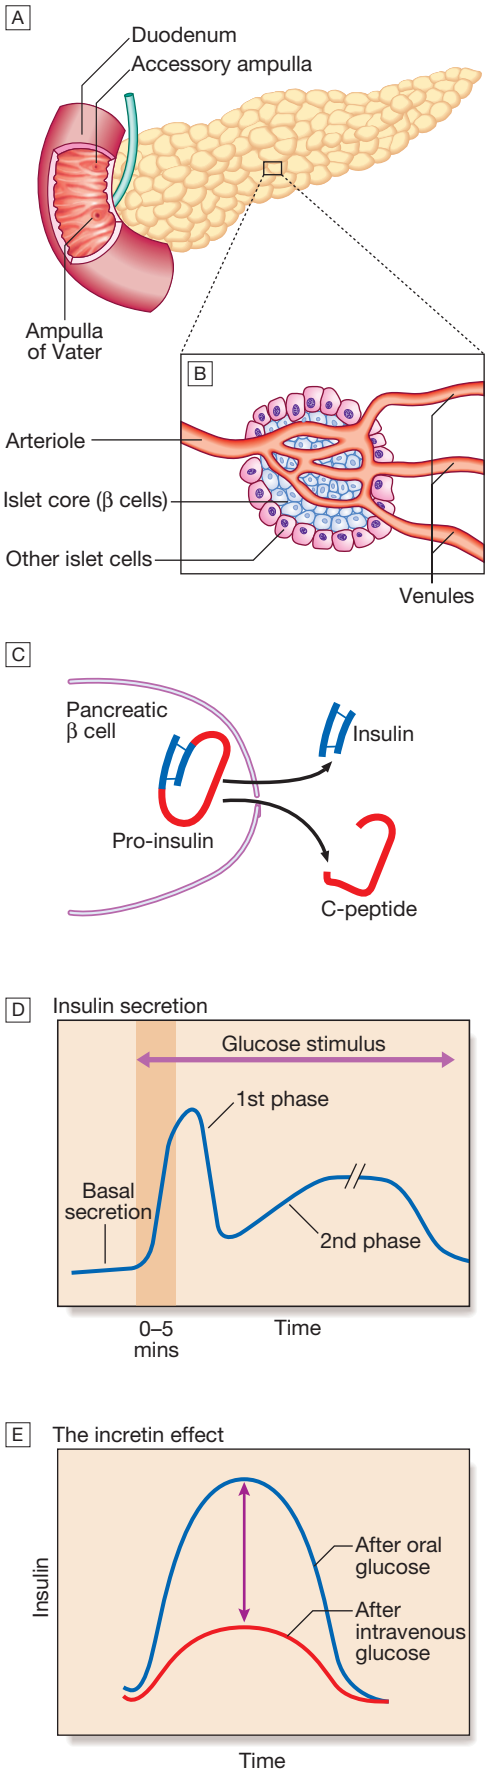

Fig. 21.3 Pancreatic structure and endocrine function. A The normal adult pancreas contains about 1 million islets, which are scattered throughout the exocrine parenchyma. Histology is shown in Figure 21.4. B The core of each islet consists of β cells that produce insulin, and is surrounded by a cortex of endocrine cells that produce other hormones, including glucagon (α cells), somatostatin (δ cells) and pancreatic polypeptide (PP cells). C Pro-insulin in the pancreatic β cell is cleaved to release insulin and equimolar amounts of inert C-peptide (connecting peptide). Measurement of C-peptide can be used to assess endogenous insulin secretory capacity. D An acute first phase of insulin secretion occurs in response to an elevated blood glucose, followed by a sustained second phase. E The incretin effect describes the observation that insulin secretion is greater when glucose is given by mouth than when glucose is administered intravenously to achieve the same rise in blood glucose concentrations. The additional stimulus to insulin secretion is mediated by release of peptides from the gut and these actions are exploited in incretin-based therapies (p. 823).

glucagon concentrations, suppresses hepatic glucose production and results in net hepatic glucose uptake. Depending on the size of the carbohydrate load, around one-quarter to one-third of ingested glucose is taken up in the liver. In addition, insulin stimulates glucose uptake in skeletal muscle and fat, mediated by the glucose transporter, GLUT 4.

When intestinal glucose absorption declines between meals, portal vein insulin and glucose concentrations fall while glucagon levels rise. This leads to increased hepatic glucose output via gluconeogenesis and glycogen breakdown. The liver now resumes net glucose production and glucose homeostasis is maintained. The main substrates for gluconeogenesis are glycerol and amino acids, as shown in Figure 21.2.

Adipocytes (and the liver) synthesise triglyceride from non-esterified ('free') fatty acids (FFAs) and glycerol. Insulin is the major regulator not only of glucose metabolism but also of fatty acid metabolism. High insulin levels after meals promote triglyceride accumulation. In contrast, in the fasting state, low insulin levels permit lipolysis and the release into the circulation of FFAs (and glycerol), which can be oxidised by many tissues. Their partial oxidation in the liver provides energy to drive gluconeogenesis and also produces ketone bodies (acetoacetate, which can be reduced to 3-hydroxybutyrate or decarboxylated to acetone), which are generated in hepatocyte mitochondria. Ketone bodies are organic acids which, when formed in small amounts, are oxidised and utilised as metabolic fuel. However, the rate of utilisation of ketone bodies by peripheral tissues is limited, and when the rate of production by the liver exceeds their removal, hyperketonaemia results. This occurs physiologically during starvation, when low insulin levels and high catecholamine levels increase lipolysis and delivery of FFAs to the liver.

Aetiology and pathogenesis of diabetes

In both of the common types of diabetes, environmental factors interact with genetic susceptibility to determine which people develop the clinical syndrome, and the

timing of its onset. However, the underlying genes, precipitating environmental factors and pathophysiology differ substantially between type 1 and type 2 diabetes. Type 1 diabetes was previously termed 'insulin-dependent diabetes mellitus' (IDDM) and is invariably associated with profound insulin deficiency requiring replacement therapy. Type 2 diabetes was previously termed 'non-insulin-dependent diabetes mellitus' (NIDDM) because patients retain the capacity to secrete some insulin but exhibit impaired sensitivity to insulin (insulin resistance) and initially can usually be treated without insulin replacement therapy. However, 20% or more of patients with type 2 diabetes will ultimately develop profound insulin deficiency requiring replacement therapy, so that IDDM and NIDDM were misnomers.

Type 1 diabetes

Pathology

Type 1 diabetes is a T cell-mediated autoimmune disease (p. 86) involving destruction of the insulin-secreting β cells in the pancreatic islets. Progressive loss of β cell function takes place over a prolonged period (months to years), but marked hyperglycaemia, accompanied by the classical symptoms of diabetes, occurs only when 80–90% of the functional capacity of β cells has been lost.

The pathology in the pre-diabetic pancreas is characterised by 'insulitis' (Fig. 21.4), with infiltration of the islets by mononuclear cells containing activated macrophages, helper cytotoxic and suppressor T lymphocytes, natural killer cells and B lymphocytes. Initially, these lesions are patchy and, until a very late stage, lobules containing heavily infiltrated islets are seen adjacent to unaffected lobules. The destructive process is β cell-specific, the glucagon and other hormone-secreting cells in the islet remaining intact.

Islet cell antibodies are present before the clinical presentation of type 1 diabetes, and their detection can be useful in confirming a diagnosis of type 1 diabetes, but they are poorly predictive of disease progression and disappear over time (see Fig. 21.4). Type 1 diabetes is associated with other autoimmune disorders (Ch. 4), including thyroid disease (p. 738), coeliac disease (p. 880), Addison's disease (p. 777), pernicious anaemia (p. 1025) and vitiligo (p. 1295).

Genetic predisposition

Genetic factors account for about one-third of the susceptibility to type 1 diabetes, the inheritance of which is polygenic (Box 21.2). Over 20 different regions of the human genome show some linkage with type 1 diabetes but most interest has focused on the human leucocyte antigen (HLA) region within the major histocompatibility complex on the short arm of chromosome 6; this locus is designated IDDM 1. The HLA haplotypes *DR3* and/or *DR4* are associated with increased susceptibility to type 1 diabetes in Caucasians and are in 'linkage disequilibrium', i.e. they tend to be transmitted together, with the neighbouring alleles of the *HLA-DQA1* and *DQB1* genes. The latter may be the main determinants of genetic susceptibility, since these HLA class II genes code for proteins on the surface of cells which present foreign and self antigens to T lymphocytes (p. 87). Candidate gene and genome-wide association studies have also implicated other genes in type 1 diabetes, e.g. *CD25*, *PTPN22*, *IL2RA* and *IL-10*, which are involved in immune recognition of pancreatic islet antigens, T-cell development and immune regulation. The genes associated with type 1 diabetes overlap with those for other

21.2 Risk of type 1 diabetes among first-degree relatives of patients with type 1 diabetes

Relative with type 1 diabetes	% overall risk
Identical twin	35
Non-identical twin	20
HLA-identical sibling	16
Non-HLA-identical sibling	3
Father	9
Mother	3
Both parents	Up to 30

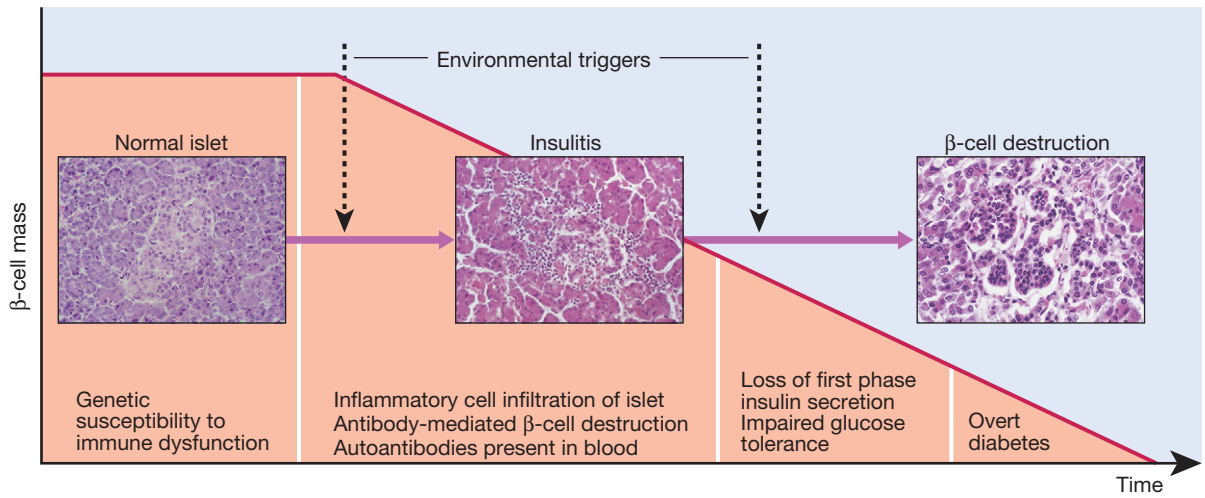

Fig. 21.4 Pathogenesis of type 1 diabetes. Proposed sequence of events in the development of type 1 diabetes. Environmental triggers are described in the text.

autoimmune disorders, such as coeliac disease and thyroid disease, consistent with clustering of these conditions in individuals or families.

Environmental predisposition

Although genetic susceptibility appears to be a prerequisite for type 1 diabetes, the concordance rate between monozygotic twins is less than 40% (see Box 21.2), and wide geographic and seasonal variations in incidence suggest that environmental factors have an important role in precipitating disease.

Although hypotheses abound, the nature of these environmental factors is uncertain. They may trigger type 1 diabetes through direct toxicity to β cells or by stimulating an autoimmune reaction directed against β cells. Potential candidates fall into three main categories: viruses, specific drugs or chemicals, and dietary constituents. Viruses implicated in the aetiology of type 1 diabetes include mumps, Coxsackie B4, retroviruses, rubella (in utero), cytomegalovirus and Epstein–Barr virus. Various dietary nitrosamines (found in smoked and cured meats) and coffee have been proposed as potentially diabetogenic toxins. Bovine serum albumin (BSA), a major constituent of cow's milk, has been implicated, since children who are given cow's milk early in infancy are more likely to develop type 1 diabetes than those who are breastfed. BSA may cross the neonatal gut and raise antibodies which cross-react with a heat-shock protein expressed by β cells. It has also been proposed that reduced exposure to microorganisms in early childhood limits maturation of the immune system and increases susceptibility to autoimmune disease (the 'hygiene hypothesis').

Metabolic disturbances in type 1 diabetes

Patients with type 1 diabetes present when progressive β-cell destruction has crossed a threshold at which adequate insulin secretion and normal blood glucose levels can no longer be sustained. Above a certain level, high glucose levels may be toxic to the remaining β cells, so that profound insulin deficiency rapidly ensues, causing the metabolic sequelae shown in Figure 21.5. Hyperglycaemia leads to glycosuria and dehydration, causing fatigue, polyuria, nocturia, thirst and polydipsia, susceptibility to urinary and genital tract infections, and later tachycardia and hypotension. Unrestrained lipolysis and proteolysis result in weight loss. Ketoacidosis occurs when generation of ketone bodies exceeds the capacity for their metabolism. Elevated blood H^+ ions drive K^+ out of the intracellular compartment, while secondary hyperaldosteronism encourages urinary loss of K^+. Thus patients usually present with a short history (typically a few weeks) of hyperglycaemic symptoms (thirst, polyuria, nocturia and fatigue), infections and weight loss, and may have developed ketoacidosis (p. 811).

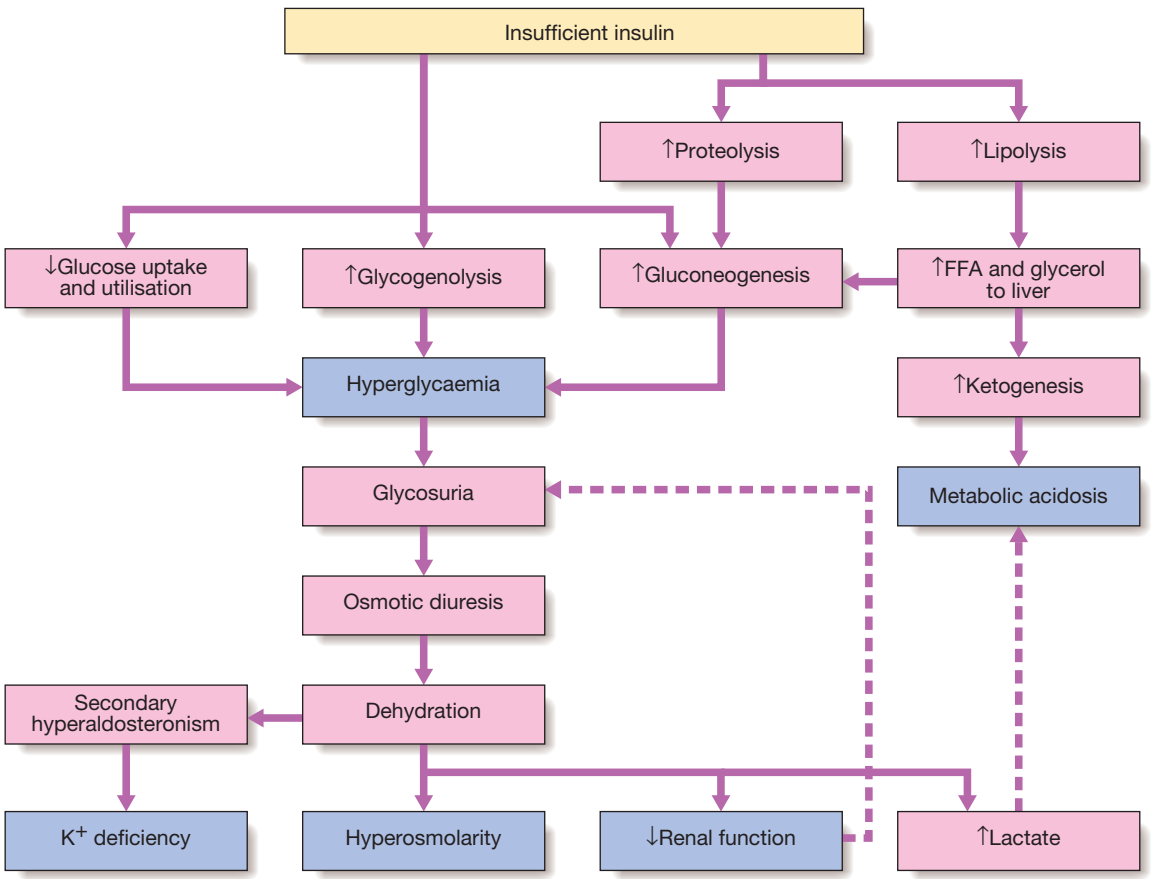

Fig. 21.5 Acute metabolic complications of insulin deficiency. (FFA = free fatty acids.)

Type 2 diabetes

Pathology

Type 2 diabetes is a diagnosis of exclusion, i.e. it is made when type 1 diabetes and other types of diabetes (see Box 21.5, p. 807) are ruled out, and is highly heterogeneous. The natural history of typical type 2 diabetes is shown in Figure 21.6. Initially, insulin resistance leads to elevated insulin secretion in order to maintain normal blood glucose levels. However, in susceptible individuals, the pancreatic β cells are unable to sustain the increased demand for insulin and a slowly progressive insulin deficiency develops. Some patients develop diabetes at a young age, usually driven by insulin resistance due to obesity and ethnicity; others, particularly the elderly, develop diabetes despite being non-obese and may have more pronounced β-cell failure. The key feature is a 'relative' insulin deficiency, such that there is insufficient insulin production to overcome the resistance to insulin action. This contrasts with type 1 diabetes, in which there is rapid loss of insulin production and an absolute deficiency, resulting in ketoacidosis and death if the insulin is not replaced.

Insulin resistance

Type 2 diabetes, or its antecedent, impaired glucose tolerance, is one of a cluster of conditions thought to be caused by resistance to insulin action. Thus, patients with type 2 diabetes often have associated disorders including hypertension, dyslipidaemia (characterised by elevated levels of small dense low-density lipoprotein (LDL) cholesterol and triglycerides, and a low level of high-density lipoprotein (HDL) cholesterol), non-alcoholic fatty liver (p. 959) and, in women, polycystic ovarian syndrome. This cluster has been termed the 'insulin resistance syndrome' or 'metabolic syndrome', and is much more common in patients who are obese.

The primary cause of insulin resistance remains unclear; it is likely that there are multiple defects in insulin signalling, affecting several tissues. One theory is centred around the adipocyte; this is particularly appealing, as obesity is a major cause of increased insulin resistance. Intra-abdominal 'central' adipose tissue is metabolically active, and releases large quantities of FFAs, which may induce insulin resistance because they compete with glucose as a fuel supply for oxidation in peripheral tissues such as muscle. In addition, adipose tissue releases a number of hormones (including a variety of peptides, called 'adipokines' because they are structurally similar to immunological 'cytokines') which act on specific receptors to influence sensitivity to insulin in other tissues. Because the venous drainage of visceral adipose tissue is into the portal vein, central obesity may have a particularly potent influence on insulin sensitivity in the liver, and thereby adversely affect gluconeogenesis and hepatic lipid metabolism.

Physical activity is another important determinant of insulin sensitivity. Inactivity is associated with down-regulation of insulin-sensitive kinases and may promote accumulation of FFAs within skeletal muscle. Sedentary people are therefore more insulin-resistant than active people with the same degree of obesity. Moreover, physical activity allows non-insulin-dependent glucose uptake into muscle, reducing the 'demand' on the pancreatic β cells to produce insulin.

Deposition of fat in the liver is a common association with central obesity and is exacerbated by insulin resistance and/or deficiency. Many patients with type 2 diabetes have evidence of fatty infiltration of the liver (non-alcoholic fatty liver disease (NAFLD)). This condition may improve with effective treatment of the diabetes and dyslipidaemia, but despite this, a few patients progress to non-alcoholic steatohepatitis (NASH, p. 959) and cirrhosis.

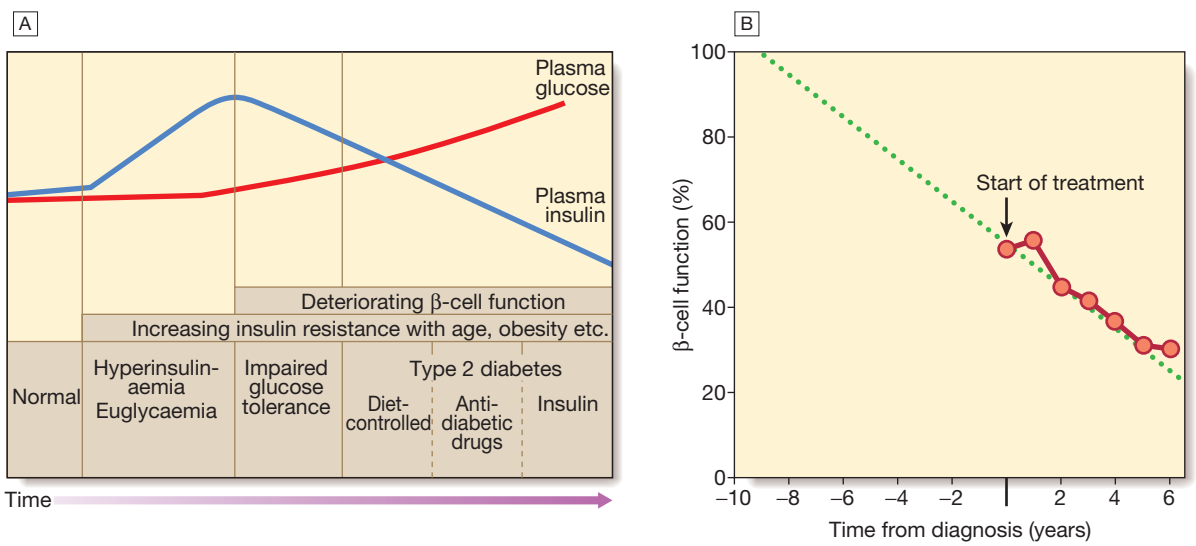

Fig. 21.6 Natural history of type 2 diabetes. A In the early stage of the disorder, the response to progressive insulin resistance is an increase in insulin secretion by the pancreatic cells, causing hyperinsulinaemia. Eventually, the β cells are unable to compensate adequately and blood glucose rises, producing hyperglycaemia. With further β-cell failure, glycaemic control deteriorates and treatment requirements escalate. B Progressive pancreatic β-cell failure in patients with type 2 diabetes in the United Kingdom Prospective Diabetes Study (UKPDS). Beta-cell function was estimated using the homeostasis model assessment (HOMA) and was already below 50% at the time of diagnosis. Thereafter, long-term incremental increases in fasting plasma glucose were accompanied by progressive β-cell dysfunction. If the slope of this progression is extrapolated, it appears that pancreatic dysfunction may have been developing for many years before diagnosis of diabetes. Part B adapted from Holman 1998 – see p. 836.

Pancreatic β-cell failure

In the early stages of type 2 diabetes, reduction in the total mass of pancreatic islet tissue is modest. At the time of diagnosis, around 50% of β-cell function has been lost and this declines progressively (see Fig. 21.6B). Some pathological changes are typical of type 2 diabetes, the most consistent of which is deposition of amyloid in the islets. In addition, elevated plasma glucose and FFAs exert toxic effects on pancreatic β cells to impair insulin secretion. However, while β-cell numbers are reduced, β-cell mass is unchanged and glucagon secretion is increased, which may contribute to hyperglycaemia.

Genetic predisposition

Genetic factors are important in type 2 diabetes, as shown by marked differences in susceptibility in different ethnic groups and by studies in monozygotic twins where concordance rates for type 2 diabetes approach 100%. However, many genes are involved and the chance of developing diabetes is also influenced very powerfully by environmental factors (Box 21.3). Genome-wide association studies have identified over 65 genes or gene regions that are associated with type 2 diabetes, each exerting a small effect. The largest effect is seen with variation in *TCF7L2*; the 10% of the population with two copies of the risk variant for this gene have a nearly twofold increase in risk of developing type 2 diabetes. Most of the genes known to contribute to risk of type 2 diabetes are involved in β-cell function or in regulation of cell cycling and turnover, suggesting that altered regulation of β-cell mass is a key factor.

21.3 Risk of developing type 2 diabetes for siblings of and individuals with type 2 diabetes

Age at onset of type 2 diabetes in proband	Age-corrected risk of type 2 diabetes for siblings (%)
25–44	53
45–54	37
55–64	38
65–80	31

Environmental and other risk factors

Diet and obesity

Epidemiological studies show that type 2 diabetes is associated with overeating, especially when combined with obesity and underactivity. Middle-aged people with diabetes eat significantly more and are fatter and less active than their non-diabetic siblings. The risk of developing type 2 diabetes increases tenfold in people with a body mass index (BMI) of more than 30 kg/m^2 (p. 115). However, although the majority of patients with type 2 diabetes are obese, only a minority of obese people develop diabetes, as the majority of obese patients are able to increase insulin secretion to compensate for the increased demand resulting from obesity and insulin resistance. Those who develop diabetes may have genetically impaired β-cell function, reduced β-cell mass, or a susceptibility of β cells to attack by toxic substances such as FFAs or inflammatory cytokines.

21.4 Diagnosis of diabetes mellitus in old age

- **Prevalence**: increases with age, affecting ~10% of people over 65 years. Half of these people are undiagnosed. Impaired β-cell function and exaggerated insulin resistance with ageing both contribute.
- **Glycosuria**: the renal threshold for glucose rises with age, so glycosuria may not develop until the blood glucose concentration is markedly raised.
- **Pancreatic carcinoma**: may present in old age with the development of diabetes, in association with weight loss and diminished appetite.

Age

Type 2 diabetes is more common in the middle-aged and elderly (Box 21.4). In the UK, it affects 10% of the population over 65, and over 70% of all cases of diabetes occur after the age of 50 years.

Metabolic disturbances in type 2 diabetes

Patients with type 2 diabetes have a slow onset of 'relative' insulin deficiency. Relatively small amounts of insulin are required to suppress lipolysis, and some glucose uptake is maintained in muscle, so that, in contrast with type 1 diabetes, lipolysis and proteolysis are not unrestrained and weight loss and ketoacidosis seldom occur. In type 2 diabetes, hyperglycaemia tends to develop slowly over months or years; because of this insidious onset many cases of type 2 diabetes are discovered coincidentally and a large number are undetected. At diagnosis, patients are often asymptomatic or give a long history (typically many months) of fatigue, with or without 'osmotic symptoms' (thirst and polyuria). In some patients with type 2 diabetes, presentation is late and pancreatic β-cell failure has reached an advanced stage of insulin deficiency (see type 1 diabetes, p. 803). These patients may present with weight loss but ketoacidosis is uncommon. However, in some ethnic groups, such as African Americans, half of those whose first presentation is with diabetic ketoacidosis have type 2 diabetes.

Intercurrent illness, e.g. with infections, increases the production of stress hormones which oppose insulin action, such as cortisol, growth hormone and catecholamines. This can precipitate an acute exacerbation of insulin resistance and insulin deficiency, and result in more severe hyperglycaemia and dehydration (see hyperglycaemic hyperosmolar state, p. 814).

Other forms of diabetes

Other causes of diabetes are shown in Box 21.5. In most cases, there is an obvious cause of destruction of pancreatic β cells. Some acquired disorders, notably other endocrine diseases such as acromegaly (p. 792) or Cushing's syndrome (p. 773), can precipitate type 2 diabetes in susceptible individuals.

A number of unusual genetic diseases are associated with diabetes. In rare families, diabetes is caused by single gene defects with autosomal dominant inheritance. These subtypes constitute less than 5% of all cases of diabetes and typically present as 'maturity-onset diabetes of the young' (MODY), i.e. non-insulin-requiring

21.5 Aetiological classification of diabetes mellitus

Type 1 diabetes
- Immune-mediated
- Idiopathic

Type 2 diabetes

Other specific types
- Genetic defects of β-cell function (see Box 21.6)
- Genetic defects of insulin action (e.g. leprechaunism, lipodystrophies)
- Pancreatic disease (e.g. pancreatitis, pancreatectomy, neoplastic disease, cystic fibrosis, haemochromatosis, fibrocalculous pancreatopathy)
- Excess endogenous production of hormonal antagonists to insulin, e.g.
  Growth hormone – acromegaly
  Glucocorticoids – Cushing's syndrome
  Glucagon – glucagonoma
  Catecholamines – phaeochromocytoma
  Thyroid hormones – thyrotoxicosis
- Drug-induced (e.g. corticosteroids, thiazide diuretics, phenytoin)
- Uncommon forms of immune-mediated diabetes (e.g. IPEX (immunodysregulation polyendocrinopathy X) syndrome)
- Associated with genetic syndromes (e.g. Down's syndrome; Klinefelter's syndrome; Turner's syndrome; DIDMOAD (Wolfram's syndrome) – diabetes insipidus, diabetes mellitus, optic atrophy, nerve deafness; Friedreich's ataxia; myotonic dystrophy)

Gestational diabetes

21.6 Monogenic diabetes mellitus: maturity-onset diabetes of the young (MODY)

Functional defect	Main type*	Gene mutated*
β-cell glucose sensing	MODY2	*GCK*
The set point for basal insulin release is altered, causing a high fasting glucose, but sufficient insulin is released after meals. As a result, the HbA_{1c} is often normal and microvascular complications are rare. Treatment is rarely required		
β-cell transcriptional regulation	MODY3 MODY5 MODY1	*HNF-1α* *HNF-1β* *HNF-4α*
Diabetes develops during adolescence/early adulthood and can be managed with diet and tablets for many years, but ultimately, insulin treatment is required. The HNF-1α and 4α forms respond particularly well to sulphonylurea drugs. All types are associated with microvascular complications. HNF-1β mutations also cause renal cysts and renal failure		

*Other gene mutations have been found in rare cases. For further information, see http://diabetesgenes.org.

diabetes presenting before the age of 25 years (Box 21.6). Very rarely, diabetes can develop at or soon after birth. This neonatal diabetes is usually genetic in origin, with 50% due to mutations in the K_{ATP} channel of the pancreatic β cell causing insulin deficiency and diabetic ketoacidosis. However, sulphonylurea drugs overcome the defect in potassium channel signalling, so that insulin therapy is not necessary in these cases.

INVESTIGATIONS

Urine testing

Glucose

Testing the urine for glucose with dipsticks is a common screening procedure for detecting diabetes. If possible, testing should be performed on urine passed 1–2 hours after a meal to maximise sensitivity. Glycosuria always warrants further assessment by blood testing (see below). The greatest disadvantage of urinary glucose measurement is the individual variation in renal threshold for glucose. The most frequent cause of glycosuria is a low renal threshold, which is common during pregnancy and in young people; the resulting 'renal glycosuria' is a benign condition unrelated to diabetes. Another disadvantage is that some drugs (such as β-lactam antibiotics, levodopa and salicylates) may interfere with urine glucose tests.

Ketones

Ketone bodies can be identified by the nitroprusside reaction, which measures acetoacetate, using either tablets or dipsticks. Ketonuria may be found in normal people who have been fasting or exercising strenuously for long periods, who have been vomiting repeatedly, or who have been eating a diet high in fat and low in carbohydrate. Ketonuria is therefore not pathognomonic of diabetes but, if associated with glycosuria, the diagnosis of diabetes is highly likely. In diabetic ketoacidosis (p. 811), ketones can also be detected in plasma using test sticks (see below).

Protein

Standard dipstick testing for albumin detects urinary albumin at concentrations above 300 mg/L, but smaller amounts (microalbuminuria, see Box 17.13, p. 476) can only be measured using specific albumin dipsticks or by quantitative biochemical laboratory measurement. Microalbuminuria or proteinuria, in the absence of urinary tract infection, is an important indicator of diabetic nephropathy and/or increased risk of macrovascular disease (p. 830).

Blood testing

Glucose

Laboratory glucose testing in blood relies upon an enzymatic reaction (glucose oxidase) and is cheap, usually automated and highly reliable. However, blood glucose levels depend on whether the patient has eaten recently, so it is important to consider the circumstances in which the blood sample was taken.

Blood glucose can also be measured with colorimetric or other testing sticks, which are often read with a portable electronic meter. These are used for capillary (fingerprick) testing to monitor diabetes treatment (p. 810). There is some debate as to whether self-monitoring in people with type 2 diabetes improves glycaemic control. Many countries now only offer self-monitoring to people with type 2 diabetes taking insulin therapy. To make the diagnosis of diabetes, the blood glucose concentration should be estimated using an accurate laboratory method rather than a portable technique.

Glucose concentrations are lower in venous than arterial or capillary (fingerprick) blood. Whole blood glucose concentrations are lower than plasma concentrations because red blood cells contain relatively little glucose. Venous plasma values are usually the most reliable for diagnostic purposes (Boxes 21.10 and 21.11).

Ketones

Blood ketone monitoring is increasingly available. Urinary ketone measurements described above are semi-quantitative, difficult to perform and retrospective (i.e. the urine has accumulated over several hours), and do not measure the major ketone in blood during diabetic ketoacidosis (DKA), beta-hydroxybutyrate (β-OHB). Whole blood ketone monitoring detects β-OHB and is useful in assisting with insulin adjustment during intercurrent illness or sustained hyperglycaemia to prevent or detect DKA. Blood ketone monitoring is also useful in monitoring resolution of DKA in hospitalised patients (Box 21.7).

21.7 Interpretation of capillary blood ketone measurements

Measurement*	Interpretation
< 0.6 mmol/L	Normal; no action required
0.6–1.5 mmol/L	Suggests metabolic control may be deteriorating; continue to monitor and seek medical advice if sustained/progressive
1.5–3.0 mmol/L	With high blood glucose (> 10 mmol/L), there is a high risk of diabetic ketoacidosis; seek medical advice
> 3.0 mmol/L	Severe ketosis; in the presence of high glucose (> 10 mmol/L) suggests presence of diabetic ketoacidosis; seek urgent medical help

*To convert to mg/dL, divide values by 0.098.

Glycated haemoglobin

Glycated haemoglobin provides an accurate and objective measure of glycaemic control integrated over a period of weeks to months.

In diabetes, the slow non-enzymatic covalent attachment of glucose to haemoglobin (glycation) increases the amount in the HbA_1 (HbA_{1c}) fraction relative to non-glycated adult haemoglobin (HbA_0). These fractions can be separated by chromatography; laboratories may report glycated haemoglobin as total glycated haemoglobin (GHb), HbA_1 or HbA_{1c}. In most countries, HbA_{1c} is the preferred measurement. The rate of formation of HbA_{1c} is directly proportional to the ambient blood glucose concentration; a rise of 1% in HbA_{1c} corresponds to an approximate average increase of 2 mmol/L (36 mg/dL) in blood glucose. Although HbA_{1c} concentration reflects the integrated blood glucose control over the lifespan of erythrocytes (120 days), HbA_{1c} is most sensitive to changes in glycaemic control occurring in the month before measurement.

Various assay methods are used to measure HbA_{1c}, but most laboratories have been reporting HbA_{1c} values (as %) aligned with the reference range that was used in the Diabetes Control and Complications Trial (DCCT).

21.8 Conversion between DCCT and IFCC units for HbA_{1c}

DCCT units (%)	IFCC units (mmol/mol)
4	20
5	31
6	42
7	53
8	64
9	75
10	86

$$\text{IFCC } HbA_{1c} \text{ (mmol/mol)} = [\text{DCCT } HbA_{1c}(\%) - 2.15] \times 10.929$$

(DCCT = Diabetes Control and Complications Trial; IFCC = International Federation of Clinical Chemistry and Laboratory Medicine

To allow worldwide comparisons of HbA_{1c} values, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has developed a standard method; IFCC-standardised HbA_{1c} values are reported in mmol/mol. In 2011, many countries adopted the IFCC reference method (Box 21.8).

HbA_{1c} estimates may be erroneously diminished in anaemia or during pregnancy, and may be difficult to interpret with some assay methods in patients who have uraemia or a haemoglobinopathy.

PRESENTING PROBLEMS IN DIABETES MELLITUS

Newly discovered hyperglycaemia

Hyperglycaemia is a very common biochemical abnormality. It is frequently detected on routine biochemical analysis of asymptomatic patients, following routine dipstick testing of urine showing glycosuria, or during severe illness ('stress hyperglycaemia'). Alternatively, hyperglycaemia may present with the symptoms described in Box 21.9. Occasionally, patients present as an emergency with acute metabolic decompensation (see below). The key goals are to establish whether the patient has diabetes, and if so, what type of diabetes it is and how it should be treated.

Establishing the diagnosis of diabetes

Glycaemia can be classified into three categories: normal, impaired (pre-diabetes) and diabetes (Boxes 21.10 and 21.11). The glucose cut-off that defines diabetes is based upon the level above which there is a significant risk of microvascular complications (retinopathy, nephropathy, neuropathy). People categorised as having pre-diabetes have blood glucose levels that carry a negligible risk of microvascular complications but are at increased risk of developing diabetes. Also, because there is a continuous risk of macrovascular disease (atheroma of large conduit blood vessels) with increasing glycaemia in the population, people with pre-diabetes have increased risk of cardiovascular disease (myocardial infarction, stroke and peripheral vascular disease).

When a person has symptoms of diabetes, the diagnosis can be confirmed with either a fasting glucose

≥ 7.0 mmol/L (126 mg/dL) or a random glucose ≥11.1 mmol/L (200 mg/dL) (see Box 21.10). Asymptomatic individuals should have a second confirmatory test. Diabetes should not be diagnosed by capillary blood glucose results. The World Health Organization (WHO) guidelines (2011) introduced the use of HbA_{1c} for diagnosis of diabetes, with an IFCC HbA_{1c} of more than 48 mmol/mol also being diagnostic.

Pre-diabetes can be diagnosed either as 'impaired fasting glucose' (IFG), based upon a fasting plasma glucose result, or 'impaired glucose tolerance' (IGT), based upon the fasting and 2-hour oral glucose tolerance test results (OGTT; see Box 21.11). Patients with pre-diabetes should be advised of their risk of progression to diabetes, given advice about lifestyle modification to reduce this risk (as for type 2 diabetes, p. 820), and be ensured of aggressive management of cardiovascular risk factors such as hypertension and dyslipidaemia.

In some people, an abnormal blood glucose result is observed under conditions which impose a burden on the pancreatic β cells, e.g. during pregnancy, infection, myocardial infarction or other severe stress, or during treatment with diabetogenic drugs such as corticosteroids. This 'stress hyperglycaemia' usually disappears after the acute illness has resolved. However, blood glucose should be remeasured and an OGTT will often show persistence of impaired glucose tolerance.

The diagnostic criteria recommended for diabetes in pregnancy are more stringent than those for non-pregnant subjects (see Box 21.23, p. 817). Pregnant women with abnormal glucose tolerance should be referred urgently to a specialist unit for full evaluation.

21.9 Symptoms of hyperglycaemia

- Thirst, dry mouth
- Polyuria
- Nocturia
- Tiredness, fatigue, lethargy
- Change in weight (usually weight loss)
- Blurring of vision
- Pruritus vulvae, balanitis (genital candidiasis)
- Nausea
- Headache
- Hyperphagia; predilection for sweet foods
- Mood change, irritability, difficulty in concentrating, apathy

21.10 Diagnosis of diabetes and pre-diabetes

Diabetes is confirmed by either:

- Plasma glucose in random sample or 2 hrs after a 75 g glucose load ≥ 11.1 (200 mg/dL) **or**
- Fasting plasma glucose ≥ 7.0 mmol/L (126 mg/dL)

In asymptomatic patients, two diagnostic tests are required to confirm diabetes.

'Pre-diabetes' is classified as:

- Impaired fasting glucose = fasting plasma glucose ≥ 6.0 (108 mg/dL) and < 7.0 mmol/L (126 mg/dL)
- Impaired glucose tolerance = fasting plasma glucose < 7.0 mmol/L (126 mg/dL) **and** 2-hr glucose after 75 g oral glucose drink 7.8–11.1 mmol/L (140–200 mg/dL)

When a diagnosis of diabetes is confirmed, other investigations should include plasma urea, creatinine and electrolytes, lipids, liver and thyroid function tests, and urine testing for ketones, protein or microalbuminuria.

Clinical assessment and classification

Hyperglycaemia causes a wide variety of symptoms (see Box 21.9). The classical clinical features of the two main types of diabetes are compared in Box 21.12. Symptoms of thirst, polyuria, nocturia and rapid weight loss are prominent in type 1 diabetes, but are often absent in patients with type 2 diabetes, many of whom are asymptomatic or have non-specific complaints such as chronic fatigue and malaise. Uncontrolled diabetes is associated

21.11 How to perform an oral glucose tolerance test (OGTT)

Which patients to test

- Fasting plasma glucose 6.1–7.0 mmol/L (110–126 mg/dL)
- Uncertainty about the diagnosis of diabetes

Preparation before the test

- Unrestricted carbohydrate diet for 3 days
- Fasted overnight for at least 8 hrs
- Rest for 30 mins
- Remain seated for the duration of the test, with no smoking

Sampling

- Measure plasma glucose before and 2 hrs after a 75 g oral glucose drink

Interpretation (venous plasma glucose)

	Fasting	2 hrs after glucose load
Impaired fasting glucose	6.1–6.9 mmol/L (110–125 mg/dL)	< 7.8 mmol/L (< 140 mg/dL)
Impaired glucose tolerance	< 7.0 mmol/L (< 126 mg/dL)	7.8–11.0 mmol/L (140–199 mg/dL)
Diabetes	≥ 7.0 mmol/L (> 126 mg/dL)	≥ 11.1 mmol/L (> 200 mg/dL)

21.12 Classical features of type 1 and type 2 diabetes

	Type 1	Type 2
Typical age at onset	< 40 yrs	> 50 yrs
Duration of symptoms	Weeks	Months to years
Body weight	Normal or low	Obese
Ketonuria	Yes	No
Rapid death without treatment with insulin	Yes	No
Autoantibodies	Positive in 80–90%	Negative
Diabetic complications at diagnosis	No	25%
Family history of diabetes	Uncommon	Common
Other autoimmune disease	Common	Uncommon

with an increased susceptibility to infection and patients may present with skin sepsis (boils) or genital candidiasis, and complain of pruritus vulvae or balanitis.

While the distinction between type 1 and type 2 diabetes is usually obvious, overlap occurs, particularly in age at onset, duration of symptoms and family history. There are many patients in whom the type of diabetes is not immediately apparent. For example, patients with type 2 diabetes may present with marked and rapid weight loss and even diabetic ketoacidosis, and type 2 diabetes is increasingly diagnosed in children and young adults. Type 1 diabetes can occur at any age, not just in younger people, and may develop more insidiously; the presence of pancreatic autoantibodies confirms the diagnosis of slow-onset type 1 diabetes, termed latent autoimmune diabetes of adults (LADA). Pancreatic autoantibodies are detectable at high titre in 80–90% of patients with type 1 diabetes, so a negative result should prompt consideration of other aetiologies. Other causes of diabetes (see Box 21.5, p. 807), such as MODY, should not be forgotten, particularly in those presenting in childhood or as young adults. A history of pancreatic disease, particularly in patients with a history of alcohol excess, makes insulin deficiency more likely. Sometimes the definitive classification of the type of diabetes is only made later, once the natural history or responsiveness to different therapies becomes apparent.

Physical signs in patients with type 2 diabetes at diagnosis depend on the mode of presentation. In Western populations, more than 80% are overweight, and the obesity is often central (truncal or abdominal). Obesity is much less evident in Asians. Hypertension is present in at least 50% of patients with type 2 diabetes. Although dyslipidaemia is also common, skin lesions such as xanthelasma and eruptive xanthomas are rare. An increasing number of patients now present with NAFLD, usually identified by their elevated blood transaminase values, but they may also have non-tender hepatomegaly.

Management

The aims of management are to improve symptoms of hyperglycaemia and to minimise the risks of long-term microvascular and macrovascular complications. Treatment methods for diabetes include dietary/lifestyle modification, oral anti-diabetic drugs and injected therapies. These are described in detail on page 821. In patients with suspected type 1 diabetes, urgent treatment with insulin is required and prompt referral to a specialist is usually needed. In patients with suspected type 2 diabetes, first-line therapy involves advice about dietary and lifestyle modification. Oral anti-diabetic drugs are usually added in those who do not achieve glycaemic targets as a result, or who have severe symptomatic hyperglycaemia at diagnosis and a high HbA_{1c}. However, the guidelines in some countries are to introduce medication immediately upon diagnosis of diabetes without waiting to assess the impact of diet and lifestyle changes.

In parallel with treatment of hyperglycaemia, other risk factors for complications of diabetes need to be addressed, including treatment of hypertension (p. 609) and dyslipidaemia (p. 456), and advice on smoking cessation (p. 100).

Educating patients

It is essential that people with diabetes understand their disorder and learn to handle all aspects of their management as comprehensively and quickly as possible. Ideally, this can be achieved by a multidisciplinary team (doctor, dietitian, specialist nurse and podiatrist) in the outpatient setting. For those with newly diagnosed type 2 diabetes, structured education can be given in groups by trained educators. Those requiring insulin need to learn how to measure doses of insulin accurately with an insulin syringe or pen device, how to inject, and how to adjust the dose on the basis of blood glucose values and in relation to factors such as exercise, illness and episodic hypoglycaemia. They must therefore acquire a working knowledge of diabetes, be familiar with the symptoms of hypoglycaemia (see Box 21.19, p. 815), and have ready access to medical advice when the need arises. Information should be provided about driving (national statutory regulations and practical safety measures, Box 21.13). Providing this education is time-consuming but essential if patients are to undertake normal activities safely while maintaining good control.

Self-assessment of glycaemic control

In people with type 2 diabetes there is not usually a need for regular self-assessment of blood glucose, unless the patient is treated with insulin, or at risk of hypoglycaemia while taking sulphonylureas. Blood glucose testing can be used for self-education (i.e. demonstrating how different food and exercise regimes affect blood glucose), and may be useful in acute illness. Blood glucose targets vary according to individual circumstances, but, in general, pre-meal values between 4 and 7 mmol/L (72 and 126 mg/dL) and 2-hour post-meal values between 4 and 8 mmol/L represent optimal control.

Insulin-treated patients should be taught how to monitor their own blood glucose using capillary blood glucose meters. Immediate knowledge of blood glucose levels can be used by patients to guide their insulin dosing and to manage exercise and illness. This can be

21.13 Diabetes and driving

- Licensing regulations vary considerably between countries. In the UK, diabetes requiring insulin therapy or any complication that could affect driving should be declared to the Driver and Vehicle Licensing Agency; ordinary driving licences are 'period-restricted' for insulin-treated drivers; and vocational licences (large goods vehicles and public service vehicles) may be granted but require very strict criteria to be met
- The main risk to driving performance is hypoglycaemia. Visual impairment and other complications may occasionally cause problems
- Insulin-treated diabetic drivers should:
  - Check blood glucose before driving and 2-hourly during long journeys
  - Keep an accessible supply of fast-acting carbohydrate in the vehicle
  - Take regular snacks or meals during long journeys
  - Stop driving if hypoglycaemia develops
  - Refrain from driving until at least 45 mins after treatment of hypoglycaemia (delayed recovery of cognitive function)
  - Carry identification in case of injury

supplemented with blood testing for ketones when blood glucose is high and/or during intercurrent illness.

Urine testing for glucose is not recommended because variability in renal threshold means that some patients with inadequate glycaemic control will not find glucose in their urine.

Long-term supervision of diabetes

Diabetes is a complex disorder which progresses in severity with time, so people with diabetes should be seen at regular intervals for the remainder of their lives, either at a specialist diabetic clinic or in primary care where facilities are available and staff are trained in diabetes care. A checklist for follow-up visits is given in Box 21.14. The frequency of visits is variable, ranging from weekly during pregnancy to annually in the case of patients with well-controlled type 2 diabetes.

Therapeutic goals

The target HbA_{1c} depends on the individual patient. Early on in diabetes (i.e. patients managed by diet or one or two oral agents), a target of 48 mmol/mol (6.5%) or less may be appropriate. However, a higher target of 58 mmol/mol (7.5%) may be more appropriate in older patients with pre-existing cardiovascular disease, or those treated with insulin and therefore at risk of hypoglycaemia. In general, the benefits of lower target HbA_{1c} (primarily a lower risk of microvascular disease) need to be weighed against any increased risks (primarily hypoglycaemia in insulin-treated patients). Type 2 diabetes is usually a progressive condition (Fig. 21.7), unless there are major diet and lifestyle changes, so that there is usually a need to increase diabetes medication over time to achieve the individualised target HbA_{1c}.

In people with type 2 diabetes, treatment of coexisting hypertension and dyslipidaemia is usually required. This can be decided by assessing absolute risk of a cardiovascular disease event (p. 581) and adjusting targets to individual circumstances. The target for blood pressure is usually below 140/80 mmHg, although some guidelines suggest 130/80 mmHg. For lipid-lowering, there is a reduction in cardiovascular risk even with normal cholesterol levels, but statin therapy is usually recommended when the 10-year cardiovascular event risk is at least 20%. As a general rule, this means that anyone with type 2 diabetes who is over the age of 40 years should receive a statin, irrespective of baseline cholesterol levels. Some guidelines do not suggest a target level once the patient is started on a statin but others suggest a total cholesterol of less than 4.0 mmol/L (~150 mg/dL) and an LDL cholesterol of less than 2.0 mmol/L (~75 mg/dL). Similar targets are appropriate in type 1 diabetes, although there is a shortage of data from clinical trials in this group.

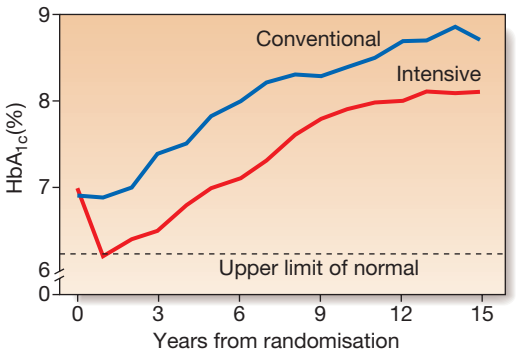

Fig. 21.7 Time course of changes in HbA_{1c} during the United Kingdom Prospective Diabetes Study (UKPDS). In the UKPDS there was loss of glycaemic control with time in patients receiving monotherapy, independently of their randomisation to conventional or intensive glycaemic control, consistent with progressive decline in β-cell function (see Fig. 21.6, p. 805). Adapted from UKPDS 1998 – see p. 836.

21.14 How to review a patient in the diabetes clinic

Lifestyle issues
- General health
- Work or school
- Smoking
- Alcohol intake
- Stress or depression
- Sexual health
- Exercise

Body weight and BMI

Blood pressure
- Individualised target of 130–140/70–80 mmHg, depending on risk factors and presence of nephropathy

Urinalysis
- Analyse fasting specimen for glucose, ketones, albumin (both macro- and micro-albuminuria)

Biochemistry
- Renal, liver and thyroid function
- Lipid profile and estimated 10-yr cardiovascular risk to guide need for lipid-lowering therapy (p. 581)

Glycaemic control
- Glycated haemoglobin (HbA_{1c}); individualised target between 48 and 58 mmol/mol (6.5 and 7.5%)
- Inspection of home blood glucose monitoring record (if carried out by patient)

Hypoglycaemic episodes
- Number and cause of severe (requiring assistance for treatment) events and frequency of mild (self-treated) episodes and biochemical hypoglycaemia
- Awareness of hypoglycaemia
- Driving advice

Assessment of injection sites if insulin-treated

Eye examination
- Visual acuities (near and distance)
- Ophthalmoscopy (with pupils dilated) or digital photography

Examination of lower limbs and feet
- Assessment of foot risk (p. 799)

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is a medical emergency and remains a serious cause of morbidity, principally in people with type 1 diabetes. Mortality is low in the UK (approximately 2%) but remains high in developing countries and among non-hospitalised patients. Mortality in DKA is most commonly caused in children and adolescents by cerebral oedema and in adults by hypokalaemia, acute respiratory distress syndrome and

comorbid conditions such as acute myocardial infarction, sepsis or pneumonia.

DKA is characteristic of type 1 diabetes (see Box 21.12) and is often the presenting problem in newly diagnosed patients. However, an increasing number of patients presenting with DKA have underlying type 2 diabetes. This appears to be particularly prevalent in African-American and Hispanic populations. In established type 1 diabetes, DKA may be precipitated by an intercurrent illness because of failure to increase insulin dose appropriately to compensate for the stress response. Sometimes, there is no evidence of a precipitating infection and DKA develops because of errors in self-management. In young patients with recurrent episodes of DKA, up to 20% may have psychological problems complicated by eating disorders.

Pathogenesis

A clear understanding of the biochemical basis and pathophysiology of DKA is essential for its efficient treatment (see Fig. 21.5, p. 804). The cardinal biochemical features are:

- hyperketonaemia (≥ 3 mmol/L) and ketonuria (more than 2+ on standard urine sticks)
- hyperglycaemia (blood glucose ≥ 11 mmol/L (~200 mg/dL))
- metabolic acidosis (venous bicarbonate < 15 mmol/L and/or venous pH < 7.3).

The hyperglycaemia causes a profound osmotic diuresis leading to dehydration and electrolyte loss, particularly of sodium and potassium. Potassium loss is exacerbated by secondary hyperaldosteronism as a result of reduced renal perfusion. Ketosis results from insulin deficiency, exacerbated by elevated catecholamines and other stress hormones, leading to unrestrained lipolysis and supply of FFAs for hepatic ketogenesis. When this exceeds the capacity to metabolise acidic ketones, these accumulate in blood. The resulting metabolic acidosis forces hydrogen ions into cells, displacing potassium ions.

The average loss of fluid and electrolytes in moderately severe DKA in an adult is shown in Box 21.15. About half the deficit of total body water is derived from the intracellular compartment and occurs comparatively early in the development of acidosis with relatively few clinical features; the remainder represents loss of extracellular fluid sustained largely in the later stages, when marked contraction of extracellular fluid volume occurs, with haemoconcentration, a decreased blood volume, and finally a fall in blood pressure with associated renal ischaemia and oliguria.

Every patient in DKA is potassium-depleted, but the plasma concentration of potassium gives very little indication of the total body deficit. Plasma potassium may even be raised initially due to disproportionate loss of water, catabolism of protein and glycogen, and displacement of potassium from the intracellular compartment by H^+ ions. However, soon after treatment is started, there is likely to be a precipitous fall in the plasma potassium due to dilution of extracellular potassium by administration of intravenous fluids, the movement of potassium into cells induced by insulin, and the continuing renal loss of potassium.

The magnitude of the hyperglycaemia does not correlate with the severity of the metabolic acidosis; moderate elevation of blood glucose may be associated with life-threatening ketoacidosis. In some cases, hyperglycaemia predominates and acidosis is minimal, with patients presenting in a hyperosmolar state (p. 814).

Clinical assessment

The clinical features of ketoacidosis are listed in Box 21.16. In the fulminating case, the striking features are those of salt and water depletion, with loss of skin turgor, furred tongue and cracked lips, tachycardia, hypotension and reduced intra-ocular pressure. Breathing may be deep and sighing, the breath is usually fetid, and the sickly-sweet smell of acetone may be apparent. Mental apathy, confusion or a reduced conscious level may be present, although coma is uncommon. Indeed, a patient with dangerous ketoacidosis requiring urgent treatment may walk into the consulting room. For this reason, the term 'diabetic ketoacidosis' is to be preferred to 'diabetic coma', which implies that there is no urgency until unconsciousness supervenes. In fact, it is imperative that energetic treatment is started at the earliest possible stage.

Abdominal pain is sometimes a feature of DKA, particularly in children, and vomiting is common. Serum amylase may be elevated but rarely indicates coexisting pancreatitis. In infected patients, pyrexia may not be present initially because of vasodilatation secondary to acidosis.

Investigations

The following are important but should not delay the institution of intravenous fluid and insulin replacement:

- *Venous blood*: for urea and electrolytes, glucose and bicarbonate (severe acidosis is indicated by a venous plasma bicarbonate < 12 mmol/L).
- *Urine or blood analysis for ketones* (p. 807).

21.15 Average loss of fluid and electrolytes in adult diabetic ketoacidosis of moderate severity

• Water: 6 L	3 L extracellular – replace with saline
• Sodium: 500 mmol • Chloride: 400 mmol	3 L intracellular – replace with dextrose
• Potassium: 350 mmol	

21.16 Clinical features of diabetic ketoacidosis

Symptoms	
• Polyuria, thirst	• Leg cramps
• Weight loss	• Blurred vision
• Weakness	• Abdominal pain
• Nausea, vomiting	
Signs	
• Dehydration	• Air hunger (Kussmaul breathing)
• Hypotension (postural or supine)	• Smell of acetone
• Cold extremities/peripheral cyanosis	• Hypothermia
• Tachycardia	• Confusion, drowsiness, coma (10%)

- *ECG.*
- *Infection screen*: full blood count, blood and urine culture, C-reactive protein, chest X-ray. Although leucocytosis invariably occurs in DKA, this represents a stress response and does not necessarily indicate infection.

Management

DKA is a medical emergency which should be treated in hospital, preferably in a high-dependency area. If available, the diabetes specialist team should be involved. Regular clinical and biochemical review is essential, particularly during the first 24 hours of treatment. Guidelines for management of DKA are shown in Box 21.17.

Insulin

A fixed-rate intravenous insulin infusion of 0.1 U/kg body weight/hr is recommended (see Box 21.17). Exceptionally, if intravenous administration is not feasible, soluble insulin can be given by intramuscular injection (loading dose of 10–20 U, followed by 5 U hourly), or a fast-acting insulin analogue can be given hourly by subcutaneous injection (initially 0.3 U/kg body weight, then 0.1 U/kg hourly). The blood glucose concentration should fall by 3–6 mmol/L (approximately 55–110 mg/dL) per hour, or blood ketone concentrations fall by at least 0.5 mmol/L/hr. A more rapid decrease in blood glucose should be avoided, as this might precipitate hypoglycaemia and the serious complication of cerebral oedema, particularly in children. Failure of blood glucose to fall within 1 hour of commencing insulin infusion should lead to a re-assessment of insulin dose. Ketosis, dehydration, acidaemia, infection and stress combine to produce severe insulin resistance in some cases, but most will respond to a low-dose insulin regimen. When the blood glucose has fallen, 10% dextrose infusion is introduced and insulin infusion continued to encourage glucose uptake into cells and restoration of normal metabolism. In recent years, it has also become increasingly common to continue with the use of long-acting insulin analogues administered subcutaneously during the initial management of DKA; this provides background insulin for when the intravenous insulin is discontinued.

Restoration of the usual insulin regimen, by subcutaneous injection, should not be instituted until the patient is both biochemically stable and able to eat and drink normally.

21.17 Management of diabetic ketoacidosis*

Time: 0–60 mins

1. Commence 0.9% sodium chloride
   - If systolic BP > 90 mmHg, give 1 L over 60 mins
   - If systolic BP < 90 mmHg, give 500 mL over 10–15 mins, then re-assess. If BP remains < 90 mmHg, seek senior review
2. Commence insulin treatment
   - 50 U human soluble insulin in 50 mL 0.9% sodium chloride infused intravenously at 0.1 U/kg body weight/hr
   - Continue with SC basal insulin analogue if usually taken by patient
3. Perform further investigations: see text
4. Establish monitoring schedule
   - Hourly capillary blood glucose and ketone testing
   - Venous bicarbonate and potassium after 1 and 2 hrs, then every 2 hrs
   - Plasma electrolytes every 4 hrs
   - Clinical monitoring of O_2 saturation, pulse, BP, respiratory rate and urine output every hour
5. Treat any precipitating cause

Time: 60 mins to 12 hrs

- IV infusion of 0.9% sodium chloride with potassium chloride added as indicated below
  - 1 L over 2 hrs
  - 1 L over 2 hrs
  - 1 L over 4 hrs
  - 1 L over 4 hrs
  - 1 L over 6 hrs
- Add 10% glucose 125 mL/hr IV when glucose < 14 mmol/L
- Be more cautious with fluid replacement in elderly, young people, pregnant patients and those with renal or heart failure. If plasma sodium is > 155 mmol/L, 0.45% sodium chloride may be used.
- Adjust potassium chloride infusion

Plasma potassium (mmol/L)	Potassium replacement (mmol/L of infusion)
> 5.5	Nil
3.5–5.5	40
< 3.5	Senior review – additional potassium required

Time: 12–24 hrs

- Ketonaemia and acidosis should have resolved (blood ketones < 0.3 mmol/L, venous bicarbonate > 18 mmol/L). Request senior review if not improving
- If patient is not eating and drinking
  - Continue IV insulin infusion at lower rate of 2–3 U/kg/hr
  - Continue IV fluid replacement and biochemical monitoring
- If ketoacidosis has resolved and patient is able to eat and drink
  - Re-initiate SC insulin with advice from diabetes team. Do not discontinue IV insulin until 30 mins after SC short-acting insulin injection

Additional procedures

- Catheterisation if no urine passed after 3 hrs
- Central venous line if cardiovascular system compromised, to allow fluid replacement to be adjusted accurately – also consider in elderly, pregnant, renal or cardiac failure, other serious comorbidities, severe DKA
- Measure arterial blood gases and repeat chest X-ray if O_2 saturation < 92%
- ECG monitoring in severe cases
- Thromboprophylaxis with low molecular weight heparin

*Adapted from Joint British Diabetes Societies guideline, NHS Diabetes (2010).

Fluid replacement

In adults, rapid fluid replacement in the first few hours is usually recommended (as in Box 21.17). Caution is recommended in children and young adults because of the risk of cerebral oedema. Most current guidelines favour correction of the extracellular fluid deficit with isotonic saline (0.9% sodium chloride). If the plasma sodium is greater than 155 mmol/L, 0.45% saline may be used initially.

Potassium

Careful monitoring of potassium is essential to the management of diabetic ketoacidosis because both hypo- and hyperkalaemia can occur and are potentially life-threatening. Potassium replacement is not usually recommended with the initial litre of fluid because prerenal failure may be present secondary to dehydration. Treatment with 0.9% sodium chloride with potassium chloride 40 mmol/L is recommended if the serum potassium is below 5.5 mmol/L and the patient is passing urine (see Box 21.17). If the potassium falls below 3.5 mmol/L, the potassium replacement regimen needs to be reviewed. Cardiac rhythm should be monitored in severe DKA because of the risk of electrolyte-induced cardiac arrhythmia.

Bicarbonate

Adequate fluid and insulin replacement should resolve the acidosis. The use of intravenous bicarbonate therapy is currently not recommended. Acidosis may reflect an adaptive response, improving oxygen delivery to the tissues, and so excessive bicarbonate may induce a paradoxical increase in cerebrospinal fluid acidosis and has been implicated in the pathogenesis of cerebral oedema in children and young adults.

Hyperglycaemic hyperosmolar state

Hyperglycaemic hyperosmolar state (HHS) is characterised by severe hyperglycaemia (> 30 mmol/L (600 mg/dL)), hyperosmolality (serum osmolality > 320 mOsm/kg), and dehydration in the absence of significant hyperketonaemia (< 3 mmol/L) or acidosis (pH > 7.3, bicarbonate > 15 mmol/L). It was previously referred to as hyperosmolar non-ketotic (HONK) coma but, as in DKA, coma is not invariable. As with DKA, there is glycosuria, leading to an osmotic diuresis, with loss of water, sodium, potassium and other electrolytes. However, in HHS, hyperglycaemia usually develops over a longer period (a few days to weeks), causing more profound hyperglycaemia and dehydration (fluid loss may be 10–22 litres in a person weighing 100 kg). The reason that patients with HHS do not develop significant ketoacidosis is unclear, although it has been speculated that insulin levels may be too low to stimulate glucose uptake in insulin-sensitive tissues, but still sufficient to prevent lipolysis and subsequent ketogenesis. A mixed picture of HHS and DKA can occur.

Although typically occurring in the elderly, HHS is increasingly seen in younger adults. Common precipitating factors include infection, myocardial infarction, cerebrovascular events or drug therapy (e.g. corticosteroids). Poor prognostic signs include hypothermia, hypotension (systolic blood pressure < 90 mmHg), tachy- or bradycardia, severe hypernatraemia (sodium > 160 mmol/L), serum osmolality > 360 mOsm/kg, and the presence of other serious comorbidities. Mortality rates are higher than in DKA – up to 20% in the USA, reflecting the age and frailty of the population and more frequent presence of comorbidities.

21.18 Principles of management of hyperglycaemic hyperosmolar state

- Measure or calculate serum osmolality frequently
- Give fluid replacement with 0.9% sodium chloride (IV). Use 0.45% sodium chloride only if osmolality is increasing, despite positive fluid balance. Target fall in plasma sodium is ≤ 10 mmol/L at 24 hrs
- Aim for positive fluid balance of 3–6 L by 12 hrs, and replacement of remaining estimated loss over next 12 hrs
- Initiate insulin IV infusion (0.05 U/kg body weight/hr) only when blood glucose is not falling with 0.9% sodium chloride alone *OR* if there is significant ketonaemia (3β-hydroxybutyrate > 1 mmol/L or urine ketones > 2+). Reduce blood glucose by no more than 5 mmol/L/hr
- Treat coexisting conditions
- Give prophylactic anticoagulation
- Assume high risk of foot ulceration

The principles of therapy are shown in Box 21.18. The aims are to normalise osmolality, replace fluid and electrolyte losses, and normalise blood glucose, at the same time preventing complications such as arterial or venous thrombosis, cerebral oedema and central pontine demyelinosis (Ch. 16). Comorbidities also need to be taken into account; for example, rapid fluid replacement may precipitate cardiac failure in patients with coronary artery disease. Historically, management of HHS has followed DKA guidelines, but increasing recognition of the differences between HHS and DKA has led to new approaches in HHS. In particular, rapid shifts in osmolality should be avoided through more measured fluid replacement regimens that are guided by serial calculations of serum osmolality. A key recommendation is that 0.9% sodium chloride solution alone is used for initial treatment, and that insulin is introduced only when the rate of fall in blood glucose has plateaued.

If osmolality cannot be measured frequently, osmolarity can be calculated as follows and used as a surrogate (based on plasma values in mmol/L):

$$\text{Plasma osmolarity} = 2[Na^+] + [\text{glucose}] + [\text{urea}]$$

The normal value is 280–290 mmol/L and consciousness is impaired when it is high (> 340 mmol/L), as commonly occurs in HHS.

Hypoglycaemia

Hypoglycaemia (blood glucose < 3.5 mmol/L (63 mg/dL)) in diabetes results in most circumstances from insulin therapy, less frequently from use of oral insulin secretagogues such as sulphonylurea drugs, and rarely with other anti-diabetic drugs. When hypoglycaemia develops in non-diabetic people, it is called 'spontaneous' hypoglycaemia, the causes and investigation of which are described on page 783. Hypoglycaemia can be

a frequent occurrence in the lives of people with type 1 diabetes and has a major impact on their willingness and ability to achieve target glucose levels.

In health, a number of mechanisms are in place to ensure that glucose homeostasis is maintained. If blood glucose falls, three primary physiological defence mechanisms operate: endogenous insulin release from pancreatic β cells is suppressed; release of glucagon from pancreatic α cells is increased; and the autonomic nervous system is activated, with release of catecholamines both systemically and within the tissues. In addition, stress hormones, such as cortisol and growth hormone, are increased in the blood. These actions reduce whole-body glucose uptake and increase hepatic glucose production, maintaining a glucose supply to the brain. People with type 1 diabetes cannot regulate insulin once it is injected subcutaneously, and so it continues to act, despite developing hypoglycaemia. In addition, within 5 years of diagnosis, most patients will have lost their ability to release glucagon specifically during hypoglycaemia. This is thought to result mainly from loss of α-cell regulation by β cells. These two primary defects mean that hypoglycaemia occurs much more frequently in people with type 1 and longer-duration type 2 diabetes.

Clinical assessment

Symptoms of hypoglycaemia (Box 21.19) comprise two main groups: those related to acute activation of the autonomic nervous system and those secondary to glucose deprivation of the brain (neuroglycopenia). Symptoms of hypoglycaemia are idiosyncratic and differ with age and duration of diabetes. Hypoglycaemia also affects mood, inducing a state of increased tension and low energy. Learning to recognise the early onset of hypoglycaemia is an important aspect of the education of diabetic patients treated with insulin. The severity of hypoglycaemia is defined by the ability to self-treat; 'mild' episodes are self-treated, while 'severe' episodes require assistance for recovery.

Circumstances of hypoglycaemia

Risk factors and causes of hypoglycaemia in patients taking insulin or sulphonylurea drugs are listed in Box 21.20. Severe hypoglycaemia can have serious morbidity (e.g. convulsions, coma, focal neurological lesions) and has a mortality of up to 4% in insulin-treated patients. Rarely, sudden death during sleep occurs in otherwise healthy young patients with type 1 diabetes ('dead-in-bed syndrome') and may result from hypoglycaemia-induced cardiac arrhythmia. Severe hypoglycaemia is very disruptive and impinges on many aspects of the patient's life, including employment, driving (see Box 21.13, p. 810), travel, sport and personal relationships.

Nocturnal hypoglycaemia in patients with type 1 diabetes is common but often undetected, as hypoglycaemia does not usually waken a person from sleep. Patients may describe poor quality of sleep, morning headaches and vivid dreams or nightmares, or a partner may observe profuse sweating, restlessness, twitching or even seizures. The only reliable way to identify this problem is to measure blood glucose during the night.

Exercise-induced hypoglycaemia occurs in people with well-controlled, insulin-treated diabetes because of hyperinsulinaemia. Suppression of endogenous insulin secretion to allow increased hepatic glucose production to meet the increased metabolic demand is key to the normal physiological response to exercise. In insulin-treated diabetes, insulin levels may actually increase with exercise because of improved blood flow at the site of injection and this increases the risk of hypoglycaemia.

Awareness of hypoglycaemia

For most individuals, the glucose level (threshold) at which they first become aware of hypoglycaemia is not

21.19 Most common symptoms of hypoglycaemia

Autonomic	
• Sweating	• Hunger
• Trembling	• Anxiety
• Pounding heart	
Neuroglycopenic	
• Confusion	• Inability to concentrate
• Drowsiness	• Incoordination
• Speech difficulty	• Irritability, anger
Non-specific	
• Nausea	• Headache
• Tiredness	

N.B. Symptoms differ with age; children exhibit behavioural changes (such as naughtiness or irritability), while elderly people experience more prominent neurological symptoms (such as visual disturbance and ataxia).

21.20 Hypoglycaemia in diabetes: common causes and risk factors

Causes of hypoglycaemia

- Missed, delayed or inadequate meal
- Unexpected or unusual exercise
- Alcohol
- Errors in oral anti-diabetic agent(s) or insulin dose/schedule/administration
- Poorly designed insulin regimen, particularly if predisposing to nocturnal hyperinsulinaemia
- Lipohypertrophy at injection sites causing variable insulin absorption
- Gastroparesis due to autonomic neuropathy causing variable carbohydrate absorption
- Malabsorption, e.g. coeliac disease
- Unrecognised other endocrine disorder, e.g. Addison's disease
- Factitious (deliberately induced)
- Breastfeeding

Risk factors for severe hypoglycaemia

- Strict glycaemic control
- Impaired awareness of hypoglycaemia
- Age (very young and elderly)
- Long duration of diabetes
- Sleep
- C-peptide negativity (indicating complete insulin deficiency)
- History of previous severe hypoglycaemia
- Renal impairment
- Genetic, e.g. angiotensin-converting enzyme (ACE) genotype

constant but varies according to the circumstances in which hypoglycaemia arises (e.g. during the night or during exercise). In addition, with longer duration of disease, and particularly in response to frequent hypoglycaemia, the threshold for generation of symptom responses to hypoglycaemia shifts to a lower glucose concentration. This cerebral adaptation has a similar effect on the counter-regulatory hormonal response to hypoglycaemia. Taken together, this means that individuals with type 1 diabetes may have reduced (impaired) awareness of hypoglycaemia. Symptoms can be experienced less intensely, or even be absent, despite blood glucose concentrations below 2.5 mmol/L (45 mg/dL). Such individuals are at an especially high risk of severe hypoglycaemia. The prevalence of impaired awareness of hypoglycaemia increases with time; overall, it affects around 20–25% of people with type 1 diabetes and under 10% with insulin-treated type 2 diabetes.

Management

Acute treatment of hypoglycaemia

Treatment of hypoglycaemia depends on its severity and on whether the patient is conscious and able to swallow (Box 21.21). Oral carbohydrate usually suffices if hypoglycaemia is recognised early. If parenteral therapy is required, then as soon as the patient is able to swallow, glucose should be given orally. Full recovery may not occur immediately and reversal of cognitive impairment may not be complete until 60 minutes after normoglycaemia is restored. When hypoglycaemia has occurred in a patient treated with a long- or intermediate-acting insulin or a long-acting sulphonylurea, such as glibenclamide, the possibility of recurrence should be anticipated; to prevent this, infusion of 10% dextrose, titrated to the patient's blood glucose, may be necessary.

If the patient fails to regain consciousness after blood glucose is restored to normal, then cerebral oedema and other causes of impaired consciousness – such as alcohol intoxication, a post-ictal state or cerebral haemorrhage – should be considered. Cerebral oedema has a high mortality and morbidity, and requires urgent treatment with mannitol and high-dose oxygen.

Following recovery, it is important to try to identify a cause and make appropriate adjustments to the patient's therapy. Unless the reason for a hypoglycaemic episode is clear, the patient should reduce the next dose of insulin by 10–20% and seek medical advice about further adjustments in dose.

The management of self-poisoning with oral antidiabetic agents is described on page 216.

Prevention of hypoglycaemia

Patient education is fundamental to the prevention of hypoglycaemia. Risk factors for, and treatment of hypoglycaemia should be discussed. The importance of regular blood glucose monitoring and the need to have glucose (and glucagon) readily available should be stressed. A review of insulin and carbohydrate management during exercise is particularly useful. Advice for patients when travelling is summarised in Box 21.22.

Relatives and friends also need to be familiar with the symptoms and signs of hypoglycaemia and should be instructed in how to help (including how to inject glucagon).

It is important to recognise that all current insulin replacement regimens are suboptimal and do not accurately replicate normal physiological insulin profiles. Understanding the pharmacokinetics and pharmacodynamics of the insulin regimen in use by the patient will help prevent further hypoglycaemia (p. 824). For example, an individual experiencing regular nocturnal hypoglycaemia between midnight and 0200 hours may be found to be taking twice-daily soluble and intermediate-acting insulins before breakfast and before the main evening meal between 1700 and 1900 hours. In this case, the peak action of the isophane insulin will coincide with the period of maximum sensitivity to insulin – namely, 2300–0200 hours – and increase the risk of nocturnal hypoglycaemia. To address this, the evening dose of depot intermediate-acting insulin should be deferred until bedtime (after 2300 hours), shifting its peak action period to 0500–0700 hours. It is also a sensible precaution for patients to measure their blood glucose before they retire to bed and to have a carbohydrate snack if the reading is less than 6.0 mmol/L (approximately 110 mg/dL).

21.21 Emergency treatment of hypoglycaemia

Mild (self-treated)

- Oral fast-acting carbohydrate (10–15 g) is taken as glucose drink or tablets or confectionery
- This should be followed with a snack containing complex carbohydrate

Severe (external help required)

- If patient is semiconscious or unconscious, parenteral treatment is required:
  IV 75 mL 20% dextrose (= 15 g; give 0.2 g/kg in children)*
  Or
  IM glucagon (1 mg; 0.5 mg in children)
- If patient is conscious and able to swallow:
  Give oral refined glucose as drink or sweets (= 25 g)
  Or
  Apply glucose gel or jam or honey to buccal mucosa

*Use of 50% dextrose is no longer recommended.

21.22 Avoidance and treatment of hypoglycaemia during travel

- Carry a supply of fast-acting carbohydrate (non-perishable, in suitable containers)
  Screwtop plastic bottles for glucose drinks
  Packets of powdered glucose (for use in hot, humid climates)
  Confectionery (foil-wrapped in hot climates)
- Companions should carry additional oral carbohydrate, and glucagon
- Perform frequent blood glucose testing (carry spare meter and/or visually read strips)
- Use fast-acting insulin analogues for long-distance air travel

Diabetes in pregnancy

During pregnancy, maternal glucose metabolism changes to optimise glucose and other nutrient delivery to the fetus. This is particularly apparent in the second half of pregnancy, when there is an increase in maternal tissue insulin resistance, such that glucose is preferentially supplied to the fetus rather than maternal tissue. This is largely driven by the maternal hormonal environment, with increased oestrogens and progestogens, and, in particular, human placental lactogen (hPL). The delivery of the placenta results in rapid decline in hPL with a rapid reversal of insulin resistance soon after birth. During pregnancy, fasting plasma glucose decreases slightly, while post-prandial blood glucose may be increased. The renal threshold for glycosuria (p. 807) is reduced in pregnancy.

In the fetus, insulin secretion is driven by fetal blood glucose levels, which are determined by the maternal glucose concentrations. Thus maternal hyperglycaemia drives fetal hyperinsulinaemia. Since insulin is a major fetal growth factor, hyperinsulinaemia in turn drives increased fetal growth, resulting in increased birth weight ('macrosomia').

Gestational diabetes

Gestational diabetes is defined as diabetes with first onset or recognition during pregnancy. This definition will include a few patients who develop type 1 diabetes during pregnancy, where prompt action and early insulin treatment will be required, and some patients who develop type 2 diabetes, or had unknown pre-existing type 2 diabetes, in whom the diabetes does not remit after pregnancy. However, the majority of gestational diabetes develops due to an inability to increase insulin secretion adequately to compensate for pregnancy-induced insulin resistance, and most women can expect to return to normal glucose tolerance immediately after pregnancy.

In contrast to non-gestational diabetes, for which the diagnostic thresholds for diabetes are based upon risk of microvascular complications, the diagnosis of gestational diabetes is based upon maternal blood glucose measures that are associated with increased fetal growth. An international consensus recommended that glucose values diagnostic of gestational diabetes should be lower than those for non-gestational diabetes (Box 21.23). Controversy remains about who should be screened, and in part the screening strategy depends on the population risk. It is widely accepted that women at high risk for gestational diabetes should have an oral glucose tolerance test at 24–28 weeks, with some guidelines recommending that all are screened by measuring HbA_{1c}, fasting blood glucose or random blood glucose at the first booking visit. With the increasing use of HbA_{1c} to diagnose diabetes, it should be noted that HbA_{1c} is unreliable after early pregnancy, when it falls due to increased red cell turnover.

Management of gestational diabetes

The aim is to normalise the maternal blood glucose and thereby reduce excessive fetal growth. The first element of management is dietary modification, in particular by reducing consumption of quick-acting refined carbohydrate. Women with gestational diabetes should undertake regular pre- and post-prandial self-monitoring of blood glucose, aiming for pre-meal blood glucose levels of less than 5.5 mmol/L (100 mg/dL) or post-meal blood glucose levels of less than 7.0 mmol/L (125 mg/dL). If treatment is necessary, metformin or glibenclamide is considered safe to use in pregnancy. Glibenclamide should be used rather than other sulphonylureas because it does not cross the placenta. Other oral therapies or injectable incretin-based therapies should not be given in pregnancy. Insulin may be required, especially in the later stages of pregnancy. If the maternal blood glucose is not well controlled prior to, and during, delivery, the resulting fetal hyperinsulinaemia leads to neonatal hyperinsulinaemia, which in turn can cause neonatal hypoglycaemia.

After delivery, maternal glucose usually rapidly returns to pre-pregnancy levels. Woman should be tested at least 6 weeks post-partum with an oral glucose tolerance test. In women with persistent mild fasting hyperglycaemia (glucose over 5.5 mmol/L (100 mg/dL)) who have a small increment (less than 3.5 mmol/L) in plasma glucose 2 hours after oral glucose, monogenic diabetes due to a mutation in GCK (encoding glucokinase) should be considered (see Box 21.6, p. 807). Those who have returned to normal glucose tolerance remain at considerable risk for developing type 2 diabetes, with a 5-year risk between 15 and 50%, depending on the population. Therefore, all women who have had gestational diabetes should be given diet and lifestyle advice to reduce their risk of developing type 2 diabetes (p. 820).

21.23 Identifying patients with gestational diabetes

Women at high risk of gestational diabetes

- BMI > 30 kg/m^2
- A previous macrosomic baby weighing ≥ 4.5 kg at birth
- Previous gestational diabetes
- A first-degree relative with diabetes
- A high-risk ethnicity – South Asian, black Caribbean or Middle Eastern

Diagnosis

- High-risk women should have a 75 g oral glucose tolerance test before 28 weeks' gestation
- Gestational diabetes is diagnosed when:
  Fasting plasma glucose ≥ 5.1 mmol/L (92 mg/dL) *or*
  1-hr plasma glucose (after glucose load) ≥ 10 mmol/L (180 mg/dL) *or*
  2-hr plasma glucose (after glucose load) ≥ 8 mmol/L (144 mg/dL)
- Consider testing high-risk women at first booking visit with an HbA_{1c} or fasting blood glucose

Pregnancy in women with established diabetes

Maternal hyperglycaemia early in pregnancy (during the first 6 weeks post-conception) can adversely affect fetal development. Consequences include cardiac, renal and skeletal malformations, of which the caudal regression syndrome is the most characteristic. The risk of fetal anomaly is about 2% for non-diabetic women,

about 4% for women with well-controlled diabetes (HbA_{1c} below 53 mmol/mol (7%)), but more than 20% for those with poor glycaemic control (HbA_{1c} greater than 97 mmol/mol (11%)). Therefore, a woman with diabetes should, if possible, be helped to achieve excellent glycaemic control *before* becoming pregnant. In addition, high-dose folic acid (5 mg, rather than the usual 400 µg, daily) should be initiated before conception to reduce the risk of neural tube defects.

As for gestational diabetes, mothers should attempt to maintain near-normal blood glucose levels whilst avoiding hypoglycaemia throughout their pregnancy, as this minimises excessive fetal growth and neonatal hypoglycaemia. However, this is often difficult to achieve. Pregnancy is also associated with an increased potential for ketosis, particularly, but not exclusively, in women with type 1 diabetes. Ketoacidosis during pregnancy is dangerous for the mother and is associated with a high rate (10–35%) of fetal mortality.

Pregnancy is associated with a worsening of diabetic complications, most notably retinopathy and nephropathy, so careful monitoring of eyes and kidneys is required throughout pregnancy. If heavy proteinuria and/or renal dysfunction exist prior to pregnancy, there is a marked increase in the risk of pre-eclampsia, and renal function can deteriorate irreversibly during pregnancy. These risks need to be carefully discussed before a woman with diabetes is considering pregnancy. While the outlook for mother and child has been vastly improved over recent years, pregnancy outcomes are still not equivalent to those of non-diabetic mothers. Perinatal mortality rates remain 3–4 times those of the non-diabetic population (at around 30–40 per 1000 pregnancies) and the rate of congenital malformation is increased 5–6-fold overall.

Children, adolescents and young adults with diabetes

The management of diabetes in children and adolescents presents particular challenges, which should be addressed in specialised clinics (Box 21.24).

Hyperglycaemia in acute myocardial infarction

Hyperglycaemia is often found in patients who have sustained an acute myocardial infarction. In some, this represents stress hyperglycaemia (p. 808), some have previously undiagnosed diabetes, and many have established diabetes. Many patients with stress hyperglycaemia will have impaired glucose tolerance on a subsequent glucose tolerance test. Over and above the standard management of myocardial infarction (p. 593), hyperglycaemia should be treated with insulin rather than oral anti-diabetic agents in the peri-infarct period, aiming for near-normalisation of blood glucose. Studies have suggested that good glycaemic control using insulin therapy in hyperglycaemic patients with acute myocardial infarction may reduce their long-term mortality from coronary heart disease.

21.24 Diabetes in adolescence

- **Type of diabetes**: type 1 diabetes is predominant in children and adolescents, but type 2 diabetes is now presenting in unprecedented numbers of obese, inactive teenagers. Monogenic diabetes (MODY) should also be considered (see Box 21.6, p. 807).
- **Physiological changes**: hormonal, physical and lifestyle changes in puberty affect dietary intake, exercise patterns and sensitivity to insulin, necessitating alterations in insulin regimen.
- **Emotional changes**: adolescence is a phase of transition into independence (principally from parental care). Periods of rebellion against parental control, experimentation (e.g. with alcohol) and a more chaotic lifestyle are common, and often impact adversely on control of diabetes.
- **Glycaemic control**: a temporary deterioration in control is common, although not universal. It is sometimes more important to maintain contact and engagement with a young person than to insist on tight glycaemic control.
- **Diabetic ketoacidosis**: a few adolescents and young adults present with frequent episodes of DKA, often because of non-adherence to insulin therapy. This is more common in females. Motivating factors may include weight loss, rebellion, and manipulation of family or schooling circumstances.
- **Adolescent diabetes clinics**: these challenges are best tackled with support from a specialised multidisciplinary team, including paediatricians, physicians, nurses and psychologists. Support is required for the patient and parents.

Surgery and diabetes

Patients with diabetes are reported to have up to 50% higher peri-operative mortality than patients without diabetes. Surgery causes catabolic stress and secretion of counter-regulatory hormones (including catecholamines and cortisol) in both normal and diabetic subjects. This results in increased glycogenolysis, gluconeogenesis, lipolysis, proteolysis and insulin resistance. Starvation exacerbates this process by increasing lipolysis. In the non-diabetic person, these metabolic effects lead to a secondary increase in the secretion of insulin, which exerts a controlling influence. In diabetic patients, either there is absolute deficiency of insulin (type 1 diabetes) or insulin secretion is delayed and impaired (type 2 diabetes), so that in untreated or poorly controlled diabetes, the uptake of metabolic substrate into tissues is significantly reduced, catabolism is increased and, ultimately, metabolic decompensation in the form of diabetic ketoacidosis may develop in both types of diabetes. In addition, hyperglycaemia impairs wound healing and innate immunity, leading to increased risk of infection. Patients with diabetes are also more likely to have underlying pre-operative morbidity, especially cardiovascular disease. Finally, management errors with diabetes may cause dangerous hyperglycaemia or hypoglycaemia. Careful pre-operative assessment and peri-operative management are therefore essential, ideally with support from the diabetes specialist team.

Pre-operative assessment

Unless a surgical intervention is an emergency, patients with diabetes should be assessed well in advance of surgery so that poor glycaemic control and other risk factors can be addressed (Box 21.25). There is good evidence that higher HbA_{1c} is associated with adverse peri-operative outcome. In general, an upper limit for an acceptable HbA_{1c} should be between 64 and 75 mmol/mol (8 and 9%). However, since optimisation of care may take weeks or months to achieve, the benefits need to be weighed against the need for early surgical intervention.

21.25 How to carry out pre-operative assessment of patients with diabetes

- Assess glycaemic control
  - Consider delaying surgery and referral to the diabetes team if HbA_{1c} > 75 mmol/mol (9%). This should be weighed against the need for surgery
- Assess cardiovascular status
  - Optimise blood pressure
  - ECG for evidence of (possibly silent) ischaemic heart disease and to assess QTc (p. 532)
- Assess foot risk (p. 833)
  - Patients with high-risk feet should have suitable pressure relief provided during post-operative nursing
- For minor/moderate operations where only one meal will be omitted, plan for the patient to be first on the list

Peri-operative management

Figure 21.8 outlines a general approach to peri-operative management of diabetes, although this may need to be adapted according to the patient, the surgical procedure and local guidelines. Patients with diabetes who are considered low-risk can attend as day cases or be admitted on the day of surgery. However, patients are often admitted the night before to ensure optimal management, and to begin intravenous insulin to optimise blood glucose, if required.

Post-operative management

Patients who need to continue fasting after surgery should be maintained on intravenous insulin and fluids until they are able to eat and drink (see Fig. 21.8). During this time, care must be taken with fluid balance and electrolyte levels. Insulin infusion necessitates dextrose infusion to maintain a supply of glucose, but this combination drives down plasma potassium (p. 440) and can result in hyponatraemia. Intravenous fluids during prolonged insulin infusion should therefore include saline and potassium supplementation. UK guidelines recommend use of dextrose/saline (0.45% saline with 5% dextrose and 0.15% potassium chloride).

Once a patient's usual treatment has been reinstated, care must be taken to continue to control the blood glucose, ideally between 4 and 10 mmol/L (70–180 mg/dL), in order to optimise wound healing and recovery.

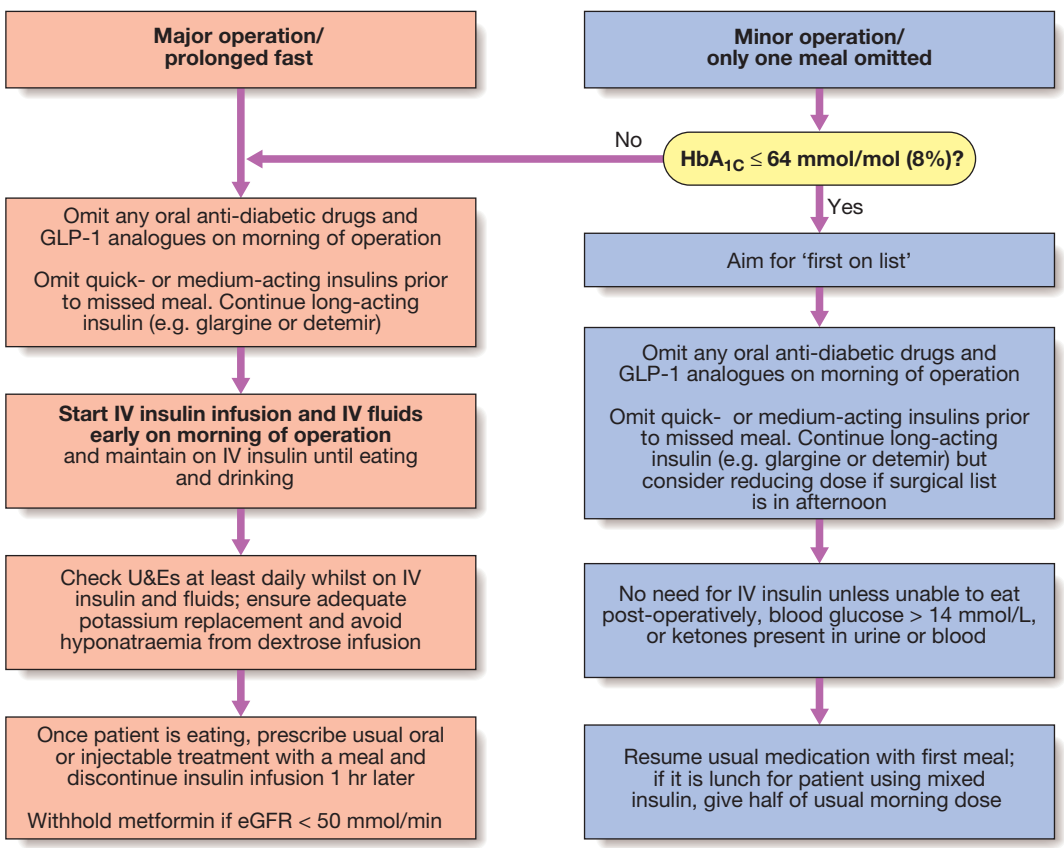

Fig. 21.8 Management of diabetic patients undergoing surgery and general anaesthesia. (Glucose > 14 mmol/L ≅ 250 mg/dL) (eGFR = estimated glomerular filtration rate; GLP-1 = glucagon-like peptide 1)

Patients normally controlled on tablets may require temporary subcutaneous insulin treatment until the increased 'stress' of surgery, wound healing or infection has resolved.

Complications of diabetes

Patients with long-standing diabetes are at risk of developing a variety of complications (see Box 21.31, p. 826). Moreover, as many as 25% of people with type 2 diabetes have evidence of diabetic complications at the time of initial diagnosis. Thus, diabetes may be first suspected when a patient visits an optometrist or podiatrist, or presents with hypertension or a vascular event such as an acute myocardial infarction or stroke. Blood glucose should therefore be checked in all patients presenting with such pathology. The detailed investigation and management of diabetic complications are described on pages 826–836.

MANAGEMENT OF DIABETES

In new cases of diabetes, adequate glycaemic control can be obtained by diet and lifestyle advice alone in approximately 50%, 20–30% will need oral anti-diabetic medication, and 20–30% will require insulin. Regardless of aetiology, the choice of treatment is determined by the adequacy of residual β-cell function. However, this cannot be determined easily by measurement of plasma insulin concentration because a level which is adequate in one patient may be inadequate in another, depending upon sensitivity to insulin. Consideration of the features in Box 21.12 (p. 809), and in particular the age and weight of the patient at diagnosis, usually indicate the type of treatment required. However, in each individual, the regimen adopted is effectively a therapeutic trial and should be reviewed regularly.

The ideal management for diabetes would allow the person to lead a completely normal life, to remain not only symptom-free but in good health, to achieve a normal metabolic state and to escape the long-term complications of diabetes. This is achievable to a variable degree. Setting individual goals for each patient is discussed on page 811.

Patients whose glycaemic control deteriorates after a period of satisfactory control need their therapy to be adjusted. However, this is not a homogeneous group; it includes some patients with late-onset type 1 diabetes who develop an absolute deficiency of insulin, some with type 2 diabetes whose β-cell failure is advanced, and others who are not adhering to the recommended lifestyle changes or medication. Weight loss suggests worsening β-cell function. During continuing follow-up, the majority of patients will require combinations of anti-diabetic drugs, often with additional insulin replacement, to obtain satisfactory glycaemic control.

Diet and lifestyle

The importance of lifestyle changes such as undertaking regular physical activity, observing a healthy diet and reducing alcohol consumption should not be underestimated in improving glycaemic control, but many people, particularly the middle-aged and elderly, find them difficult to sustain. Patients should also be encouraged to stop smoking.

Healthy eating

All people with diabetes need to pay special attention to their diet (Box 21.26; see also p. 110). They should have access to a dietitian at diagnosis, at review and at times of treatment change. Nutritional advice should be tailored to individuals and take account of their age and lifestyle. Many people with type 2 diabetes require dietary advice for achieving weight loss, to include caloric restriction and, in particular, reduced fat intake. Structured education programmes are available for both common types of diabetes.

Carbohydrate

Both the amount and source of carbohydrate determine post-prandial glucose (p. 112). The glycaemic index (GI) of a carbohydrate-containing food is a measure of the change in blood glucose following its ingestion relative to the rise in blood glucose observed following a liquid oral glucose tolerance test. Different foods can be ranked by their effect on post-prandial glycaemia. Consumption of foods with a low GI is encouraged because they produce a slow, gradual rise in blood glucose. Examples include starchy foods such as basmati rice, spaghetti, porridge, noodles, granary bread, and beans and lentils. However, different methods of food processing and preparation can influence the GI of foods, as can the ripeness of some foods and differences in strains of rice. In addition, while consideration of GI is useful in choosing between types of carbohydrate, it does not address the total amount consumed. Recent studies suggest short-term (6 months), very low carbohydrate diets (containing as little as 50 g carbohydrate per day – 13% of daily energy) are safe and effective means of reducing

21.26 Dietary management of diabetes

Aims of dietary management

- Achieve good glycaemic control
- Reduce hyperglycaemia and avoid hypoglycaemia
- Assist with weight management:
  - Weight maintenance for type 1 diabetes and non-obese type 2 diabetes
  - Weight loss for overweight and obese type 2 diabetes
- Reduce the risk of micro- and macrovascular complications
- Ensure adequate nutritional intake
- Avoid 'atherogenic' diets or those that aggravate complications, e.g. high protein intake in nephropathy

Dietary constituents and recommended % of energy intake

- Carbohydrate: 45–60%
  - Sucrose: up to 10%
- Fat (total): < 35%
  - n-6 Polyunsaturated: < 10%
  - n-3 Polyunsaturated: eat 1 portion (140 g) oily fish once or twice weekly
  - Monounsaturated: 10–20%
  - Saturated: < 10%
- Protein: 10–15% (do not exceed 1 g/kg body weight/day)
- Fruit/vegetables: 5 portions daily

weight and improving glycaemic control. However, high dropout rates and poor adherence suggest that this type of diet is not widely applicable.

In type 1 diabetes, the development of modern insulin regimens, particularly using insulin analogues or continuous subcutaneous insulin infusion (CSII; p. 824), has allowed increased flexibility in the timing and choice of carbohydrate intake. It is now possible to match the amount of carbohydrate in a meal with a dose of short-acting insulin using methods such as Dose Adjustment for Normal Eating (DAFNE), although this is demanding and requires extensive patient education. This approach enables motivated individuals with type 1 diabetes to achieve and maintain good glycaemic control, while avoiding post-prandial hyper- and hypoglycaemia.

Fat

The intake of total fat should be restricted to less than 35% of energy intake, with less than 10% as saturated fat, and 10–20% from monounsaturated fat through consumption of oils and spreads made from olive, rapeseed or groundnut oils (see Box 21.26). The influence of dietary fats on plasma lipid profile and cardiovascular disease is discussed on page 113.

Salt

People with diabetes should follow the advice given to the general population: namely, to limit sodium intake to no more than 6 g daily.

Weight management

In patients with diabetes, weight management is important, as a high percentage of people with type 2 diabetes are overweight or obese, and many anti-diabetic drugs, including insulin, encourage weight gain. Obesity, particularly central obesity with increased waist circumference, also predicts insulin resistance and cardiovascular risk.

Management of obesity is described on page 117. Weight loss can be achieved through a reduction in energy intake and an increase in energy expenditure through physical activity. Lifestyle interventions or pharmacotherapy for obesity when associated with weight reduction have beneficial effects on HbA_{1c}, but long-term benefits in terms of glycaemic control and microvascular disease have not been adequately assessed. More recently, bariatric surgery has been shown to induce marked weight loss in obese individuals with type 2 diabetes and this is often associated with significant improvements in HbA_{1c} and withdrawal of or reduction in diabetes medications.

Exercise

All patients with diabetes should be advised to achieve a significant level of physical activity and to maintain this in the long term. This can include activities such as walking, gardening, swimming or cycling. Supervised and structured exercise programmes may be of particular benefit to people with type 2 diabetes. Various guidelines exist for physical activity in the general population. Those from the US Department of Health and Human services (2008) suggest that adults (18–64 years) should build up to achieve a weekly minimum of 2.5 hours of moderate-intensity exercise or 75 minutes of vigorous-intensity exercise, or a combination thereof. The aerobic (moderate-intensity) activity should be performed for at least 10 minutes each time and spread throughout the week, with at least 30 minutes on at least 5 days of the week. Older adults should also follow these guidelines as far as their abilities allow. Recently, it has also been suggested that a combination of both aerobic and resistance exercise may lead to greater improvements in glycaemic control.

In type 1 diabetes, exercise can increase the risk of hypoglycaemia, so patients should seek specialist advice on taking extra carbohydrate, reducing insulin doses and choosing an injection site.

Alcohol

Alcohol is recognised as having both beneficial and harmful effects on cardiovascular disease and this also appears to apply in patients with diabetes. Alcohol can therefore be taken in moderation in diabetes with the aim of keeping within national guidelines relating to recommendations for people without diabetes (e.g. in the UK, the weekly recommended maximum is 14 U for women and 21 U for men). However, alcohol can reduce hypoglycaemia awareness and, by suppressing gluconeogenesis, increase hypoglycaemia risk. In addition, all patients with diabetes should be made aware of the high calorie content of alcohol and the implications for body weight management, which are often overlooked.

Drugs to reduce hyperglycaemia

For many years, there were only a few choices of drugs available for type 2 diabetes – the biguanide metformin, the sulphonylureas and insulin. Insulin is the only treatment for type 1 diabetes. Acarbose was also available but little used in most countries. Since the late 1990s, however, several new classes of agents have been approved for use in type 2 diabetes, with more in development. Newer drugs include thiazolidinediones, dipeptidyl peptidase 4 (DPP-4) inhibitors, glucagon-like peptide 1 (GLP-1) receptor agonists, and sodium and glucose transporter 2 (SGLT2) inhibitors. The effects of these drugs are compared in Box 21.27. This makes for an exciting time in diabetes pharmacotherapy, but exactly how, when and in what order these agents should be used remains uncertain. The older drugs are cheaper and have established benefits for reducing microvascular disease; they are therefore usually recommended as first-line therapy. Use of the newer drugs is not supported by evidence for reduction in microvascular disease (because the trials have not yet been done) and they are much more expensive, so are often reserved for later therapy after failure of metformin and sulphonylureas. One guideline which follows these principles is shown in Figure 21.9. However, this does not necessarily reflect the optimum positioning of these newer drugs. As large trials, which aim to establish their cardiovascular benefit, report in the next few years, these recommendations may change dramatically.

Biguanides

Metformin is the only biguanide now available. Its long-term benefits were shown in the UK Prospective Diabetes Study (UKPDS) (p. 827), and it is now widely used

21.27 Effects of drugs used in the treatment of type 2 diabetes

	Insulin	Sulphonylureas and meglitinides	Metformin	Acarbose	Thiazolidinediones (glitazones)	DPP-4 inhibitors (gliptins)	GLP-1 receptor agonists	SGLT2 inhibitors
Fasting blood glucose	↓	↓	↓	↘	↓	↓	↓	↓
Post-prandial blood glucose	↓	↓	↓	↓	↓	↓	↓	↓
Plasma insulin	↑	↑	↓	↓	↓	↑	↑	↓
Body weight	↑	↑	→	→	↑	→	↓	↓
Risk of hypoglycaemia	++	+	–	–	–	–	–	–
Tolerability	Good	Good	Moderate	Moderate	Moderate	Good	Moderate	Limited experience

(DPP-4 = dipeptidyl peptidase 4; GLP-1 = glucagon-like peptide 1; SGLT2 = sodium and glucose transporter 2)

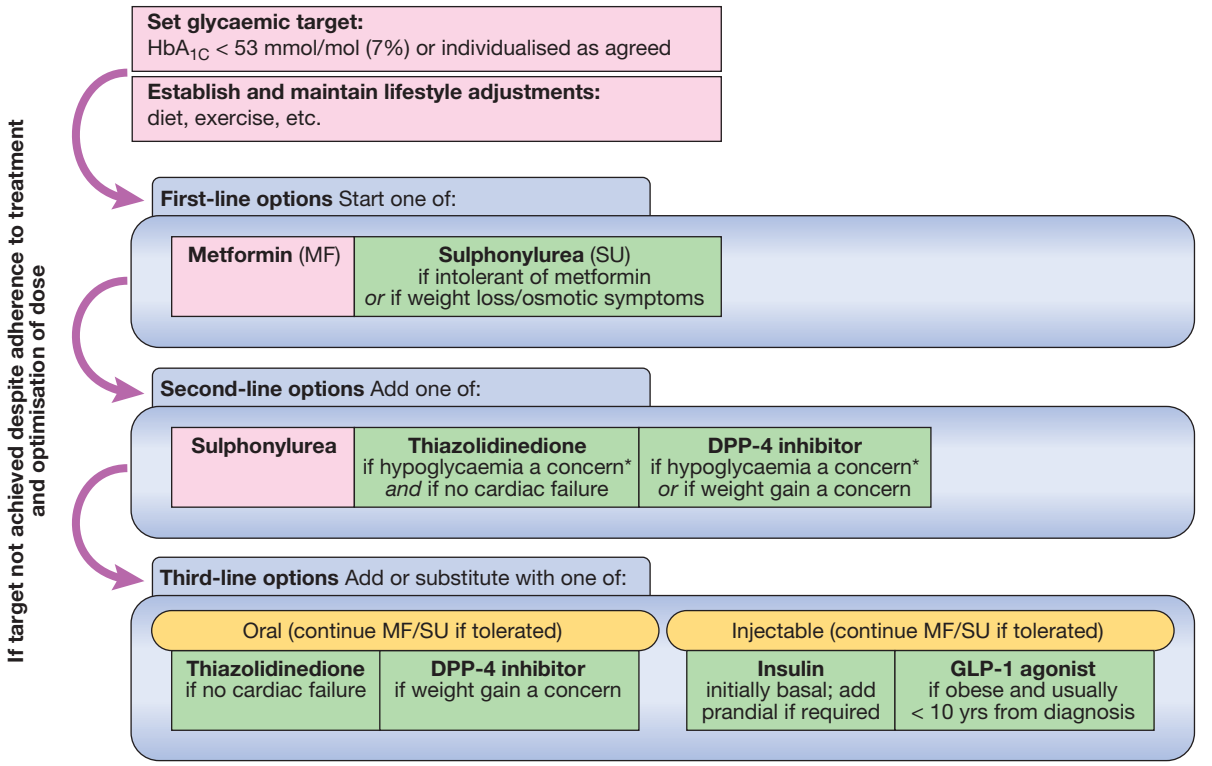

Fig. 21.9 Management of hyperglycaemia in type 2 diabetes. Purple boxes indicate the usual approach, and green boxes show alternatives which are selected according to individual circumstances. *Hypoglycaemia risk includes driving, occupational hazards and risk of falls. Note that SGLT2 inhibitors were not available when this guideline was produced. (DPP-4 = dipeptidyl peptidase 4; GLP-1 = glucagon-like peptide 1). Adapted from SIGN 116 – see p. 836.

as first-line therapy for type 2 diabetes, irrespective of body weight. Metformin is also given increasingly as an adjunct to insulin therapy in obese patients with type 1 diabetes. Approximately 25% of patients develop mild gastrointestinal side-effects with metformin, but only 5% are unable to tolerate it even at low dose. The main side-effects are diarrhoea, abdominal cramps, bloating and nausea.

Mechanism of action

The mechanism of action of metformin has not been precisely defined. Whilst classically considered an 'insulin sensitiser' because it lowers insulin levels, its main effects are on fasting glucose and are insulin-independent. Metformin reduces hepatic glucose production, may also increase insulin-mediated glucose uptake, and has effects on gut glucose uptake and

utilisation. At the molecular level, metformin acts as a weak inhibitor of mitochondrial respiration, which increases intracellular adenosine monophosphate (AMP) and reduces adenosine triphosphate (ATP). This has direct effects on the flux through gluconeogenesis, and activates the intracellular energy sensor AMP-activated protein kinase (AMPK), leading to multiple beneficial metabolic effects.

Clinical use

Metformin is a potent blood glucose-lowering treatment that is weight-neutral, does not cause hypoglycaemia and has established benefits in microvascular disease. It is employed as first-line therapy in all patients who tolerate it, and its use is maintained when additional agents are added as glycaemia deteriorates (see Fig. 21.9). Metformin is usually introduced at low dose (500 mg twice daily) to minimise the risk of gastrointestinal side-effects. The usual maintenance dose is 1 g twice daily. There is a modified-release formulation of metformin which may be better tolerated by patients with gastrointestinal side-effects.

Metformin can increase susceptibility to lactic acidosis, although this is much less common than was previously thought. As metformin is cleared by the kidneys, it can accumulate in renal impairment, so the dose should be halved when estimated glomerular filtration rate (eGFR) is 30–45 mL/min, and it should not be used below an eGFR of 30 mL/min. Its use is also contraindicated in patients with impaired hepatic function and in those who drink alcohol in excess, in whom the risk of lactic acidosis is significantly increased. It should be discontinued, at least temporarily, if any other serious medical condition develops, especially one causing severe shock or hypoxia. In such circumstances, treatment with insulin should be substituted if required.

Sulphonylureas

Sulphonylureas are 'insulin secretagogues', i.e. they promote pancreatic β-cell insulin secretion. Similar to metformin, the long-term benefits of sulphonylureas in lowering microvascular complications of diabetes were established in the UK Prospective Diabetes Study (p. 827).

Mechanism of action

Sulphonylureas act by closing the pancreatic β-cell ATP-sensitive potassium (K_{ATP}) channel, decreasing K^+ efflux, which ultimately triggers insulin secretion. Meglitinides (e.g. repaglinide and nateglinide) also work in this way and, although short-acting, are essentially sulphonylurea-like drugs.

Clinical use

Sulphonylureas are an effective therapy for lowering blood glucose and are often used as an add-on to metformin, if glycaemia is inadequately controlled on metformin alone (see Fig. 21.9). The main adverse effects of sulphonylureas are weight gain and hypoglycaemia. The weight gain is not ideal in patients with diabetes who are already overweight or obese, although sulphonylureas are effective treatments in this group. Hypoglycaemia occurs because the closure of K_{ATP} channels brings about unregulated insulin secretion, even with normal or low blood glucose levels.

There are a number of sulphonylureas. In the UK, gliclazide is the most commonly used; in contrast, in the USA, glibenclamide (also known as glyburide) is widely used. Glibenclamide, however, is long-acting and prone to induce hypoglycaemia, so should be avoided in the elderly. Other sulphonylureas include glimepiride and glipizide. The dose–response of all sulphonylureas is steepest at low doses; little additional benefit is obtained when the dose is increased to maximal levels.

Alpha-glucosidase inhibitors

The α-glucosidase inhibitors delay carbohydrate absorption in the gut by inhibiting disaccharidases. Acarbose and miglitol are available and are taken with each meal. Both lower post-prandial blood glucose and modestly improve overall glycaemic control. They can be combined with a sulphonylurea. The main side-effects are flatulence, abdominal bloating and diarrhoea. They are used widely in the Far East but infrequently in the UK.

Thiazolidinediones

Mechanism of action

These drugs (also called TZDs, 'glitazones' or PPARγ agonists) bind and activate peroxisome proliferator-activated receptor-γ, a nuclear receptor present mainly in adipose tissue that regulates the expression of several genes involved in metabolism. TZDs enhance the actions of endogenous insulin, in part directly (in the adipose cells) and in part indirectly (by altering release of 'adipokines', such as adiponectin, which alter insulin sensitivity in the liver). Plasma insulin concentrations are not increased and hypoglycaemia does not occur. TZDs increase pre-adipocyte differentiation, resulting in an increase in fat mass and in body weight.

Clinical use

TZDs have been prescribed widely since the late 1990s, but recently a number of adverse effects have become apparent and their use has declined. One popular TZD, rosiglitazone, was reported to increase the risk of myocardial infarction and was withdrawn in 2010. The other TZD in common use, pioglitazone, does not appear to increase the risk of myocardial infarction but it does exacerbate cardiac failure by causing fluid retention, and recent data show that it increases the risk of bone fracture, and possibly bladder cancer. These observations have reduced the use of pioglitazone dramatically.

Pioglitazone can be very effective at lowering blood glucose in some patients and appears more effective in insulin-resistant patients. In addition, it has a beneficial effect in reducing fatty liver and NASH (p. 805). Pioglitazone is usually added to metformin with or without sulphonylurea therapy (see Fig. 21.9). It may be given with insulin therapy, when it can be very effective, but the combination of insulin and TZDs markedly increases fluid retention and risk of cardiac failure, so should be used with caution.

Incretin-based therapies: DPP-4 inhibitors and GLP-1 analogues

The incretin effect is the augmentation of insulin secretion seen when a glucose stimulus is given orally rather than intravenously, and reflects the release of incretin peptides from the gut (see Fig. 21.3, p. 802). The incretin

hormones are primarily glucagon-like peptide 1 (GLP-1) and gastric inhibitory polypeptide (GIP). These are rapidly broken down by the peptidase DPP-4 (dipeptidyl peptidase 4). The incretin effect is diminished in type 2 diabetes, and this has stimulated the development of two incretin-based therapeutic approaches.

The 'gliptins', or DPP-4 inhibitors, prevent breakdown and therefore enhance concentrations of endogenous GLP-1 and GIP. The first DPP-4 inhibitor to market was sitagliptin; others now available include vildagliptin, saxagliptin and linagliptin. These drugs are very well tolerated and are weight-neutral (see Box 21.27).

The GLP-1 receptor agonists have a similar structure to GLP-1 but have been modified to resist breakdown by DPP-4. These agents are not orally active and have to be given by subcutaneous injection. However, they have a key advantage over the DPP-4 inhibitors: because the GLP-1 activity achieved is supra-physiological, it delays gastric emptying and, at the level of the hypothalamus, decreases appetite. Thus, injectable GLP-1 analogues lower blood glucose and result in weight loss – an appealing therapy, as the majority of patients with type 2 diabetes are obese. Currently available GLP-1 receptor agonists include exenatide (twice daily), exenatide MR (once weekly) and liraglutide (once daily).

Unlike sulphonylureas, both incretin-based therapies only promote insulin secretion when there is a glucose 'trigger' for insulin secretion. Thus, when the blood glucose is normal, the insulin secretion is not augmented and so these agents do not cause hypoglycaemia.

SGLT2 inhibitors

The sodium and glucose transporter 2 (SGLT2) inhibitor, dapagliflozin, was licensed for use in 2012. Glucose is filtered freely in the renal glomeruli and reabsorbed in the proximal tubules. SGLT2 is involved in reabsorption of glucose. Inhibition results in approximately 25% of the filtered glucose not being reabsorbed, with consequent glycosuria. Although this helps to lower blood glucose and results in calorie loss and subsequent weight loss, the glycosuria does result in increased urinary tract and genital fungal infections. With limited experience and evidence to date, the most appropriate position for SGLT2 inhibitors in the therapy of type 2 diabetes has yet to be established.

Insulin therapy

Manufacture and formulation

Insulin was discovered in 1921 and transformed the management of type 1 diabetes, until then a fatal disorder. Until the 1980s, insulin was obtained by extraction and purification from pancreata of cows and pigs (bovine and porcine insulins), and some patients still prefer to use animal insulins. Recombinant DNA technology enabled large-scale production of human insulin. More recently, the amino acid sequence of insulin has been altered to produce analogues of insulin, which differ in their rate of absorption from the site of injection.

The duration of action of short-acting, unmodified insulin ('soluble' or 'regular' insulin), which is a clear solution, can be extended by the addition of protamine and zinc at neutral pH (isophane or NPH insulin) or excess zinc ions (lente insulins). These modified 'depot' insulins are cloudy preparations. Pre-mixed formulations containing short-acting and isophane insulins in various proportions are available. The pharmacokinetics of these various insulins are shown in Box 21.28.

21.28 Duration of action (in hours) of insulin preparations

Insulin	Onset	Peak	Duration
Rapid-acting (insulin analogues: lispro, aspart, glulisine)	< 0.5	0.5–2.5	3–4.5
Short-acting (soluble (regular))	0.5–1	1–4	4–8
Intermediate-acting (isophane (NPH), lente)	1–3	3–8	7–14
Long-acting (bovine ultralente)	2–4	6–12	12–30
Long-acting (insulin analogues: glargine, detemir)	1–2	None	18–24

In most countries, the insulin concentration in available formulations has been standardised at 100 U/mL.

Subcutaneous multiple dose insulin therapy

In most patients, insulin is injected subcutaneously several times a day into the anterior abdominal wall, upper arms, outer thighs and buttocks (Box 21.29). Accidental intramuscular injection often occurs in children and thin adults. The rate of absorption of insulin may be influenced by many factors other than the insulin formulation, including the site, depth and volume of injection, skin temperature (warming), local massage and exercise. Absorption is delayed from areas of lipohypertrophy at injection sites (p. 799), which results from the local trophic action of insulin, so repeated injection at the same site should be avoided. Other routes of administration (intravenous and intraperitoneal) are reserved for specific circumstances.

Once absorbed into the blood, insulin has a half-life of just a few minutes. It is removed mainly by the liver and also the kidneys, so plasma insulin concentrations are elevated in patients with liver disease or renal failure. Rarely, the rate of clearance can be affected by binding to insulin antibodies (induced by use of animal insulins).

Insulin can be administered using a disposable plastic syringe with a fine needle (which can be re-used several times), but this has largely been replaced by pen

21.29 How to inject insulin subcutaneously

- Needle sited at right angle to the skin
- Subcutaneous (not intramuscular) injection
- Delivery devices: glass syringe (requires re-sterilisation), plastic syringe (disposable), pen device (reusable, some disposable), infusion pump

21.30 Side-effects of insulin therapy

- Hypoglycaemia
- Weight gain
- Peripheral oedema (insulin treatment causes salt and water retention in the short term)
- Insulin antibodies (with animal insulins)
- Local allergy (rare)
- Lipohypertrophy or lipoatrophy at injection sites

injectors containing insulin in cartridges sufficient for multiple dosing. These are also available as pre-loaded disposable pens.

For the most part, insulin analogues have replaced soluble and isophane insulins, especially for people with type 1 diabetes, because they allow more flexibility and convenience (see Box 21.28). Unlike soluble insulin, which should be injected 30 minutes before eating, rapid-acting insulin analogues can be administered immediately before, during or even after meals. Long-acting insulin analogues are better able than isophane insulin to maintain 'basal' insulin levels for up to 24 hours, so need only be injected once daily. Despite these pharmacokinetic benefits, the impact of insulin analogues on glycaemic control and adverse events appears to be minor.

The complications of insulin therapy are listed in Box 21.30; the most important of these is hypoglycaemia (p. 814). A common problem is fasting hyperglycaemia ('the dawn phenomenon'), which arises through a combination of the normal circadian rhythm and release of counter-regulatory hormones (growth hormone and cortisol) during the later part of the night, as well as diminishing levels of overnight isophane insulin.

Insulin dosing regimens

The choice of regimen depends on the desired degree of glycaemic control, the severity of underlying insulin deficiency, the patient's lifestyle, and his or her ability to adjust the insulin dose. The time–action profile of different insulin regimens, compared to the secretory pattern of insulin in the non-diabetic state, is shown in Figure 21.10. Most people with type 1 diabetes require two or more injections of insulin daily. In type 2 diabetes, insulin is usually initiated as a once-daily long-acting insulin, either alone or in combination with oral hypoglycaemic agents. However, in time, more frequent insulin injections are usually required.

Twice-daily administration of a short-acting and intermediate-acting insulin (usually soluble and isophane insulins), given in combination before breakfast and the evening meal, is the simplest regimen and is still used commonly in many countries. Initially, two-thirds of the total daily requirement of insulin is given in the morning in a ratio of short-acting to intermediate-acting of 1:2, and the remaining third is given in the evening. Pre-mixed formulations are available containing different proportions of soluble and isophane insulins (e.g. 30:70 and 50:50). These are useful for patients who have difficulty mixing insulins, but are inflexible as the individual components cannot be adjusted independently. They need to be resuspended by shaking the vial several times before administration. Fixed-mixture insulins also have altered pharmacodynamic profiles, such that the peak insulin action and time to peak effect are significantly reduced compared with injecting the same insulins separately.

Multiple injection regimens (intensive insulin therapy) are popular, with short-acting insulin being taken before each meal, and intermediate- or long-acting insulin being injected once or twice daily (basal-bolus regimen). This type of regimen allows greater freedom with regard to meal timing and more variable day-to-day physical activity.

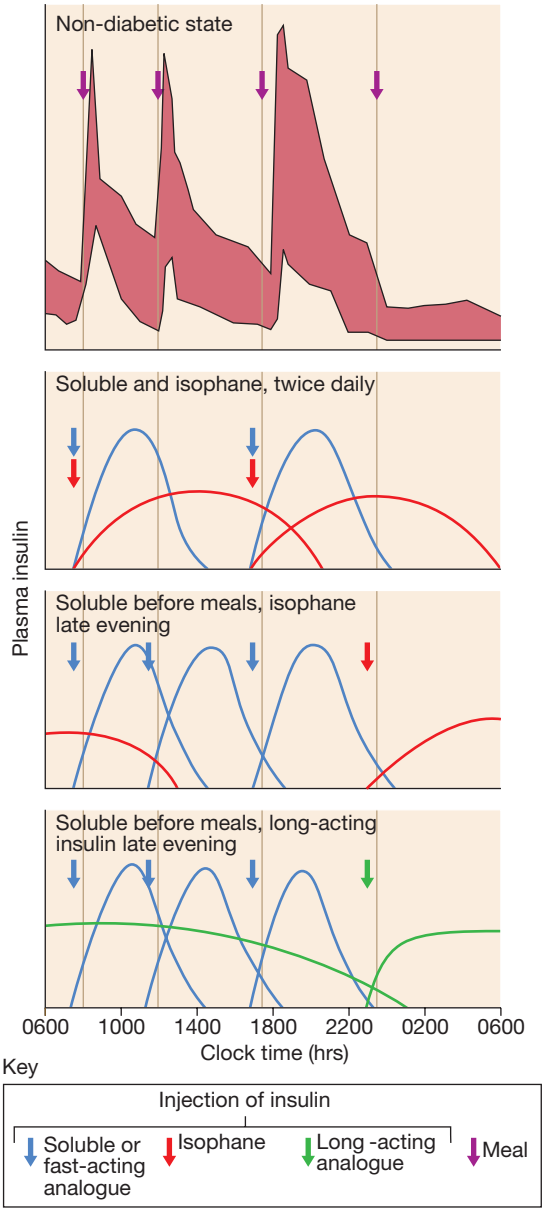

Fig. 21.10 Profiles of plasma insulin associated with different insulin regimens. The schematic profiles are compared with the insulin responses (mean ± one standard deviation) observed in non-diabetic adults shown in the top panel (shaded area). These are theoretical patterns of plasma insulin and may differ considerably in magnitude and duration of action between individuals.

Alternative insulin therapies

'Open-loop' systems are battery-powered portable pumps providing continuous subcutaneous (CSII), intraperitoneal or intravenous infusion of insulin without reference to the blood glucose concentration. The rate of insulin infusion is variable; it can be programmed to match the patient's diurnal variation in requirements and then manually boosted at mealtimes. In practice, the 'loop' is closed by the patient performing blood glucose estimations, and the use of these devices requires a high degree of patient motivation. These increasingly sophisticated systems can achieve excellent glycaemic control but widespread therapeutic use is limited by cost. The 'Artificial Pancreas' project aims to close the loop by using miniaturised glucose sensors to communicate wirelessly with the insulin pump, which would automatically adjust its rate, but this has not yet reached widespread clinical practice.

Alternative routes of insulin delivery have been investigated. Clinical trials with intrapulmonary (inhalation), transdermal and oral insulins are ongoing but as yet none has proven commercially viable.

Transplantation

Whole pancreas transplantation is carried out in a small number of patients with diabetes each year, but it presents problems relating to exocrine pancreatic secretions and long-term immunosuppression is necessary. While results are steadily improving, they remain less favourable than for renal transplantation. At present, the procedure is usually undertaken only in patients with end-stage renal failure who require a combined pancreas/kidney transplantation and in whom diabetes control is particularly difficult, e.g. because of recurrent hypoglycaemia.

Transplantation of isolated pancreatic islets (usually into the liver via the portal vein) has been achieved safely in an increasing number of centres around the world. Progress is being made towards meeting the needs of supply, purification and storage of islets, but the problems of transplant rejection, and of destruction by the patient's autoantibodies against β cells, remain. Nevertheless, the development of methods of inducing tolerance to transplanted islets and the potential use of stem cells (p. 69) means that this may still prove the most promising approach in the long term.

COMPLICATIONS OF DIABETES

Despite all the treatments now available, the outcome for patients with diabetes remains disappointing. Long-term complications of diabetes still cause significant morbidity and mortality (Boxes 21.31 and 21.32).

Excess mortality in diabetes is caused mainly by large blood vessel disease, particularly myocardial infarction and stroke. Macrovascular disease also causes substantial morbidity from myocardial infarction, stroke, angina, cardiac failure and intermittent claudication. The pathological changes of atherosclerosis in diabetic patients are similar to those in the non-diabetic population but occur earlier in life and are more extensive and severe. Diabetes amplifies the effects of the other major cardiovascular risk factors: smoking, hypertension and dyslipidaemia (Fig. 21.11). Moreover, patients with type 2 diabetes are more likely to have additional cardiovascular risk factors, which co-segregate with insulin resistance in the metabolic syndrome (p. 805).

Disease of small blood vessels is a specific complication of diabetes and is termed diabetic microangiopathy. It contributes to mortality through renal failure caused

21.31 Complications of diabetes

Microvascular/neuropathic

Retinopathy, cataract
- Impaired vision

Nephropathy
- Renal failure

Peripheral neuropathy
- Sensory loss
- Pain
- Motor weakness

Autonomic neuropathy
- Gastrointestinal problems (gastroparesis; altered bowel habit)
- Postural hypotension

Foot disease
- Ulceration
- Arthropathy

Macrovascular

Coronary circulation
- Myocardial ischaemia/infarction

Cerebral circulation
- Transient ischaemic attack
- Stroke

Peripheral circulation
- Claudication
- Ischaemia

21.32 Mortality in diabetes

Risk versus non-diabetic controls (mortality ratio)

• Overall	2.6
• Coronary heart disease Cerebrovascular disease Peripheral vascular disease	2.8
• All other causes, including renal failure	2.7

Causes of death in diabetes (approximate proportion)

• Cardiovascular disease	70%
• Renal failure	10%
• Cancer	10%
• Infections	6%
• Diabetic ketoacidosis	1%
• Other	3%

Risk factors for increased morbidity and mortality in diabetes
- Duration of diabetes
- Early age at onset of disease
- High glycated haemoglobin (HbA_{1c})
- Raised blood pressure
- Proteinuria; microalbuminuria
- Dyslipidaemia
- Obesity

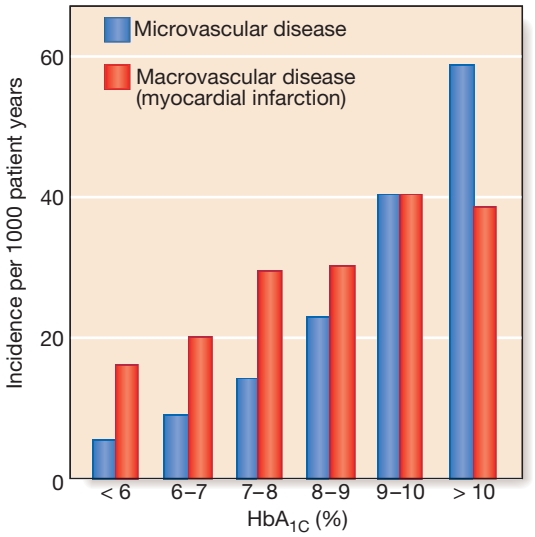

Fig. 21.11 Association between HbA_{1c} and risk of microvascular and macrovascular diabetes complications. These data were obtained amongst participants in the UK Prospective Diabetes Study and were adjusted for effects of age, sex and ethnicity; the incidences show what could be expected amongst white men aged 50–54 years at diagnosis of type 2 diabetes, followed up for 10 years. Microvascular disease included retinopathy requiring photocoagulation, vitreous haemorrhage and renal failure. Macrovascular disease included fatal and non-fatal myocardial infarction and sudden death. A 1% change in HbA_{1c} is equivalent to a reduction of 11 mmol/mol.

by diabetic nephropathy, and is responsible for substantial morbidity and disability: for example, blindness from diabetic retinopathy, difficulty in walking, chronic ulceration of the feet from peripheral neuropathy, and bowel and bladder dysfunction from autonomic neuropathy. The risk of microvascular disease is positively correlated with the duration and degree of sustained hyperglycaemia, however caused and at whatever age it develops.

Pathophysiology

The histopathological hallmark of diabetic microangiopathy is thickening of the capillary basement membrane, with associated increased vascular permeability, which occurs throughout the body. The development of the characteristic clinical syndromes of diabetic retinopathy, nephropathy, neuropathy and accelerated atherosclerosis is thought to result from the local response to generalised vascular injury. For example, in the wall of large vessels, increased permeability of arterial endothelium, particularly when combined with hyperinsulinaemia and hypertension, may increase the deposition of atherogenic lipoproteins. The mechanisms linking hyperglycaemia to these pathological changes are, however, poorly characterised.

Preventing diabetes complications

Glycaemic control

The evidence that improved glycaemic control decreases the risk of developing microvascular complications of diabetes was established by the Diabetes Control and Complications Trial (DCCT) in type 1 diabetes, and the UK Prospective Diabetes Study (UKPDS) in type 2 diabetes. The DCCT was a large study that lasted 9 years.

EBM 21.33 Glycaemic control in type 1 diabetes

'In patients with type 1 diabetes, strict glycaemic control (mean HbA_{1c} 53 mmol/mol (7%)) reduced the development of retinopathy and other microvascular complications by 76% compared with conventional therapy (mean HbA_{1c} 75 mmol/mol (9%)). On longer-term follow-up, strict glycaemic control also reduced cardiovascular events, including myocardial infarction, stroke and death from cardiovascular disease.'

- Diabetes Control and Complications Trial Research Group. N Engl J Med 1993; 329:977–986.
- Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) Study Research Group. N Engl J Med 2005; 353:2643–2653.

For further information: www.diabetes.niddk.nih.gov/dm/pubs/control/

EBM 21.34 Glycaemic control in type 2 diabetes

'In patients with type 2 diabetes, intensive glycaemic control (mean HbA_{1c} 53 mmol/mol (7%)) with oral anti-diabetic drugs or insulin reduced the development of microvascular complications, particularly retinopathy, by 25% compared with conventional treatment (mean HbA_{1c} 64 mmol/mol (8%)). On longer-term follow-up, there was a significant reduction in myocardial infarction and all-cause mortality in intensively controlled patients.'

- UKPDS Group. Lancet 1998; 352:837–853, 854–865.
- Holman RR, et al. N Engl J Med 2008; 359:1577–1589.

For further information: www.dtu.ox.ac.uk

There was a 60% overall reduction in the risk of developing diabetic complications in patients with type 1 diabetes on intensive therapy with strict glycaemic control, compared with those on conventional therapy (Box 21.33). No single factor other than glycaemic control had a significant effect on outcome. However, the group who were intensively treated to lower blood glucose had three times the rate of severe hypoglycaemia. The UKPDS showed that, in type 2 diabetes, the frequency of diabetic complications is lower and progression is slower with good glycaemic control and effective treatment of hypertension, irrespective of the type of therapy used (Box 21.34). Extrapolation from the UKPDS suggests that, for every 11 mmol/mol (1%) reduction in HbA_{1c}, there is a 21% reduction in death related to diabetes, a 14% reduction in myocardial infarction and 30–40% reduction in risk of microvascular complications (see Fig. 21.11).

These landmark trials demonstrated that diabetic complications are preventable and that the aim of treatment should be 'near-normal' glycaemia. However, more recent studies, such as the Action to Control Cardiovascular Risk in Diabetes (ACCORD), showed increased mortality in a subgroup of patients who were aggressively treated to lower HbA_{1c} to a target of less than 48 mmol/mol (6.5%). The patients in this study had poor glycaemic control at baseline, a long duration of diabetes and a high prevalence of cardiovascular disease. It appears that, whilst a low target HbA_{1c} is appropriate in younger patients with earlier diabetes who do not

21.35 Diabetes management in old age

- **Glycaemic control**: the optimal target for glycaemic control in older people has yet to be determined. Strict glycaemic control should be avoided in frail patients with comorbidities and in older patients with long duration of diabetes.
- **Cognitive function and affect**: may benefit from improving glycaemic control.
- **Hypoglycaemia**: older people have reduced symptomatic awareness of hypoglycaemia and limited knowledge of symptoms, and are at greater risk of, and from, hypoglycaemia.
- **Mortality**: the mortality rate of older people with diabetes is more than double that of age-matched non-diabetic people, largely because of increased deaths from cardiovascular disease.

have underlying cardiovascular disease, aggressive glucose-lowering is not beneficial in older patients with long duration of diabetes and multiple comorbidities (Box 21.35).

Control of other risk factors

Randomised controlled trials have shown that aggressive management of blood pressure minimises the microvascular and macrovascular complications of diabetes. Angiotensin-converting enzyme (ACE) inhibitors are valuable in improving outcome in heart disease and in treating diabetic nephropathy (p. 830). The management of dyslipidaemia with a statin limits macrovascular disease in people with diabetes (p. 456). This often results in the necessary use of multiple medications, which exacerbates the problem of adherence to therapy by patients; it is not unusual for a patient to be taking two or more diabetes therapies, two or more blood pressure drugs and a statin.

Diabetic retinopathy

Diabetic retinopathy (DR) is one of the most common causes of blindness in adults between 30 and 65 years of age in developed countries. The prevalence of DR increases with duration of diabetes, and almost all individuals with type 1 diabetes and the majority of those with type 2 diabetes will have some degree of DR after 20 years.

Pathogenesis

Hyperglycaemia increases retinal blood flow and disrupts intracellular metabolism in retinal endothelial cells and pericytes (pericytes wrap around the outside of the capillary wall and influence blood flow and capillary permeability). This leads to impaired vascular autoregulation, increased production of vasoactive substances and endothelial cell proliferation. The resulting capillary hypoperfusion and closure cause chronic retinal ischaemia, stimulating the production of growth factors, including vascular endothelial growth factor (VEGF), which further stimulates deleterious endothelial cell growth (causing new vessel formation) and increased vascular permeability (causing retinal leakage and exudation).

21.36 Risk factors for diabetic retinopathy

- Long duration of diabetes
- Poor glycaemic control
- Hypertension
- Hyperlipidaemia
- Pregnancy
- Nephropathy/renal disease
- Others: obesity, smoking

Clinical features

The major risk factors for DR are shown in Box 21.36. DR is a progressive condition, often classified into two stages: non-proliferative ('background') and proliferative. The earliest signs of non-proliferative DR are microaneurysms and retinal haemorrhages, sometimes inaccurately called 'dot' and 'blot' haemorrhages, respectively (Fig. 21.12A and B). As DR progresses and there is continuing capillary hypoperfusion, cotton wool spots, venous beading and intra-retinal microvascular abnormalities can be seen (Fig. 21.12C–E); this stage is referred to as pre-proliferative DR. The disease may then progress to proliferative DR, which is characterised by growth of new blood vessels on the retina or optic disc (Fig. 21.12F and G). The new vessels are abnormal and often bleed, leading to vitreous haemorrhage, subsequent fibrosis and scarring, and finally tractional retinal detachment.

In addition to proliferative and non-proliferative DR, patients may also develop clinically significant macular oedema (CSMO; see Fig. 21.12C). This can occur at any stage of DR and is characterised by increased vascular permeability and deposition of hard exudates in the central retina. CSMO is the most common cause of loss of vision in people with diabetes.

Proliferative retinopathy and severe ocular ischaemia may stimulate new vessels to grow on the anterior surface of the iris: 'rubeosis iridis'. These vessels may obstruct the drainage angle of the eye and the outflow of aqueous fluid, causing secondary glaucoma.

Loss of visual acuity

Microaneurysms, abnormalities of the veins, and small haemorrhages and exudates situated in the periphery will not interfere with vision. However, if these changes are observed near the macula, and in particular if they are accompanied by loss of visual acuity, CSMO should be suspected. Macular oedema can cause impairment of visual acuity even if this is associated with only mild peripheral non-proliferative retinopathy and no other obvious pathology. Macular oedema can only be confirmed or excluded on slit lamp retinal biomicroscopy.

Sudden visual loss occurs with vitreous haemorrhage or retinal detachment. In pre-proliferative and proliferative retinopathy, whether or not visual acuity is impaired, prompt laser treatment is important to reduce the risk of haemorrhage, fibrosis/gliosis and severe irreversible visual impairment.

Prevention

Glycaemic, blood pressure and lipid profile control

Many epidemiological studies have shown a clear relationship between glycaemic control and the incidence of DR. Large randomised controlled trials have shown convincingly that improved glycaemic control, particularly

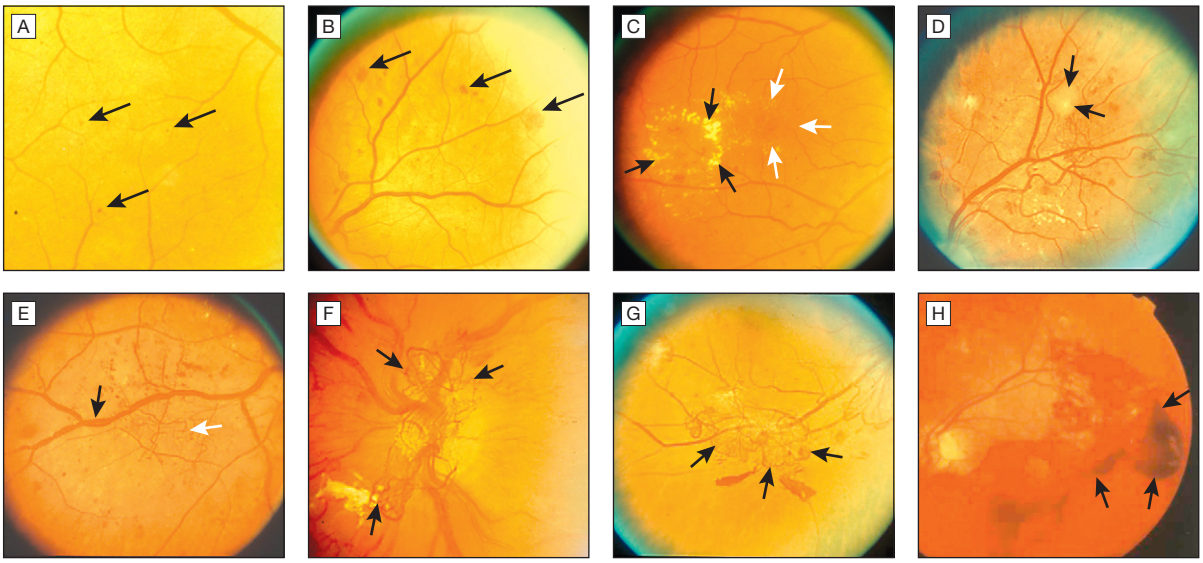

Fig. 21.12 Diabetic retinopathy. A *Microaneurysms.* Usually the earliest clinical abnormality, these tiny aneurysms arise mainly from the venous end of capillaries and appear as discrete, circular, dark red dots near to, but apparently separate from, the retinal vessels and no wider than a vessel at the optic disc margin (arrows). B *Haemorrhages.* Larger than a microaneurysm, with indistinct margins and at least as wide as a vessel at the optic disc margin, these occur in deeper layers of the retina (arrows). They result either from microaneurysms that have burst or from leaky capillaries. Superficial flame-shaped haemorrhages in the nerve fibre layer may also occur, particularly if the patient is hypertensive. C *Hard exudates.* These irregularly shaped lesions are formed from leaking of cholesterol, often through microaneurysms (black arrows). They can be associated with retinal oedema; if this affects the centre of the macula, it can cause clinically significant macular oedema (CSMO, white arrows), which is sight-threatening. D *Cotton wool spots.* These white, feathery, fluffy lesions indicate capillary infarcts within the nerve fibre layer (arrows). They are most often seen in rapidly advancing retinopathy or in association with uncontrolled hypertension. E *Venous beading.* In extensive retinal ischaemia, walls of veins develop saccular bulges, looking like a string of sausages (black arrow). Intra-retinal microvascular anomalies (IRMA) are spidery vessels, often with sharp corners that indicate dilatations of pre-existing capillaries (white arrow). F and G *Neovascularisation.* New vessel formation in response to widespread retinal ischaemia may arise from the venous circulation either on the optic *disc* (NVD, arrows in F) or *elsewhere* in the retina (NVE, arrows in G). Initially, fine tufts of delicate vessels form arcades on the surface of the retina; later, they may extend forwards on to the posterior surface of the vitreous. Leaking of serous products from new vessels stimulates a connective tissue reaction, with gliosis and fibrosis, that first appears as a white, cloudy haze among the network of new vessels and later extends to obliterate the area with a dense white sheet. H *Vitreous haemorrhage.* New vessels are fragile and liable to rupture during vitreous movement, causing a pre-retinal ('subhyaloid') or a vitreous haemorrhage (arrows), which may lead to sudden visual loss.

in the early stages of disease, reduces both the incidence and progression of DR in type 1 (see Box 21.33) and type 2 (see Box 21.34) diabetes. When blood glucose is lowered, there can be a transient deterioration of retinopathy. This relates to loss of hyperglycaemia-induced hyperperfusion in the retinal circulation and a consequent increase in ischaemia. However, this effect wears off within 18 months. Improvement in glycaemic control should therefore be effected gradually in patients with retinopathy, particularly when glycaemic control is initially poor.

Evidence from randomised controlled trials suggests that blood pressure control is also warranted to reduce the incidence and progression of DR. Early trials suggested specific benefit from angiotensin II receptor antagonists, but later studies indicate that other antihypertensive agents are similarly effective. Most guidelines recommend achieving a blood pressure of less than 130/80 mmHg. Observational studies suggest that hyperlipidaemia is a risk factor for DR, but intervention trials have not been conclusive.

Screening

Annual screening for retinopathy is essential in all diabetic patients, as the disease is asymptomatic in the early stages, when treatment is most effective. Screening is particularly important in those with risk factors. It should be undertaken by trained personnel in an organised and audited programme. The preferred method is a digital photographic system for retinal imaging, with prompt referral of patients with sight-threatening retinopathy to an ophthalmologist for examination with slit lamp biomicroscopy. If direct ophthalmoscopy is used, the pupils should be dilated for adequate examination. Unfortunately, many people with diabetes receive no regular supervision and do not attend for eye screening.

Management

Good glycaemic (HbA_{1c} around 53 mmol/mol (7%)) control and an appropriate blood pressure (< 130/80 mmHg) should be maintained to prevent onset and delay progression of diabetic eye disease. Novel agents are emerging, including ranibizumab, a monoclonal antibody fragment that binds to VEGF-A and is anti-angiogenic; it is used for diabetic macular oedema.

Retinal photocoagulation (laser treatment) is indicated in: severe proliferative or very severe non-proliferative retinopathy; new vessels elsewhere with vitreous haemorrhage; new vessels without vitreous haemorrhage in type 2 diabetes; or CSMO. Photocoagulation is used:

- to treat leaking microaneurysms and areas of retinal thickening in the macular area, and to reduce macular oedema (focal laser)

- to destroy areas of retinal ischaemia and hence lower intraocular levels of VEGF, which play a major role in the development of neovascularisation
- to reduce the risk of recurrent haemorrhage by inducing gliosis and fibrosis of new vessels (pan-retinal photocoagulation (PRP)).

Argon laser photocoagulation is the usual method. This simple procedure can be carried out under topical anaesthesia. Patients should be reviewed regularly to look for further development of new vessels and/or maculopathy. Extensive bilateral photocoagulation can cause significant visual field loss, which may interfere with driving ability and reduce night vision.

Vitrectomy is used in selected cases of advanced diabetic eye disease due to type 1 diabetes where visual loss has been caused by recurrent vitreous haemorrhage that has failed to clear or by tractional retinal detachment threatening the macula. The value of vitrectomy in type 2 diabetes is less certain. Rubeosis iridis is a severe complication requiring early and extensive PRP.

Other causes of visual loss in people with diabetes

Around 50% of visual loss in people with type 2 diabetes results from causes other than diabetic retinopathy. These include cataract, age-related macular degeneration, retinal vein occlusion, retinal arterial occlusion, non-arteritic ischaemic optic neuropathy and glaucoma. Some of these conditions are to be expected in this group, as they relate to cardiovascular risk factors (e.g. hypertension, hyperlipidaemia and smoking), all of which are prevalent in people with type 2 diabetes.

Cataract

Cataract is a permanent lens opacity and is a common cause of visual deterioration in the elderly. The lens thickens and opacifies with age; with diabetes, the increased metabolic insult to the lens causes these changes to accelerate and occur prematurely. A rare type of 'snow-flake' cataract occurs in young patients with poorly controlled diabetes. This does not usually affect vision but tends to make fundal examination difficult.

The indications for cataract extraction are similar to those for the non-diabetic population and depend on the degree of visual impairment. An additional indication in diabetes is when adequate assessment of the fundus, or laser treatment to the retina, is prevented.

Diabetic nephropathy

Diabetic nephropathy is an important cause of morbidity and mortality, and is now among the most common causes of end-stage renal failure in developed countries. About 30% of patients with type 1 diabetes have developed diabetic nephropathy 20 years after diagnosis, but the risk after this time falls to less than 1% per year, and from the outset the risk is not equal in all patients (Box 21.37). Indeed, some patients do not develop nephropathy, despite having long-standing, poorly controlled diabetes, suggesting that they are genetically protected from it. Whilst variants in a few genes have been implicated in diabetic nephropathy, the major differences in individual risk remain unexplained. Epidemiological data have indicated that the overall incidence is declining as standards of glycaemic and blood pressure control have improved.

21.37 Risk factors for diabetic nephropathy

- Poor glycaemic control
- Long duration of diabetes
- Presence of other microvascular complications
- Ethnicity (e.g. Asians, Pima Indians)
- Pre-existing hypertension
- Family history of diabetic nephropathy
- Family history of hypertension

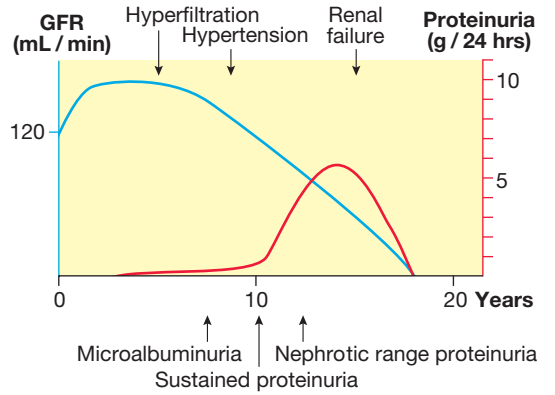

Fig. 21.13 Natural history of diabetic nephropathy. In the first few years of type 1 diabetes mellitus, there is hyperfiltration, which declines fairly steadily to return to a normal value at approximately 10 years (blue line). In susceptible patients (about 30%), after about 10 years, there is sustained proteinuria, and by approximately 14 years it has reached the nephrotic range (red line). Renal function continues to decline, with the end stage being reached at approximately 16 years.

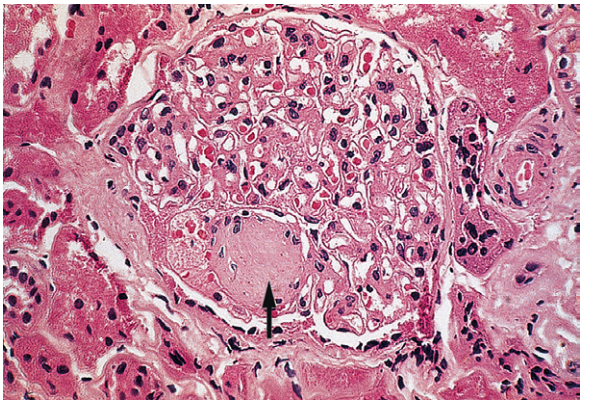

Fig. 21.14 Nodular diabetic glomerulosclerosis. There is thickening of basement membranes and mesangial expansion, and a Kimmelstiel–Wilson nodule (arrow), which is pathognomonic of diabetic kidney disease.

The pattern of progression of renal abnormalities in diabetes is shown schematically in Figure 21.13. Pathologically, the first changes coincide with the onset of microalbuminuria and include thickening of the glomerular basement membrane and accumulation of matrix material in the mesangium. Subsequently, nodular deposits (Fig. 21.14) are characteristic, and glomerulosclerosis worsens as heavy proteinuria develops, until

21.38 Screening for microalbuminuria

- Identifies incipient nephropathy in type 1 and type 2 diabetes; is an independent predictor of macrovascular disease in type 2 diabetes
- Risk factors include high blood pressure, poor glycaemic control, smoking
- Who to screen:
  - Patients with type 1 diabetes annually from 5 yrs after diagnosis
  - Patients with type 2 diabetes annually from time of diagnosis
- Early morning urine measured for albumin : creatinine ratio (ACR). Microalbuminuria present if:
  - Males ACR 2.5–30 mg/mmol creatinine
  - Females ACR 3.5–30 mg/mmol creatinine
- An elevated ACR should be followed by a repeat test:
  - Established microalbuminuria if 2 out of 3 tests positive
  - An ACR > 30 mg/mmol creatinine is consistent with overt nephropathy

glomeruli are progressively lost and renal function deteriorates.

Diagnosis and screening

Microalbuminuria (Box 21.38) is the presence in the urine of small amounts of albumin, at a concentration below that detectable using a standard urine dipstick. Overt nephropathy is defined as the presence of macroalbuminuria (albumin to creatinine ratio (ACR) > 300 mg/mmol; detectable on urine dipstick). Microalbuminuria is a good predictor of progression to nephropathy in type 1 diabetes. It is a less reliable predictor of nephropathy in older patients with type 2 diabetes, in whom it may be accounted for by other diseases (p. 476), although it is a potentially useful marker of an increased risk of macrovascular disease.

Management

The presence of established microalbuminuria or overt nephropathy should prompt vigorous efforts to reduce the risk of progression of nephropathy and of cardiovascular disease by:

- aggressive reduction of blood pressure
- aggressive cardiovascular risk factor reduction (Box 21.39).

In type 1 diabetes, ACE inhibitors have been shown to provide greater protection than equal blood pressure reduction achieved with other drugs (p. 611), and subsequent studies have shown similar benefits from angiotensin II receptor blockers (ARBs) in patients with type 2 diabetes. This benefit from blockade of the renin–angiotensin system arises from a reduction in the angiotensin II-mediated vasoconstriction of efferent arterioles in glomeruli (see Fig 17.1D, p. 465). The resulting dilatation of these vessels decreases glomeruli filtration pressure and therefore the hyperfiltration and protein leak. Both ACE inhibitors and ARBs increase risk of hyperkalaemia (p. 442) and, in the presence of renal artery stenosis (p. 494), may induce marked deterioration in renal function. Therefore, electrolytes and renal function should be checked after initiation or each dose increase. Non-dihydropyridine calcium antagonists (diltiazem, verapamil) may be suitable alternatives.

EBM 21.39 Multiple risk factor intervention in type 2 diabetes

'In type 2 patients with microalbuminuria, intensive treatment (including control of glycaemia and hypertension, with use of ACE inhibitors, statins and aspirin) reduced the risk of cardiovascular disease by 53%, of nephropathy by 61%, and of retinopathy by 58% compared with conventional treatment. On longer-term follow-up, there was a reduction in total mortality and death from cardiovascular causes.'

- Gaede P, et al. N Engl J Med 2003; 348:383–393.
- Gaede P, et al. N Engl J Med 2008; 358:580–591.

Halving the amount of albuminuria with an ACE or ARB results in a nearly 50% reduction in long-term risk of progression to end-stage renal disease. However, some patients do progress, with worsening renal function. Renal replacement therapy (p. 488) may benefit diabetic patients at an earlier stage than other patients with end-stage renal failure.

Renal transplantation dramatically improves the life of many, and any recurrence of diabetic nephropathy in the allograft is usually too slow to be a serious problem, but associated macrovascular and microvascular disease elsewhere may still progress. Pancreatic transplantation (generally carried out at the same time as renal transplantation) can produce insulin independence and delay or reverse microvascular disease, but the supply of organs is limited and this option is available to few. For further information on management, see Chapter 17.

Diabetic neuropathy

Although there is some evidence that the central nervous system is affected in long-term diabetes, the clinical impact of diabetes is mainly manifest in the peripheral nervous system. Diabetic neuropathy causes substantial morbidity and increases mortality. It is diagnosed on the basis of symptoms and signs, and after the exclusion of other causes of neuropathy (p. 1223). Depending on the criteria used for diagnosis, it affects between 50 and 90% of patients with diabetes, and of these, 15–30% will have painful diabetic neuropathy (PDN). Like retinopathy, neuropathy occurs secondary to metabolic disturbance, and prevalence is related to the duration of diabetes and the degree of metabolic control.

Pathological features can occur in any peripheral nerves. They include axonal degeneration of both myelinated and unmyelinated fibres, with thickening of the Schwann cell basal lamina, patchy segmental demyelination, and abnormal intraneural capillaries (with basement membrane thickening and microthrombi).

Various classifications of diabetic neuropathy have been proposed. One is shown in Box 21.40, but motor, sensory and autonomic nerves may be involved in varying combinations so that clinically mixed syndromes usually occur.

Clinical features

Symmetrical sensory polyneuropathy

This is frequently asymptomatic. The most common clinical signs are diminished perception of vibration

21.40 Classification of diabetic neuropathy

Somatic

- Polyneuropathy
  - Symmetrical, mainly sensory and distal
  - Asymmetrical, mainly motor and proximal (including amyotrophy)
- Mononeuropathy (including mononeuritis multiplex)

Visceral (autonomic)

- Cardiovascular
- Gastrointestinal
- Genitourinary
- Sudomotor
- Vasomotor
- Pupillary

sensation distally, 'glove and stocking' impairment of all other modalities of sensation (see Fig. 21.15), and loss of tendon reflexes in the lower limbs. In symptomatic patients, sensory abnormalities are predominant. Symptoms include paraesthesiae in the feet (and, rarely, in the hands), pain in the lower limbs (dull, aching and/or lancinating, worse at night, and mainly felt on the anterior aspect of the legs), burning sensations in the soles of the feet, cutaneous hyperaesthesia and an abnormal gait (commonly wide-based), often associated with a sense of numbness in the feet. Weakness and atrophy, in particular of the interosseous muscles, may develop, leading to structural changes in the foot with loss of lateral and transverse arches, clawing of the toes and exposure of the metatarsal heads. This results in increased pressure on the plantar aspects of the metatarsal heads, with the development of callus skin at these and other pressure points. Electrophysiological tests (p. 1151) demonstrate slowing of both motor and sensory conduction, and tests of vibration sensitivity and thermal thresholds are abnormal.

A diffuse small-fibre neuropathy causes altered perception of pain and temperature, and is associated with symptomatic autonomic neuropathy; characteristic features include foot ulcers and Charcot neuroarthropathy.

Asymmetrical motor diabetic neuropathy

Sometimes called diabetic amyotrophy, this presents as severe and progressive weakness and wasting of the proximal muscles of the lower (and occasionally the upper) limbs. It is commonly accompanied by severe pain, mainly felt on the anterior aspect of the leg, and hyperaesthesia and paraesthesiae. Sometimes there may also be marked loss of weight ('neuropathic cachexia'). The patient may look extremely ill and be unable to get out of bed. Tendon reflexes may be absent on the affected side(s). Sometimes there are extensor plantar responses and the cerebrospinal fluid protein is often raised. This condition is thought to involve acute infarction of the lower motor neurons of the lumbosacral plexus. Other lesions involving this plexus, such as neoplasms and lumbar disc disease, must be excluded. Although recovery usually occurs within 12 months, some deficits are permanent. Management is mainly supportive.

Mononeuropathy

Either motor or sensory function can be affected within a single peripheral or cranial nerve. Unlike the gradual progression of distal symmetrical and autonomic neuropathies, mononeuropathies are severe and of rapid onset, but they eventually recover. The nerves most commonly affected are the 3rd and 6th cranial nerves (resulting in diplopia), and the femoral and sciatic nerves. Rarely, involvement of other single nerves results in paresis and paraesthesiae in the thorax and trunk (truncal radiculopathies).

Nerve compression palsies are more common in diabetes, frequently affecting the median nerve, giving the clinical picture of carpal tunnel syndrome, and less commonly the ulnar nerve. Lateral popliteal nerve compression occasionally causes foot drop. Compression palsies may be more common because of glycosylation and thickening of connective tissue and/or because of increased susceptibility of nerves affected by diabetic microangiopathy.

Autonomic neuropathy

This is not necessarily associated with peripheral somatic neuropathy. Parasympathetic or sympathetic nerves may be predominantly affected in one or more visceral systems. The resulting symptoms and signs are listed in Box 21.41 and tests of autonomic function in Box 21.42. The development of autonomic neuropathy is less clearly related to poor metabolic control than somatic neuropathy, and improved control rarely results in improved symptoms. Within 10 years of developing overt symptoms of autonomic neuropathy, 30–50% of patients are dead, many from sudden cardiorespiratory arrest. Patients with postural hypotension (a drop in systolic pressure of 30 mmHg or more on standing from the supine position) have the highest subsequent mortality.

21.41 Clinical features of autonomic neuropathy

Cardiovascular

- Postural hypotension
- Resting tachycardia
- Fixed heart rate

Gastrointestinal

- Dysphagia, due to oesophageal atony
- Abdominal fullness, nausea and vomiting, unstable glycaemia, due to delayed gastric emptying ('gastroparesis')
- Nocturnal diarrhoea ± faecal incontinence
- Constipation, due to colonic atony

Genitourinary

- Difficulty in micturition, urinary incontinence, recurrent infection, due to atonic bladder
- Erectile dysfunction and retrograde ejaculation

Sudomotor

- Nocturnal sweats without hypoglycaemia
- Gustatory sweating
- Anhidrosis; fissures in the feet

Vasomotor

- Feet feel cold, due to loss of skin vasomotor responses
- Dependent oedema, due to loss of vasomotor tone and increased vascular permeability
- Bullous formation

Pupillary

- Decreased pupil size
- Resistance to mydriatics
- Delayed or absent reflexes to light

21.42 How to test cardiovascular autonomic function

Simple reflex tests

	Normal	Borderline	Abnormal
Heart rate responses			
To Valsalva manœuvre (15 secs)[1]: ratio of longest to shortest R–R interval	≥ 1.21		≤ 1.20
To deep breathing (6 breaths over 1 min): maximum–minimum heart rate	≥ 15	11–14	≤ 10
To standing after lying: ratio of R–R interval of 30th to 15th beats	≥ 1.04	1.01–1.03	≤ 1.00
Blood pressure response[2]			
To standing: systolic BP fall (mmHg)	≤ 10	11–29	≥ 30

Specialised tests

- Heart rate and blood pressure responses to sustained handgrip
- Heart rate variability using power spectral analysis of ECG monitoring
- Heart rate and blood pressure variability using time–domain analysis of ambulatory monitoring
- MIBG (met-iodobenzylguanidine) scan of the heart

[1]Omit in patients with previous laser therapy for proliferative retinopathy.
[2]Avoid arm with arteriovenous fistula in dialysed patients.

21.43 Management options for peripheral sensorimotor and autonomic neuropathies

Pain and paraesthesiae from peripheral somatic neuropathies

- Intensive insulin therapy (strict glycaemic control)
- Anticonvulsants (gabapentin, pregabalin, carbamazepine, phenytoin)
- Tricyclic antidepressants (amitriptyline, imipramine)
- Other antidepressants (duloxetine)
- Substance P depleter (capsaicin – topical)
- Opiates (tramadol, oxycodone)
- Membrane stabilisers (mexiletine, IV lidocaine)
- Antioxidant (α-lipoic acid)

Postural hypotension

- Support stockings
- Fludrocortisone
- NSAIDs
- α-adrenoceptor agonist (midodrine)

Gastroparesis

- Dopamine antagonists (metoclopramide, domperidone)
- Erythromycin
- Gastric pacemaker; percutaneous enteral (jejunal) feeding (see Fig. 5.17, p. 123)

Diarrhoea (p. 857)

- Loperamide
- Broad-spectrum antibiotics
- Clonidine
- Octreotide

Constipation

- Stimulant laxatives (senna)

Atonic bladder

- Intermittent self-catheterisation (p. 1175)

Excessive sweating

- Anticholinergic drugs (propantheline, poldine, oxybutinin)
- Clonidine
- Topical antimuscarinic agent (glycopyrrolate cream)

Erectile dysfunction (p. 474)

- Phosphodiesterase type 5 inhibitors (sildenafil, vardenafil, tadalafil) – oral
- Dopamine agonist (apomorphine) – sublingual
- Prostaglandin E1 (alprostadil) – injected into corpus cavernosum or intra-urethral administration of pellets
- Vacuum tumescence devices
- Implanted penile prosthesis
- Psychological counselling; psychosexual therapy

(NSAIDs = non-steroidal anti-inflammatory drugs)

Erectile dysfunction

Erectile failure (impotence) affects 30% of diabetic males and is often multifactorial. Although neuropathy and vascular causes are common, psychological factors, including depression, anxiety and reduced libido, may be partly responsible. Alcohol and antihypertensive drugs, such as thiazide diuretics and β-adrenoceptor antagonists (β-blockers), may cause sexual dysfunction and patients have an endocrine cause such as testosterone deficiency or hyperprolactinaemia. For further information, see page 474.

Management

Management of neuropathies is outlined in Box 21.43.

The diabetic foot

The foot is a frequent site of complications in patients with diabetes and for this reason foot care is particularly important. Tissue necrosis in the feet is a common reason for hospital admission in diabetic patients. Treatment of the foot complications of diabetes accounts for more inpatient days than any other diabetes-related complication.

Aetiology

Foot ulceration occurs as a result of trauma (often trivial) in the presence of neuropathy and/or peripheral vascular disease (see p. 600 and Fig. 21.15), with infection occurring as a secondary phenomenon following disruption of the protective epidermis. Most ulcers develop at the site of a plaque of callus skin, beneath which tissue necrosis occurs and eventually breaks through to the surface. In many cases, multiple components are involved, but sometimes neuropathy or ischaemia predominates, as illustrated in Box 21.44. Ischaemia alone accounts for a minority of foot ulcers in diabetic patients, with most being either neuropathic or neuro-ischaemic.

Charcot neuro-arthropathy is a progressive condition affecting the bones and joints of the foot; it is characterised by early inflammation and then joint dislocation, subluxation, and pathological fractures of the foot of

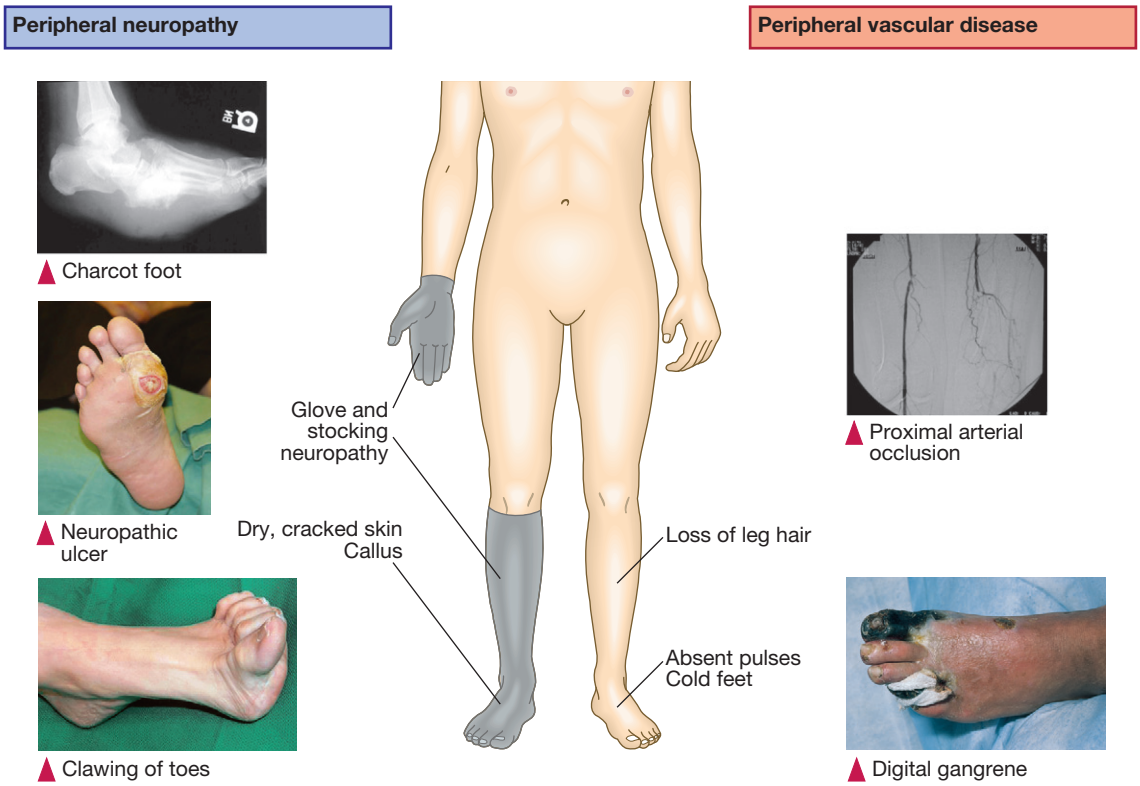

Fig. 21.15 Diabetic foot disease. Patients with diabetes can have neuropathy, peripheral vascular disease or both. Clawing of the toes is thought to be caused by intrinsic muscle atrophy and subsequent imbalance of muscle function, and causes increased pressure on the metatarsal heads and pressure on flexed toes, leading to increased callus and risk of ulceration. A Charcot foot occurs only in the presence of neuropathy, and results in bony destruction and ultimately deformity (this X-ray shows a resulting 'rocker bottom foot'). The angiogram shows disease of the superficial femoral arteries (occlusion of the left and stenosis of the right). *Insets* (*Proximal arterial occlusion*) From Medscape; (*Toe clawing*) Bowker and Pfeifer 2008; (*Neuropathic foot ulcer*) Levy and Valabhji 2008; (*Digital gangrene*) Swartz 2006 – see p. 836.

21.44 Clinical features of the diabetic foot

	Neuropathy	Ischaemia
Symptoms	None Paraesthesiae Pain Numbness	None Claudication Rest pain
Structural damage	Ulcer Sepsis Abscess Osteomyelitis Digital gangrene Charcot joint	Ulcer Sepsis Gangrene

neuropathic patients, often resulting in debilitating deformity (see Fig. 21.15 and p. 798). Charcot neuroarthropathy can arise in any condition that causes neuropathy (including syphilis, spinal cord injury, syringomyelia and so on) but diabetes is the most common cause. The pathophysiological mechanisms remain poorly understood, but may involve unperceived trauma leading to progressive destruction (the 'neurotraumatic' theory), and/or increased blood flow resulting in a mismatch of bone destruction and synthesis (the 'neurovascular' theory). More recent evidence points to disordered inflammation mediated via the nuclear factor kappa B (NFκB)/receptor activator of NFκB ligand (RANKL) pathway, opening the way for trials of the RANKL inhibitor, denosumab (p. 1124).

Management

Management can be divided into primary prevention and treatment of an active problem. All patients should be educated in preventive measures (Box 21.45). The feet of patients with diabetes should be screened annually, following the steps listed on page 799. Two simple tests are required to grade a patient's risk: a 10 g monofilament should be used to assess sensation at five points on each foot, and foot pulses should be palpated (dorsalis pedis and/or posterior tibial). Combined with the clinical scenario, these tests guide appropriate referral and monitoring (Fig. 21.16). Removal of callus skin with a scalpel is usually best done by a podiatrist who has specialist training and experience in diabetic foot problems.

Foot ulcer

Once a foot ulcer develops, patients should ideally be referred to a multidisciplinary foot team, involving a diabetes specialist, a podiatrist, a vascular surgeon and an orthotist. Treatment involves: débridement of dead tissue; prompt, often prolonged, treatment with antibiotics if required, as infection can accelerate tissue necrosis and lead to gangrene; pressure relief using dressings; use of specialised bespoke orthotic footwear;

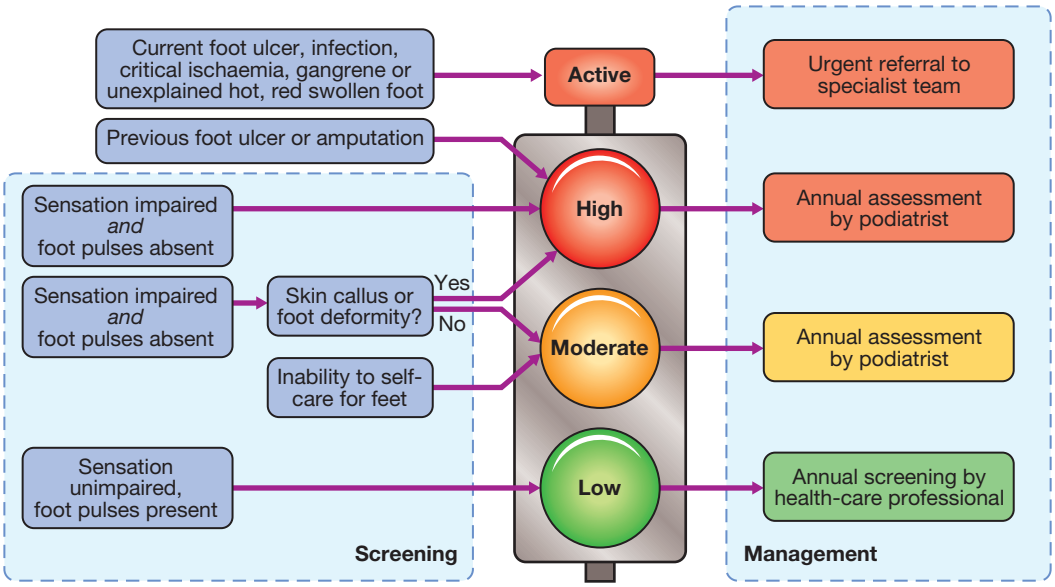

Fig. 21.16 **Risk assessment and management of foot problems in diabetes.** Adapted from SIGN 116 – see p. 836.

21.45 Care of the feet in patients with diabetes

- Preventive advice to all diabetic patients includes:
  - Inspect feet every day
  - Wash feet every day
  - Moisturise skin if dry
  - Cut or file toenails regularly
  - Change socks or stockings every day
  - Avoid walking barefoot
  - Check footwear for foreign bodies
  - Wear suitable, well-fitting shoes
  - Cover minor cuts with sterile dressings
  - Do not burst blisters
  - Avoid over-the-counter corn/callus remedies
- Advice to moderate- and high-risk patients is as above plus:
  - Do not attempt corn removal
  - Avoid high and low temperatures
- A podiatrist is an integral part of the diabetes team to ensure regular and effective podiatry and to educate patients in care of the feet
- Specially manufactured and fitted orthotic footwear is required to prevent recurrence of ulceration and to protect the feet of patients with Charcot neuroarthropathy

and sometimes total contact plaster cast or irremovable aircast boot. If an ulcer is neuro-ischaemic, a vascular assessment is often carried out, by ultrasound or angiography, as revascularisation by angioplasty or surgery may be required to allow the ulcer to heal. In cases of severe secondary infection or gangrene, an amputation may be required. This can be limited to the affected toe or involve more extensive limb amputation.

Charcot foot

Acute Charcot arthropathy almost always presents with signs of inflammation – a hot, red, swollen foot. Initial X-ray may show bony destruction but is often normal. As about 40% of patients with a Charcot joint also have a foot ulcer, it can be difficult to differentiate from osteomyelitis. Magnetic resonance imaging (MRI) of the foot is often helpful. The mainstay of treatment for an active Charcot foot is immobilisation and, ideally, avoidance of weight-bearing on the affected foot. The rationale is that if no pressure is applied through the foot, the destructive process involving the bones will not result in significant deformity when the acute inflammatory process subsides. Immobilisation is often achieved by a total contact plaster cast or 'aircast' boot. The acute phase often lasts 3–6 months and sometimes longer. In the post-acute phase, there is consolidation and remodelling of fracture fragments, eventually resulting in a stable foot.

Diseases of the gastrointestinal tract are a major cause of morbidity and mortality. Approximately 10% of all general practitioner consultations in the United Kingdom are for indigestion, and 1 in 14 is for diarrhoea. Infective diarrhoea and malabsorption are responsible for much ill health and many deaths in the developing world. The gastrointestinal tract is the most common site for cancer development. Colorectal cancer is the second most common cancer in men, and population-based screening programmes exist in many countries. Functional bowel disorders affect up to 10–15% of the population and consume considerable health-care resources. The inflammatory bowel diseases, Crohn's disease and ulcerative colitis, together affect 1 in 250 people in the Western world, with substantial associated morbidity.

FUNCTIONAL ANATOMY AND PHYSIOLOGY

Oesophagus, stomach and duodenum

This muscular tube extends 25 cm from the cricoid cartilage to the cardiac orifice of the stomach. It has an upper and a lower sphincter. A peristaltic swallowing wave propels the food bolus into the stomach (Fig. 22.1).

The stomach acts as a 'hopper', retaining and grinding food, then actively propelling it into the upper small bowel (Fig. 22.2).

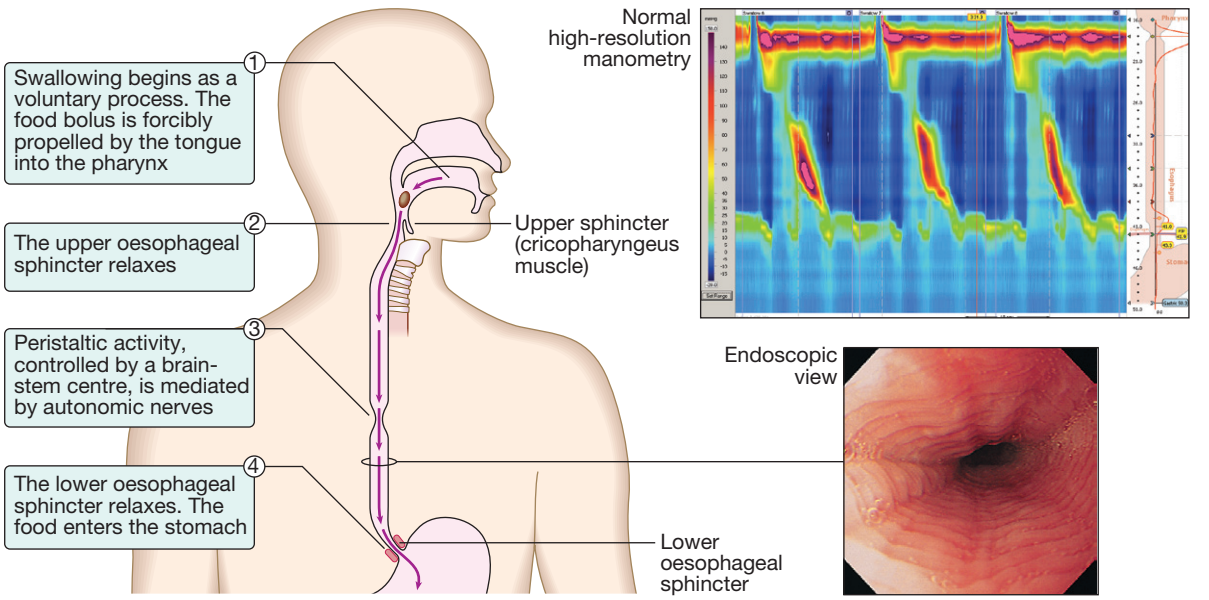

Fig. 22.1 The oesophagus: anatomy and function. The swallowing wave.

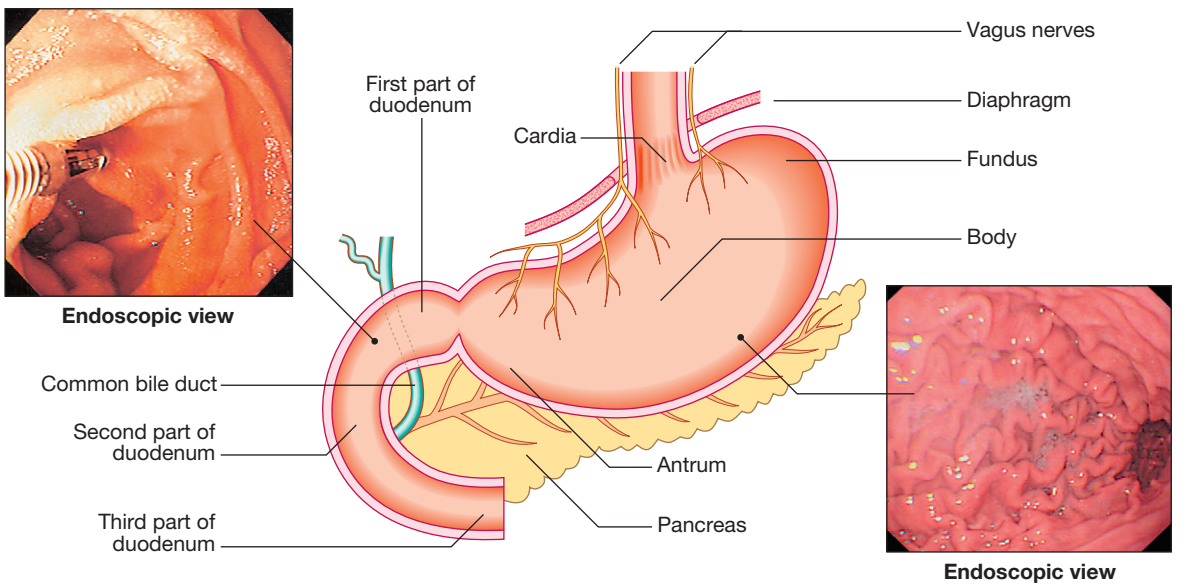

Fig. 22.2 Normal gastric and duodenal anatomy.

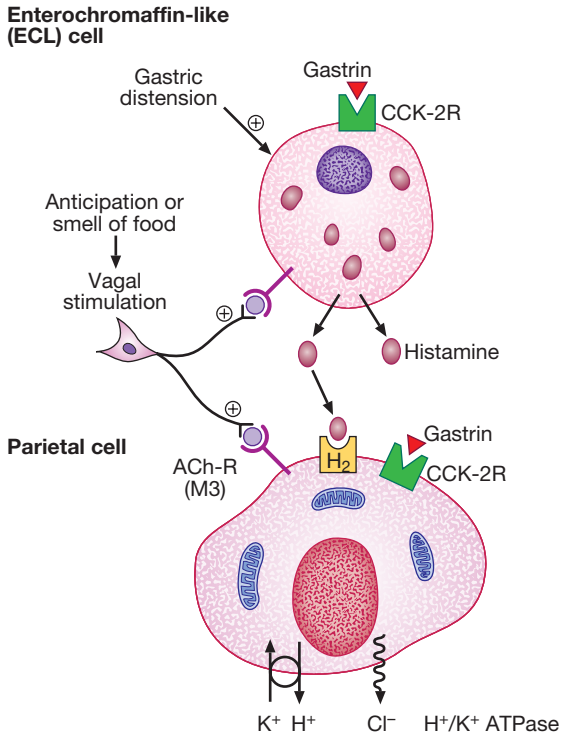

Fig. 22.3 Control of acid secretion. Gastrin released from antral G cells in response to food (protein) binds to cholecystokinin receptors (CCK-2R) on the surface of enterochromaffin-like (ECL) cells, which in turn release histamine. The histamine binds to H_2 receptors on parietal cells and this leads to secretion of hydrogen ions, in exchange for potassium ions at the apical membrane. Parietal cells also express CCK-2R and it is thought that activation of these receptors by gastrin is involved in regulatory proliferation of parietal cells. Cholinergic (vagal) activity and gastric distension also stimulate acid secretion; somatostatin, vasoactive intestinal polypeptide (VIP) and gastric inhibitory polypeptide (GIP) may inhibit it. (ACh-R = acetylcholine receptor; ATPase = adenosine triphosphatase)

Gastric secretion

Gastrin, histamine and acetylcholine are the key stimulants of acid secretion. Hydrogen and chloride ions are secreted from the apical membrane of gastric parietal cells into the lumen of the stomach by a hydrogen–potassium adenosine triphosphatase (ATPase) ('proton pump') (Fig. 22.3). The hydrochloric acid sterilises the upper gastrointestinal tract and converts pepsinogen – which is secreted by chief cells – to pepsin. The glycoprotein intrinsic factor, secreted in parallel with acid, is necessary for vitamin B_{12} absorption.

Gastrin, somatostatin and ghrelin

The hormone gastrin is produced by G cells in the antrum, whereas somatostatin is secreted from D cells throughout the stomach. Gastrin stimulates acid secretion and mucosal growth, whilst somatostatin suppresses it. Ghrelin, secreted from oxyntic glands, stimulates acid secretion but also appetite and gastric emptying.

Protective factors

Bicarbonate ions, stimulated by prostaglandins, mucins and trefoil factor family (TFF) peptides together protect the gastroduodenal mucosa from the ulcerative properties of acid and pepsin.

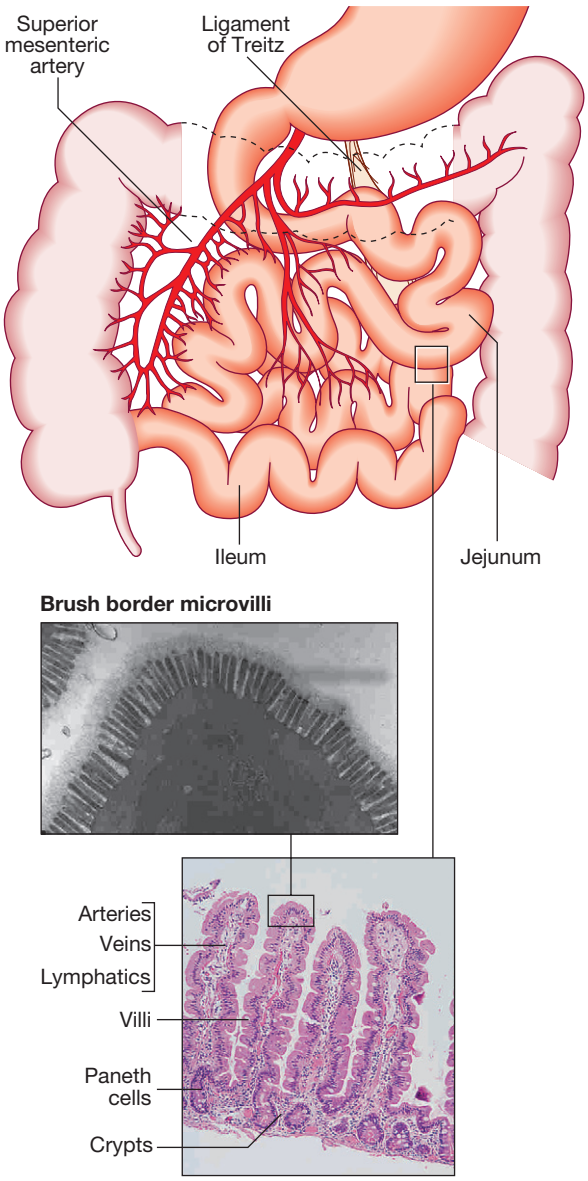

Fig. 22.4 Small intestine: anatomy. Epithelial cells are formed in crypts and differentiate as they migrate to the tip of the villi to form enterocytes (absorptive cells) and goblet cells.

Small intestine

The small bowel extends from the ligament of Treitz to the ileocaecal valve (Fig. 22.4). During fasting, a wave of peristaltic activity passes down the small bowel every 1–2 hours. Entry of food into the gastrointestinal tract stimulates small bowel peristaltic activity. Functions of the small intestine are:

- digestion (mechanical, enzymatic and peristaltic)
- absorption – the products of digestion, water, electrolytes and vitamins
- protection against ingested toxins
- immune regulation.

Digestion and absorption

Fat

Dietary lipids comprise long-chain triglycerides, cholesterol esters and lecithin. Lipids are insoluble in water

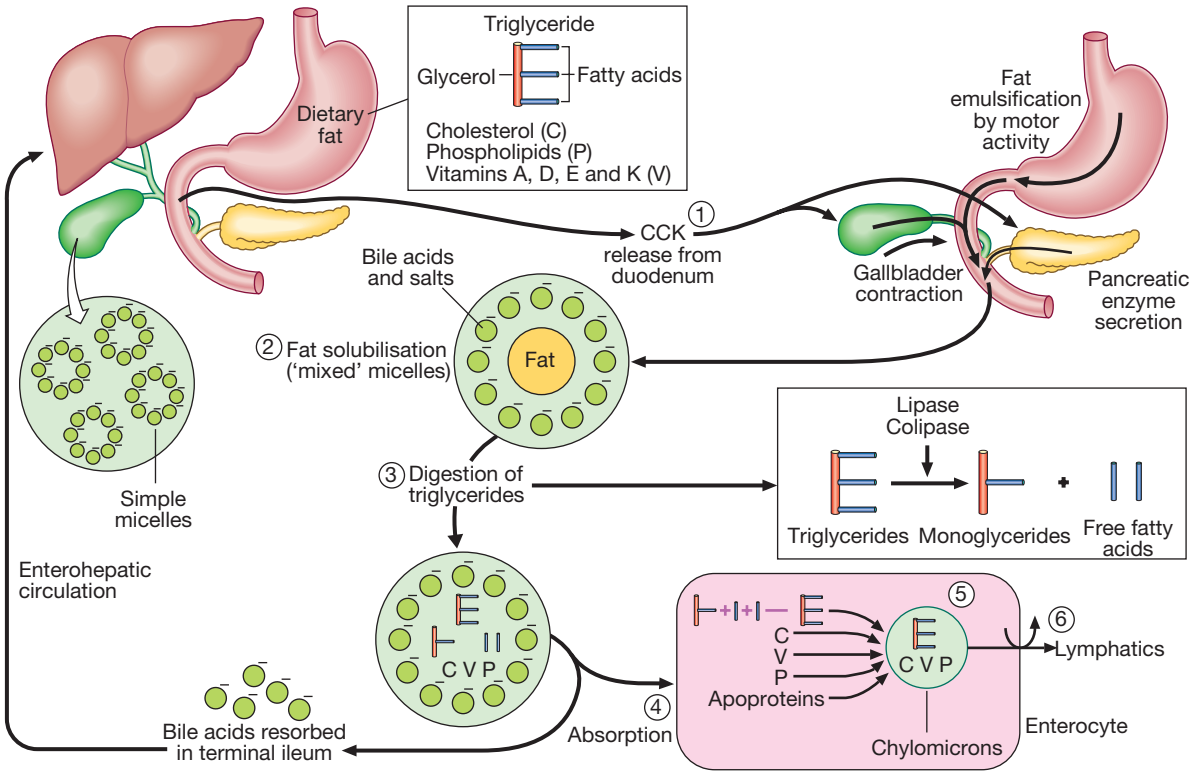

Fig. 22.5 Fat digestion. *Step 1: Luminal phase.* Fatty acids stimulate cholecystokinin (CCK) release from the duodenum and upper jejunum. The CCK stimulates release of amylase, lipase, colipase and proteases from the pancreas, causes gallbladder contraction and relaxes the sphincter of Oddi, leading bile to flow into the intestine. *Step 2: Fat solubilisation.* Bile acids and salts combine with dietary fat to form mixed micelles, which also contain cholesterol and fat-soluble vitamins. *Step 3: Digestion.* Pancreatic lipase, in the presence of its co-factor, colipase, cleaves long-chain triglycerides, yielding fatty acids and monoglycerides. *Step 4: Absorption.* Mixed micelles diffuse to the brush border of the enterocytes. Within the brush border, long-chain fatty acids bind to proteins, which transport the fatty acids into the cell, whereas cholesterol, short-chain fatty acids, phospholipids and fat-soluble vitamins enter the cell directly. The bile salts remain in the small intestinal lumen and are actively transported from the terminal ileum into the portal circulation and returned to the liver (the enterohepatic circulation). *Step 5: Re-esterification.* Within the enterocyte, fatty acids are re-esterified to form triglycerides. Triglycerides combine with cholesterol ester, fat-soluble vitamins, phospholipids and apoproteins to form chylomicrons. *Step 6: Transport.* Chylomicrons leave the enterocytes by exocytosis, enter mesenteric lymphatics, pass into the thoracic duct, and eventually reach the systemic circulation.

and undergo lipolysis and incorporation into mixed micelles before they can be absorbed into enterocytes along with the fat-soluble vitamins A, D, K and E. The lipids are processed within enterocytes and pass via lymphatics into the systemic circulation. Fat absorption and digestion can be considered as a stepwise process, as outlined in Figure 22.5.

Carbohydrates

Starch is hydrolysed by salivary and pancreatic amylases to alpha-limit dextrins containing 4–8 glucose molecules; to the disaccharide, maltose; and to the trisaccharide, maltotriose.

Disaccharides are digested by enzymes fixed to the microvillous membrane to form the monosaccharides, glucose, galactose and fructose. Glucose and galactose enter the cell by an energy-requiring process involving a carrier protein, and fructose enters by simple diffusion.

Protein

The steps involved in protein digestion are shown in Figure 22.6. Intragastric digestion by pepsin is quantitatively modest but important because the resulting polypeptides and amino acids stimulate CCK release from the mucosa of the proximal jejunum, which in turn stimulates release of pancreatic proteases, including trypsinogen, chymotrypsinogen, pro-elastases and procarboxypeptidases, from the pancreas. On exposure to brush border enterokinase, inert trypsinogen is converted to the active proteolytic enzyme trypsin, which activates the other pancreatic proenzymes. Trypsin digests proteins to produce oligopeptides, peptides and amino acids. Oligopeptides are further hydrolysed by brush border enzymes to yield dipeptides, tripeptides and amino acids. These small peptides and the amino acids are actively transported into the enterocytes, where intracellular peptidases further digest peptides to amino acids. Amino acids are then actively transported across the basal cell membrane of the enterocyte into the portal circulation and the liver.

Water and electrolytes

Absorption and secretion of electrolytes and water occur throughout the intestine. Electrolytes and water are transported by two pathways:

- *the paracellular route,* in which passive flow through tight junctions between cells is a consequence of osmotic, electrical or hydrostatic gradients
- *the transcellular route* across apical and basolateral membranes by energy-requiring specific active transport carriers (pumps).

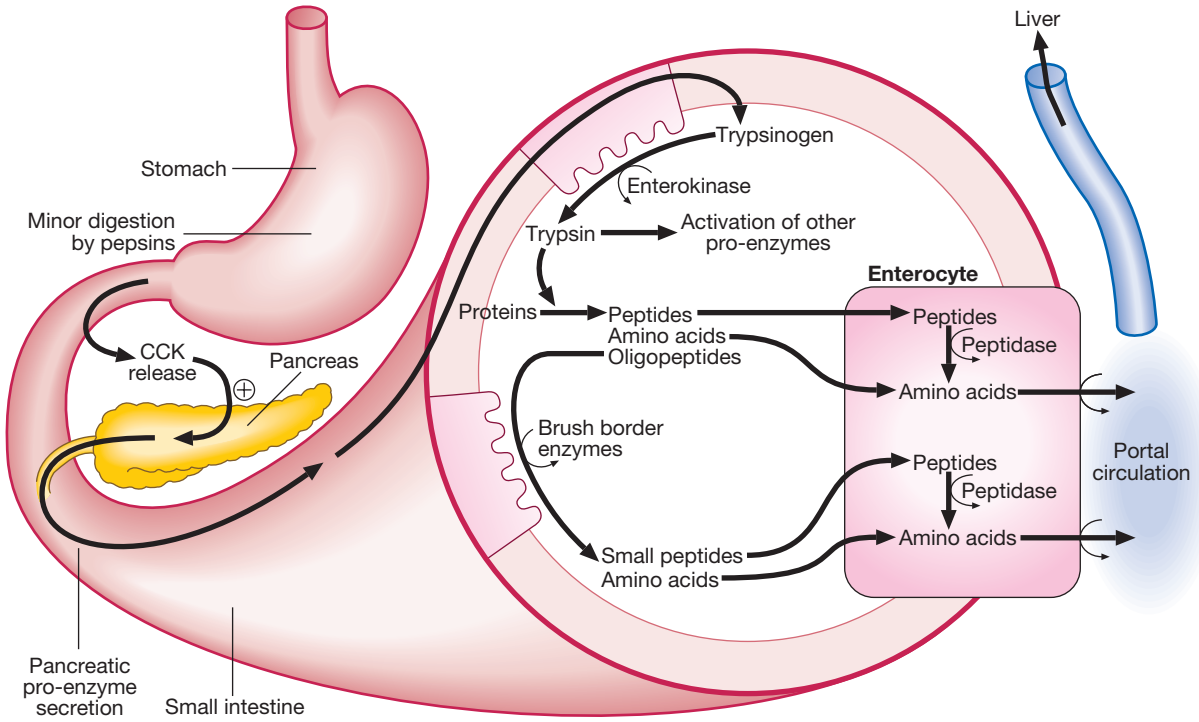

Fig. 22.6 Protein digestion.

In healthy individuals, fluid balance is tightly controlled, such that only 100 mL of the 8 litres of fluid entering the gastrointestinal tract daily is excreted in stools (Fig. 22.7).

Vitamins and trace elements

Water-soluble vitamins are absorbed throughout the intestine. The absorption of folic acid, vitamin B_{12}, calcium and iron is described on page 1024.

Protective function of the small intestine

Physical defence mechanisms

There are several levels of defence in the small bowel (Fig. 22.8). Firstly, the gut lumen contains host bacteria, mucins and secreted antibacterial products, including defensins and immunoglobulins which help combat pathogenic infections. Secondly, epithelial cells have relatively impermeable brush border membranes, and passage between cells is prevented by tight and adherens junctions. These cells can react to foreign peptides ('innate immunity') using pattern recognition receptors found on cell surfaces (Toll receptors) or intracellularly. Lastly, in the subepithelial layer, immune responses occur under control of the adaptive immune system in response to pathogenic compounds.

Immunological defence mechanisms

Gastrointestinal mucosa-associated lymphoid tissue (MALT) constitutes 25% of the total lymphatic tissue of the body and is at the heart of adaptive immunity. Within Peyer's patches, B lymphocytes differentiate to plasma cells following exposure to antigens, and these migrate to mesenteric lymph nodes, to enter the blood stream via the thoracic duct. The plasma cells return to the lamina propria of the gut through the circulation and release immunoglobulin A (IgA), which is transported into the lumen of the intestine. Intestinal T lymphocytes help localise plasma cells to the site of antigen exposure, as well as producing inflammatory mediators. Macrophages in the gut phagocytose foreign materials and secrete a range of cytokines, which mediate

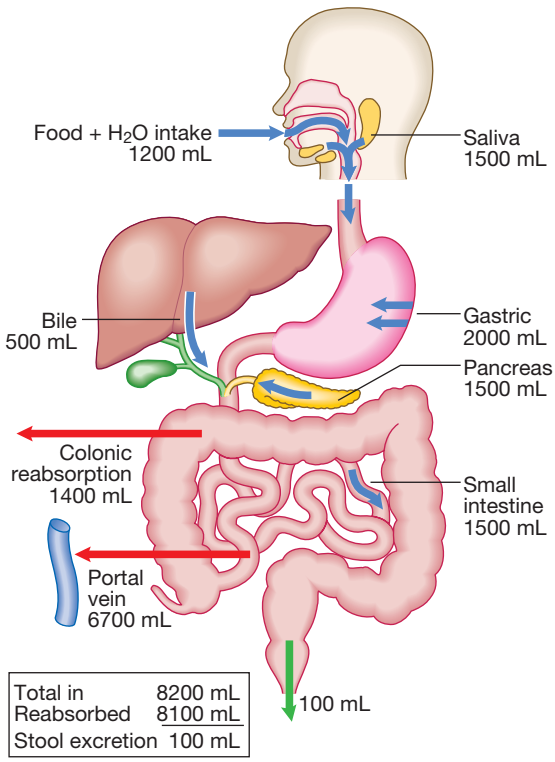

Fig. 22.7 Fluid homeostasis in the gastrointestinal tract.

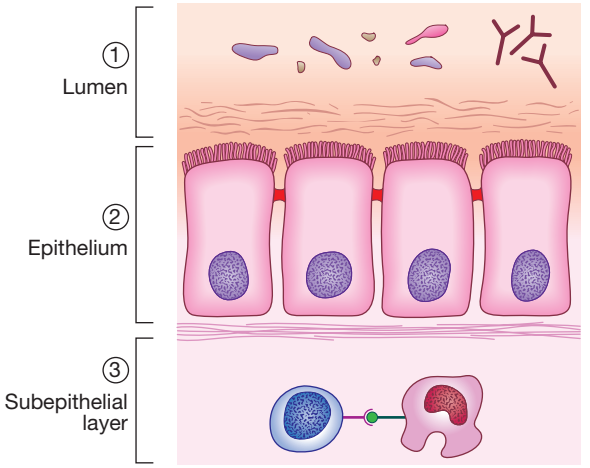

Fig. 22.8 Intestinal defence mechanisms. See text for details.

inflammation. Similarly, activation of mast-cell surface IgE receptors leads to degranulation and release of other molecules involved in inflammation.

Pancreas

The exocrine pancreas (Box 22.1) is necessary for the digestion of fat, protein and carbohydrate. Proenzymes are secreted from pancreatic acinar cells in response to circulating gastrointestinal hormones (Fig. 22.9) and are activated by trypsin. Bicarbonate-rich fluid is secreted from ductular cells to produce an optimum alkaline pH for enzyme activity.

Colon

The colon (Fig. 22.10) absorbs water and electrolytes. It also acts as a storage organ and has contractile activity. Two types of contraction occur. The first of these is segmentation (ring contraction), which leads to mixing but not propulsion; this promotes absorption of water and electrolytes. Propulsive (peristaltic contraction) waves occur several times a day and propel faeces to the rectum. All activity is stimulated after meals, probably in response to release of motilin and CCK. Faecal continence depends upon maintenance of the anorectal angle and tonic contraction of the external anal sphincters. On defecation, there is relaxation of the anorectal muscles, increased intra-abdominal pressure from the Valsalva manœuvre and contraction of abdominal muscles, and relaxation of the anal sphincters.

22.1 Pancreatic enzymes

Enzyme	Substrate	Product
Amylase	Starch and glycogen	Limit dextrans Maltose Maltriose
Lipase **Colipase**	Triglycerides	Monoglycerides and free fatty acids
Proteolytic enzymes Trypsinogen Chymotrypsinogen Pro-elastase Pro-carboxypeptidases	Proteins and polypeptides	Short polypeptides

Control of gastrointestinal function

Secretion, absorption, motor activity, growth and differentiation of the gut are all modulated by a combination of neuronal and hormonal factors.

The nervous system and gastrointestinal function

The central nervous system (CNS), the autonomic system (ANS) and the enteric nervous system (ENS) interact to regulate gut function. The ANS comprises:

- *parasympathetic pathways* (vagal and sacral efferent), which are cholinergic, and increase smooth muscle tone and promote sphincter relaxation

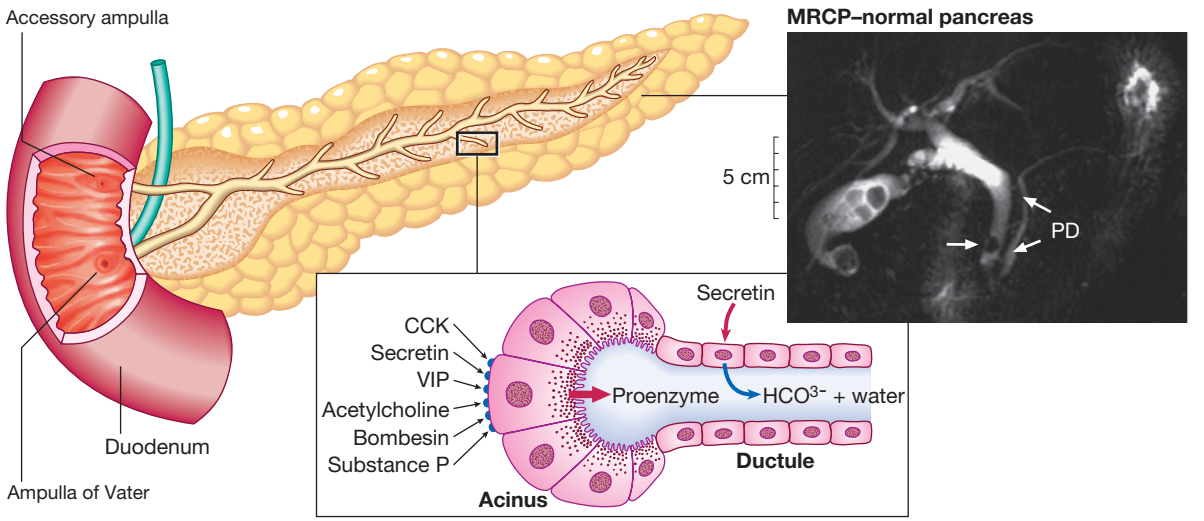

Fig. 22.9 Pancreatic structure and function. Ductular cells secrete alkaline fluid in response to secretin. Acinar cells secrete digestive enzymes from zymogen granules in response to a range of secretagogues. The photograph shows a normal pancreatic duct (PD) and side branches, as defined at magnetic resonance cholangiopancreatography (MRCP). Note the incidental calculi in the gallbladder and common bile duct (arrow). (CCK = cholecystokinin; VIP = vasoactive intestinal polypeptide)

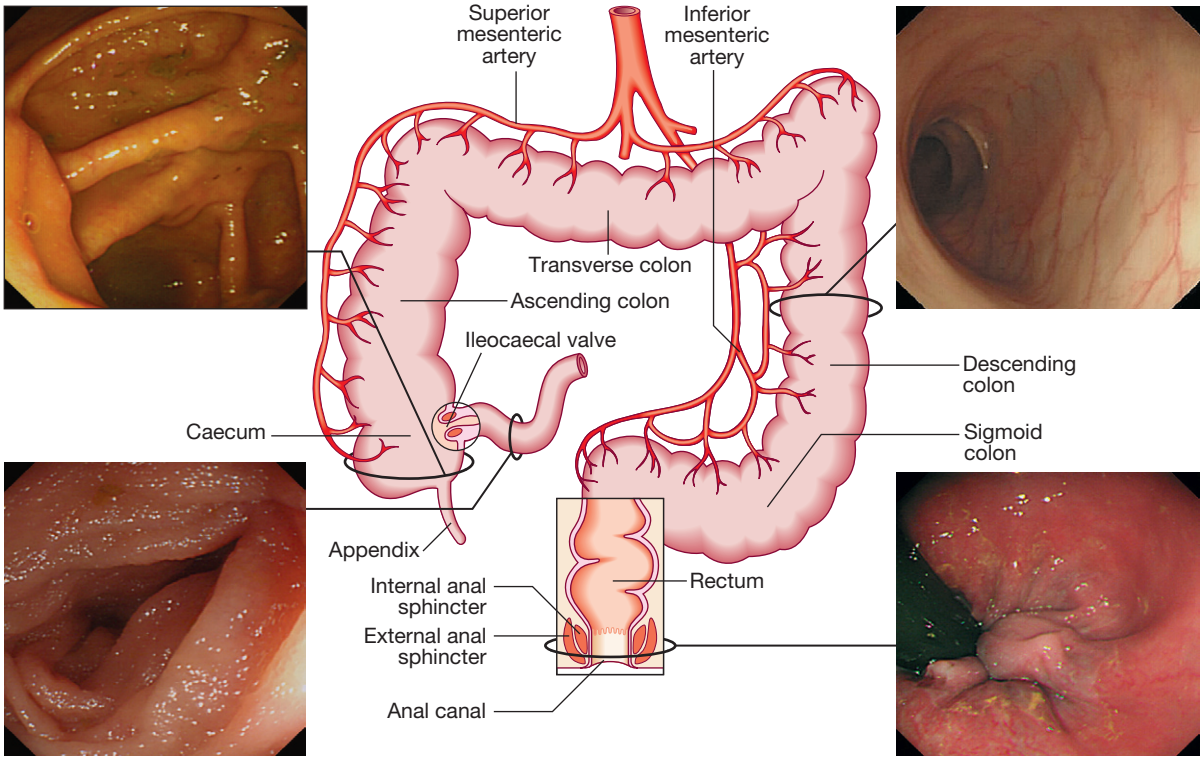

Fig. 22.10 The normal colon, rectum and anal canal.

- *sympathetic pathways*, which release noradrenaline (norepinephrine), reduce smooth muscle tone and stimulate sphincter contraction.

The enteric nervous system

In conjunction with the ANS, the ENS senses gut contents and conditions, and regulates motility, fluid exchange, secretion, blood flow and other key gut functions. It comprises two major networks intrinsic to the gut wall. The myenteric (Auerbach's) plexus in the smooth muscle layer regulates motor control; and the submucosal (Meissner's) plexus exerts secretory control over the epithelium, enteroendocrine cells and submucosal vessels. Together, these plexuses form a two-layered neuronal mesh along the length of the gut. Although connected centrally via the ANS, the ENS can function autonomously, using a variety of transmitters, including acetylcholine, noradrenaline (norepinephrine), 5-hydroxytryptamine (5-HT, serotonin), nitric oxide, substance P and calcitonin gene-related peptide (CGRP). There are local reflex loops within the ENS but also loops involving the coeliac and mesenteric ganglia and the paravertebral ganglia. The parasympathetic system generally stimulates motility and secretion, while the sympathetic system generally acts in an inhibitory manner.

Peristalsis

Peristalsis is a reflex triggered by gut wall distension, which consists of a wave of circular muscle contraction to propel contents from the oesophagus to the rectum. It can be influenced by innervation but functions independently. It results from a basic electrical rhythm originating from the interstitial cells of Cajal in the circular layer of intestinal smooth muscle. These are stellate cells of mesenchymal origin with smooth muscle features, which act as the 'pacemaker' of the gut.

Migrating motor complexes

Migrating motor complexes (MMC) are waves of contraction spreading from the stomach to the ileum, occurring at a frequency of about 5 per minute every 90 minutes or so, between meals and during fasting. They may serve to sweep intestinal contents distally in preparation for the next meal and are inhibited by eating.

Gut hormones

The origin, action and control of the major gut hormones, peptides and non-peptide signalling transmitters are summarised in Box 22.2.

INVESTIGATION OF GASTROINTESTINAL DISEASE

A wide range of tests are available for the investigation of patients with gastrointestinal symptoms. These can be classified broadly into tests of structure, tests for infection and tests of function.

Imaging

Plain X-rays

Plain X-rays of the abdomen are useful in the diagnosis of intestinal obstruction or paralytic ileus, where dilated loops of bowel and (in the erect position) fluid levels may be seen. Calcified lymph nodes, gallstones and renal stones can also be detected. Chest X-ray

22.2 Gut hormones and peptides

Hormone	Origin	Stimulus	Action
Gastrin	Stomach (G cell)	Products of protein digestion Suppressed by acid and somatostatin	Stimulates gastric acid secretion Stimulates growth of gastrointestinal mucosa
Somatostatin	Throughout GI tract (D cell)	Fat ingestion	Inhibits gastrin and insulin secretion Decreases acid secretion Decreases absorption Inhibits pancreatic secretion
Cholecystokinin (CCK)	Duodenum and jejunum (I cells); also ileal and colonic nerve endings	Products of protein digestion Fat and fatty acids Suppressed by trypsin	Stimulates pancreatic enzyme secretion Gallbladder contraction Sphincter of Oddi relaxation Satiety Decreases gastric acid secretion Reduces gastric emptying Regulates pancreatic growth
Secretin	Duodenum and jejunum (S cells)	Duodenal acid Fatty acids	Stimulates pancreatic fluid and bicarbonate secretion Decreases acid secretion Reduces gastric emptying
Motilin	Duodenum, small intestine and colon (Mo cells)	Fasting Dietary fat	Regulates peristaltic activity, including migrating motor complexes (MMC)
Gastric inhibitory polypeptide (GIP)	Duodenum (K cells) and jejunum	Glucose and fat	Stimulates insulin release (also known as glucose-dependent insulinotrophic polypeptide) Inhibits acid secretion
Vasoactive intestinal peptide (VIP)	Nerve fibres throughout GI tract	Unknown	Vasodilator Smooth muscle relaxation Water and electrolyte secretion
Ghrelin	Stomach	Fasting Inhibited by eating	Stimulates appetite, acid secretion and gastric emptying
Peptide YY	Ileum and colon	Feeding	Modulates satiety
Amylin	Pancreatic islet β-cells	Feeding	Glycaemic control

(performed with the patient in erect position) is useful in the diagnosis of suspected perforation, as it shows subdiaphragmatic free air.

Contrast studies

X-rays with contrast medium are usually performed to assess not only anatomical abnormalities but also motility. Barium sulphate provides good mucosal coating and excellent opacification but can precipitate impaction proximal to an obstructive lesion. Water-soluble contrast is used to opacify bowel prior to abdominal computed tomography and in cases of suspected perforation. The double contrast technique improves mucosal visualisation by using gas to distend the barium-coated intestinal surface. Contrast studies are useful for detecting filling defects, such as tumours, strictures, ulcers and motility disorders, but are inferior to endoscopic procedures and more sophisticated cross-sectional imaging techniques, such as computed tomography and magnetic resonance imaging. The major uses and limitations of various contrast studies are shown in Box 22.3 and Figure 22.11.

Ultrasound, computed tomography and magnetic resonance imaging

Ultrasound (US), computed tomography (CT) and magnetic resonance imaging (MRI) are key tests in the evaluation of intra-abdominal disease. They are non-invasive and offer detailed images of the abdominal contents. Their main applications are summarised in Box 22.4 and Figure 22.12.

Endoscopy

Videoendoscopes provide high-definition imaging and accessories can be passed down the endoscope to allow both diagnostic and therapeutic procedures, some of which are illustrated in Figure 22.13. Endoscopes with magnifying lenses allow almost microscopic detail to be observed, and imaging modalities, such as confocal endomicroscopy, autofluorescence and 'narrow band imaging', are increasingly used to detect subtle abnormalities not visible by standard 'white light' endoscopy.

Upper gastrointestinal endoscopy

This is performed under light intravenous benzodiazepine sedation, or using only local anaesthetic throat spray after the patient has fasted for at least 4 hours. With the patient in the left lateral position, the entire oesophagus (excluding pharynx), stomach and first two parts of duodenum can be seen. Indications, contraindications and complications are given in Box 22.5.

22.3 Contrast radiology in the investigation of gastrointestinal disease

	Barium swallow/meal	Barium follow-through	Barium enema
Indications and major uses	Motility disorders (achalasia and gastroparesis) Perforation or fistula (non-ionic contrast)	Diarrhoea and abdominal pain of small bowel origin Possible obstruction by strictures Suspected malabsorption Crohn's disease assessment	Altered bowel habit Evaluation of strictures or diverticular disease Megacolon Chronic constipation
Limitations	Risk of aspiration Poor mucosal detail Low sensitivity for early cancer Inability to biopsy	Time-consuming Radiation exposure Relative insensitivity	Difficult in frail or incontinent patients Sigmoidoscopy needed to see rectum Low sensitivity for lesions < 1 cm

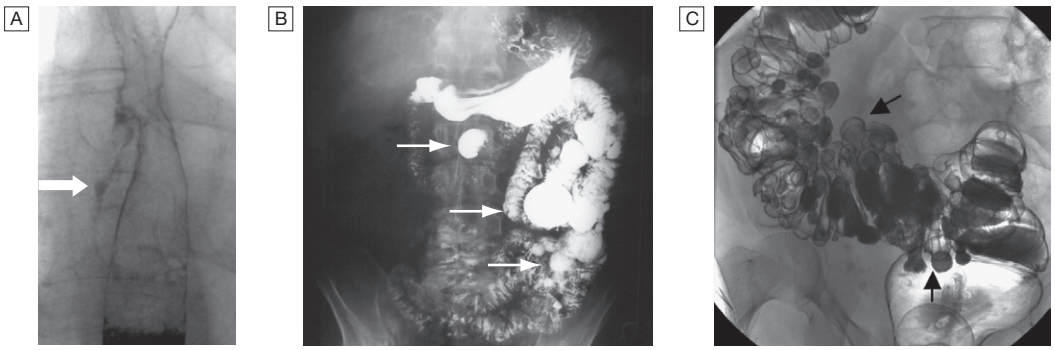

Fig. 22.11 Examples of contrast radiology. A Non-ionic contrast swallow shows leakage of contrast (arrow) into the mediastinum following stricture dilatation. B Barium follow-through. There are multiple diverticula (arrows) in this patient with jejunal diverticulosis. C Barium enema showing severe diverticular disease. There is tortuosity and narrowing of the sigmoid colon with multiple diverticula (arrows).

22.4 Imaging in gastroenterology

	Ultrasound	CT	MRI	CT-PET
Indications and major uses	Abdominal masses Organomegaly Ascites Biliary tract dilatation Gallstones Guided biopsy of lesions Small bowel imaging	Assess pancreatic disease Hepatic tumour deposits CT colonography ('virtual colonoscopy') Tumour staging Assess lesion vascularity Abscesses and collections	Hepatic tumour staging MRCP Pelvic/perianal disease Crohn's fistulae Small bowel visualisation	Detection of metastases not seen on ultrasound or CT Images can be fused with CT to form composite image
Limitations	Low sensitivity for small lesions Little functional information Operator-dependent Gas and obesity may obscure view	Cost Radiation dose	Claustrophobic patients Contraindicated in presence of metallic prostheses, cardiac pacemaker, cochlear implants	Signal detection depends on metabolic activity within tumour – not all are metabolically active

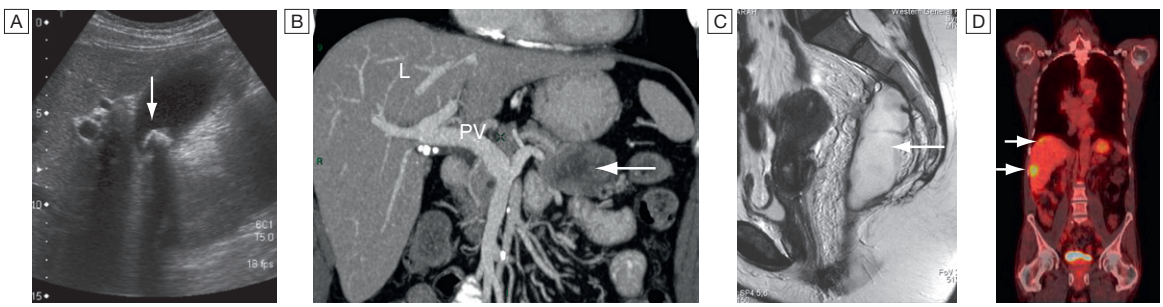

Fig. 22.12 Examples of ultrasound, CT and MRI. A Ultrasound showing large gallstone (arrow) with acoustic shadowing. B Multidetector coronal CT showing large solid and cystic malignant tumour in the pancreatic tail (arrow). (PV = portal vein; L = liver) C Pelvic MRI showing large pelvic abscess (arrow) posterior to the rectum in a patient with Crohn's disease. D Fused CT-PET image showing two liver metastases (arrows).

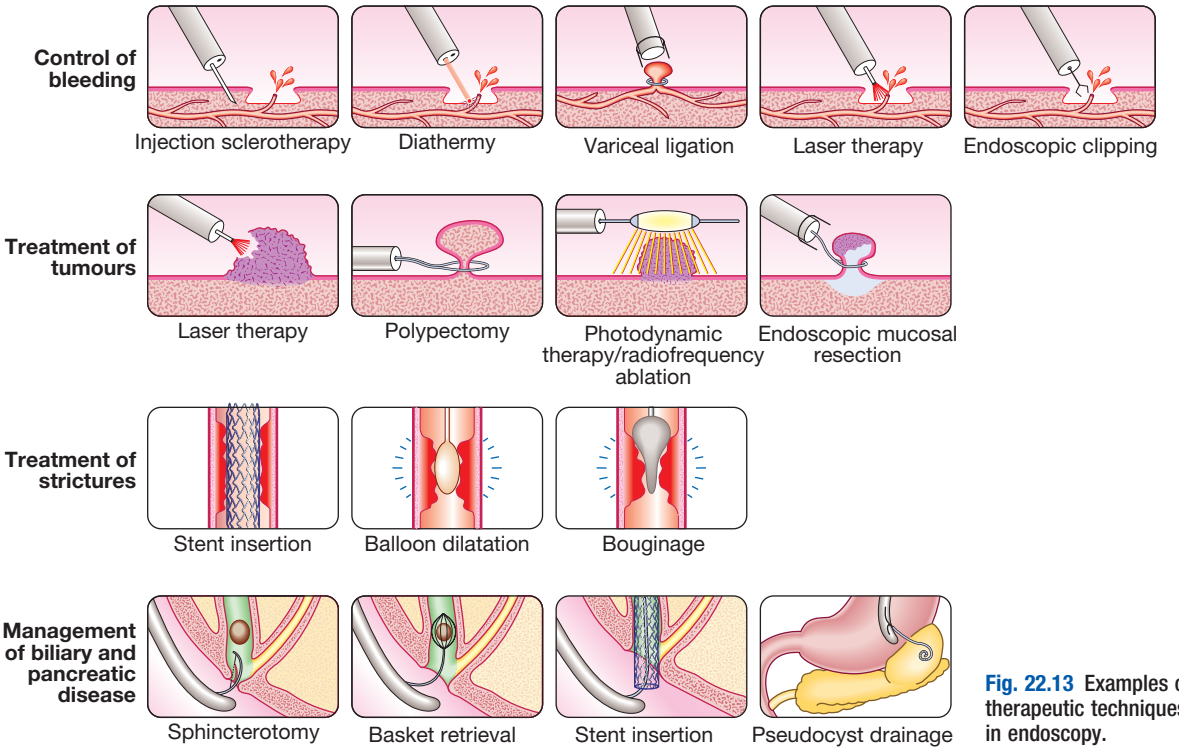

Fig. 22.13 Examples of therapeutic techniques in endoscopy.

22.5 Upper gastrointestinal endoscopy

Indications

- Dyspepsia over 55 yrs of age or with alarm symptoms
- Atypical chest pain
- Dysphagia
- Vomiting
- Weight loss
- Acute or chronic gastrointestinal bleeding
- Screening for oesophageal varices in patients with chronic liver disease
- Abnormal CT scan or barium meal
- Duodenal biopsies in the investigation of malabsorption and to confirm a diagnosis of coeliac disease prior to commencement of gluten-free diet
- Therapeutic, including treatment of bleeding lesions, banding/injection of varices, dilatation of strictures, insertion of stents, placement of percutaneous gastrostomies

Contraindications

- Severe shock
- Recent myocardial infarction, unstable angina, cardiac arrhythmia*
- Severe respiratory disease*
- Atlantoaxial subluxation*
- Possible visceral perforation

Complications

- Cardiorespiratory depression due to sedation
- Aspiration pneumonia
- Perforation

*These are 'relative' contraindications; in experienced hands, endoscopy can be safely performed.

Capsule endoscopy

Capsule endoscopy (Fig. 22.14) uses a capsule containing an imaging device, battery, transmitter and antenna; as it traverses the small intestine, it transmits images to a battery-powered recorder worn on a belt round the patient's waist. After approximately 8 hours, the capsule is excreted. Images from the capsule are analysed as a video sequence and it is usually possible to localise the segment of small bowel in which lesions are seen. Abnormalities detected usually require enteroscopy for confirmation and therapy. Indications, contraindications and complications are listed in Box 22.6.

Double balloon enteroscopy

While endoscopy can reach the proximal small intestine in most patients, a newer technique called double balloon enteroscopy is also available, which uses a long endoscope with a flexible overtube. Sequential and repeated inflation and deflation of balloons on the tip of the overtube and enteroscope allow the operator to push and pull along the entire length of the small intestine to the terminal ileum, in order to diagnose or treat small bowel lesions detected by capsule endoscopy or other imaging modalities. Indications, contraindications and complications are listed in Box 22.7.

Sigmoidoscopy and colonoscopy

Sigmoidoscopy can be carried out either in the outpatient clinic using a 20 cm rigid plastic sigmoidoscope or in the endoscopy suite using a 60 cm flexible colonoscope following bowel preparation. When sigmoidoscopy is combined with proctoscopy, accurate detection of haemorrhoids, ulcerative colitis and distal colorectal neoplasia is possible. After full bowel cleansing, it is possible to examine the entire colon and the terminal ileum using a longer colonoscope. Indications, contraindications and complications of colonoscopy are listed in Box 22.8.

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) has largely replaced endoscopic retrograde

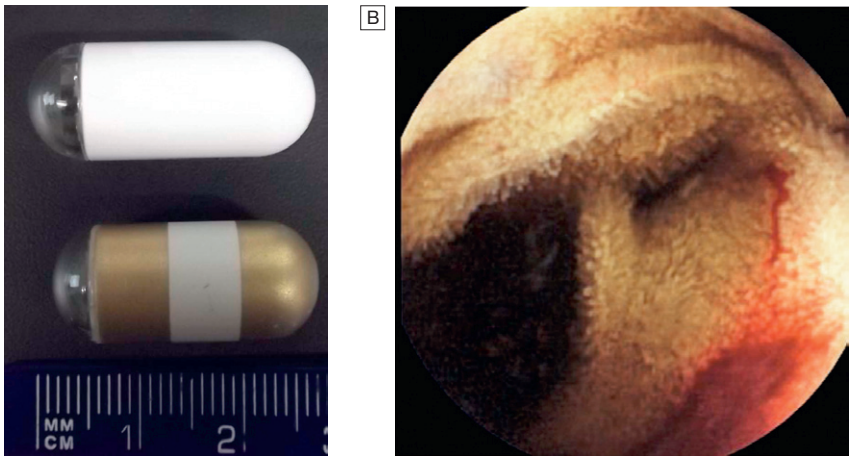

Fig. 22.14 Wireless capsule endoscopy. A Examples of capsules. B Capsule endoscopy image of bleeding jejunal vascular malformation.

22.6 Wireless capsule endoscopy

Indications

- Obscure gastrointestinal bleeding
- Small bowel Crohn's disease
- Assessment of coeliac disease and its complications
- Screening and surveillance in familial polyposis syndromes

Contraindications

- Known or suspected small bowel stricture (risk of capsule retention)
- Caution in people with pacemakers or implantable defibrillators

Complications

- Capsule retention (< 1%)

22.7 Double balloon enteroscopy

Indications

Diagnostic

- Obscure gastrointestinal bleeding
- Malabsorption or unexplained diarrhoea
- Suspicious radiological findings
- Suspected small bowel tumour
- Surveillance of polyposis syndromes

Therapeutic

- Coagulation/diathermy of bleeding lesions
- Jejunostomy placement

Contraindications

- As for upper gastrointestinal endoscopy

Complications

- As for upper gastrointestinal endoscopy
- Post-procedure abdominal pain (≤20%)
- Pancreatitis (1–3%)
- Perforation (especially after resection of large polyps)

cholangiopancreatography (ERCP) in the evaluation of obstructive jaundice since it provides comparable images of the biliary tree and pancreas, providing information that complements that obtained from CT and endoscopic ultrasound examination (EUS).

22.8 Colonoscopy

Indications*

- Suspected inflammatory bowel disease
- Chronic diarrhoea
- Altered bowel habit
- Rectal bleeding or iron deficiency anaemia
- Assessment of abnormal CT colonogram or barium enema
- Colorectal cancer screening
- Colorectal adenoma and carcinoma follow-up
- Therapeutic procedures, including endoscopic resection, dilatation of strictures, laser, stent insertion and argon plasma coagulation

Contraindications

- Acute severe ulcerative colitis (prefer unprepared flexible sigmoidoscopy)
- As for upper gastrointestinal endoscopy

Complications

- Cardiorespiratory depression due to sedation
- Perforation
- Bleeding following polypectomy

*Colonoscopy is not useful in the investigation of constipation.

Endoscopic retrograde cholangiopancreatography

Using a side-viewing duodenoscope, it is possible to cannulate the main pancreatic duct and common bile duct. Nowadays, ERCP is mainly used in the treatment of a range of biliary and pancreatic diseases that have been identified by other imaging techniques such as MRCP, EUS and CT. Indications for and risks of ERCP are listed in Box 22.9.

Histology

Biopsy material obtained during endoscopy or percutaneously can provide useful information (Box 22.11).

Tests of infection

Bacterial cultures

Stool cultures are essential in the investigation of diarrhoea, especially when it is acute or bloody, in order to identify pathogenic organisms (Ch. 13).

22.9 Endoscopic retrograde cholangiopancreatography (ERCP)

Indications

Diagnostic ERCP
- Biliary or pancreatic disease where other imaging is equivocal or is contraindicated
- Ampullary biopsy or biliary cytology

Therapeutic ERCP
- Biliary disease
  - Removal of common bile duct calculi*
  - Palliation of malignant biliary obstruction
  - Management of biliary leaks/damage complicating surgery
  - Dilatation of benign strictures
  - Primary sclerosing cholangitis
- Pancreatic disease
  - Drainage of pancreatic pseudocysts and fistulae
  - Removal of pancreatic calculi (selected cases)

Contraindications
- Severe cardiopulmonary comorbidity
- Coagulopathy

Complications
- Occur in 5–10% with a 30-day mortality of 0.5–1%

General
- As for upper endoscopy

Specific
- Biliary disease
  - Bleeding following sphincterotomy
  - Cholangitis (if biliary obstruction is not relieved by ERCP)
  - Gallstone impaction
- Pancreatic disease
  - Acute pancreatitis
  - Infection of pseudocyst

*Laparoscopic surgery is preferred in fit individuals who also require cholecystectomy.

22.10 Endoscopy in old age

- **Tolerance**: endoscopic procedures are generally well tolerated, even in very old people.
- **Side-effects from sedation**: older people are more sensitive, and respiratory depression, hypotension and prolonged recovery times are more common.
- **Bowel preparation for colonoscopy**: can be difficult in frail, immobile people. Sodium phosphate-based preparations can cause dehydration or hypotension and should be avoided in those with underlying cardiac or renal failure. Minimal preparation CT colonograms provide an excellent alternative in these individuals.
- **Antiperistaltic agents**: hyoscine should be avoided in those with glaucoma and can also cause tachyarrhythmias. Glucagon is preferred if an antiperistaltic agent is needed.

22.11 Reasons for biopsy or cytological examination

- Suspected malignant lesions
- Assessment of mucosal abnormalities
- Diagnosis of infection (*Candida*, *Helicobacter pylori*, *Giardia lamblia*)
- Analysis of genetic mutations

Serology

Detection of antibodies plays a limited role in the diagnosis of gastrointestinal infection caused by organisms such as *Helicobacter pylori*, *Salmonella* species and *Entamoeba histolytica*.

Breath tests

Non-invasive breath tests for *H. pylori* infection are discussed on page 873. Breath tests for suspected small intestinal bacterial overgrowth are discussed on page 882.

Tests of function

A number of dynamic tests can be used to investigate aspects of gut function, including digestion, absorption, inflammation and epithelial permeability. Some of the more commonly used ones are listed in Box 22.12. In the assessment of suspected malabsorption, blood tests (full blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), folate, vitamin B_{12}, iron status, albumin, calcium and phosphate) are essential, and endoscopy is undertaken to obtain mucosal biopsies. Faecal calprotectin is very sensitive at detecting mucosal inflammation.

Oesophageal motility

A barium swallow can give useful information about oesophageal motility. Videofluoroscopy, with joint assessment by a speech and language therapist and a radiologist, may be necessary in difficult cases. Oesophageal manometry (see Fig. 22.1, p. 840), often in conjunction with 24-hour pH measurements, is of value in diagnosing cases of refractory gastro-oesophageal reflux, achalasia and non-cardiac chest pain. Oesophageal impedance testing is useful for detecting non-acid or gas reflux events, especially in patients with atypical symptoms or those who respond poorly to acid suppression.

Gastric emptying

This involves administering a test meal containing solids and liquids labelled with different radioisotopes and measuring the amount retained in the stomach afterwards (Box 22.13). It is useful in the investigation of suspected delayed gastric emptying (gastroparesis) when other studies are normal.

Colonic and anorectal motility

A plain abdominal X-ray taken on day 5 after ingestion of different-shaped inert plastic pellets on days 1–3 gives an estimate of whole gut transit time. The test is useful in the evaluation of chronic constipation, when the position of any retained pellets can be observed, and helps to differentiate cases of slow transit from those due to obstructed defecation. The mechanism of defecation and anorectal function can be assessed by anorectal manometry, electrophysiological tests and defecating proctography.

Radioisotope tests

Many different radioisotope tests are used (see Box 22.13). In some, structural information is obtained, such as the localisation of a Meckel's diverticulum. Others provide functional information, such as the rate of gastric emptying or ability to reabsorb bile acids. Yet

22.12 Dynamic tests of gastrointestinal function

Process	Test	Principle	Comments
Absorption			
Lactose	Lactose H_2 breath test	Measurement of breath H_2 content after 50 g oral lactose. Undigested sugar is metabolised by colonic bacteria in hypolactasia, and expired hydrogen is measured	Non-invasive and accurate. May provoke pain and diarrhoea in sufferers
Bile acids	^{75}SeHCAT test	Isotopic quantification of 7-day whole-body retention of oral dose ^{75}Se-labelled homocholyltaurine (> 15% = normal, 5–15% borderline, < 5% = abnormal)	Accurate and specific but requires two visits and involves radiation. Results can be equivocal. Serum 7α-hydroxycholestenone is as sensitive and specific
Pancreatic exocrine function	Pancreolauryl test	Pancreatic esterases cleave fluoroscein dilaurate after oral ingestion. Fluoroscein is absorbed and quantified in urine	Accurate and avoids duodenal intubation Takes 2 days. Accurate urine collection essential. Rarely performed
	Faecal elastase	Immunoassay of pancreatic enzymes on stool sample	Simple, quick and avoids urine collection. Does not detect mild disease
Mucosal inflammation/ permeability	Faecal calprotectin	A protein secreted non-specifically by neutrophils into the colon in response to inflammation or neoplasia	Useful screening test for gastrointestinal inflammation and for monitoring patients with Crohn's disease and ulcerative colitis. Poor sensitivity for cancer

22.13 Commonly used radioisotope tests in gastroenterology

Test	Isotope	Major uses and principle of test
Gastric emptying study	^{99m}Tc-sulphur ^{111}In-DTPA	Used in assessment of gastric emptying, particularly for possible gastroparesis
Urea breath test	^{13}C-urea	Used in non-invasive diagnosis of *H. pylori*. Bacterial urease enzyme splits urea to ammonia and CO_2, which is detected in expired air
Meckel's scan	^{99m}Tc-pertechnate	Diagnosis of Meckel's diverticulum in cases of obscure gastrointestinal bleeding. Isotope is injected IV and localises in ectopic parietal mucosa within diverticulum
Somatostatin receptor scan (SRS)	^{111}In-DTPA-DPheoctreotide	Labelled somatostatin analogue binds to cell surface somatostatin receptors on pancreatic neuro-endocrine tumours

others are tests of infection and rely on the presence of bacteria to hydrolyse a radio-labelled test substance followed by detection of the radioisotope in expired air, such as the urea breath test for *H. pylori*.

PRESENTING PROBLEMS IN GASTROINTESTINAL DISEASE

Dysphagia

Dysphagia is defined as difficulty in swallowing. It may coexist with heartburn or vomiting but should be distinguished from both globus sensation (in which anxious people feel a lump in the throat without organic cause) and odynophagia (pain during swallowing, usually from gastro-oesophageal reflux or candidiasis).

Dysphagia can occur due to problems in the oropharynx or oesophagus (Fig. 22.15). Oropharyngeal disorders affect the initiation of swallowing at the pharynx and upper oesophageal sphincter. The patient has difficulty initiating swallowing and complains of choking, nasal regurgitation or tracheal aspiration. Drooling, dysarthria, hoarseness and cranial nerve or other neurological signs may be present. Oesophageal disorders cause dysphagia by obstructing the lumen or by affecting motility. Patients with oesophageal disease complain of food 'sticking' after swallowing, although the level at which this is felt correlates poorly with the true site of obstruction. Swallowing of liquids is normal until strictures become extreme.

Investigations

Dysphagia should always be investigated urgently. Endoscopy is the investigation of choice because it allows biopsy and dilatation of strictures. If no abnormality is found, then barium swallow with videofluoroscopic swallowing assessment is indicated to detect major motility disorders. In some cases, oesophageal manometry is required. High-resolution manometry allows accurate classification of abnormalities. Figure 22.15 summarises a diagnostic approach to dysphagia and lists the major causes.

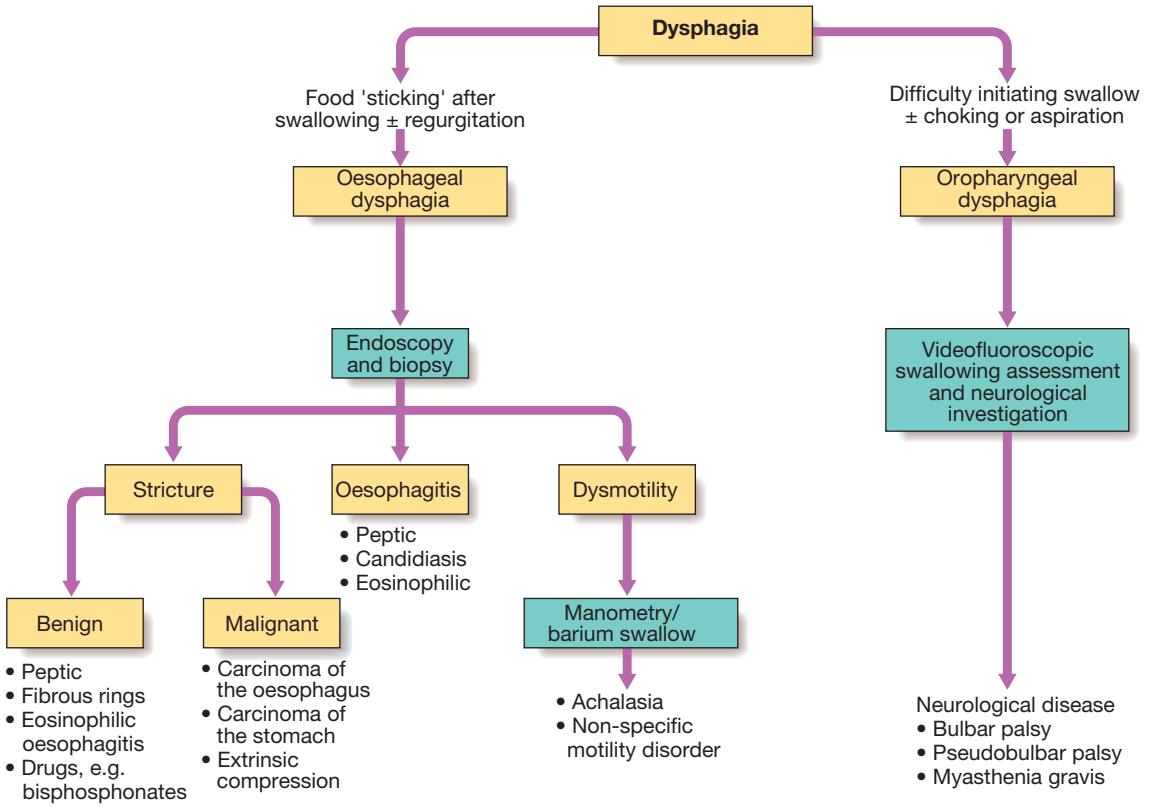

Fig. 22.15 Investigation of dysphagia.

Dyspepsia

Dyspepsia describes symptoms such as discomfort, bloating and nausea, which are thought to originate from the upper gastrointestinal tract. There are many causes (Box 22.14), including some arising outside the digestive system. Heartburn and other 'reflux' symptoms are separate entities and are considered elsewhere. Although symptoms often correlate poorly with the underlying diagnosis, a careful history is important to detect 'alarm' features requiring urgent investigation (Box 22.15) and to detect atypical symptoms which might be due to problems outside the gastrointestinal tract.

Dyspepsia affects up to 80% of the population at some time in life and most patients have no serious underlying disease. Patients who present with new dyspepsia at an age of more than 55 years and younger patients unresponsive to empirical treatment require investigation to exclude serious disease. An algorithm for the investigation of dyspepsia is outlined in Figure 22.16.

22.14 Causes of dyspepsia

Upper gastrointestinal disorders	
• Peptic ulcer disease	• Oesophageal spasm
• Acute gastritis	• Non-ulcer dyspepsia
• Gallstones	• Irritable bowel syndrome
Other gastrointestinal disorders	
• Pancreatic disease (cancer, chronic pancreatitis)	• Hepatic disease (hepatitis, metastases)
• Colonic carcinoma	
Systemic disease	
• Renal failure	• Hypercalcaemia
Drugs	
• Non-steroidal anti-inflammatory drugs (NSAIDs)	• Iron and potassium supplements
• Corticosteroids	• Digoxin
Others	
• Psychological (anxiety, depression)	• Alcohol

22.15 Alarm features in dyspepsia

- Weight loss
- Anaemia
- Vomiting
- Haematemesis and/or melaena
- Dysphagia
- Palpable abdominal mass

Heartburn and regurgitation

Heartburn describes retrosternal, burning discomfort, often rising up into the chest and sometimes accompanied by regurgitation of acidic or bitter fluid into the throat. These symptoms often occur after meals, on lying down or with bending, straining or heavy lifting. They are classical of gastro-oesophageal reflux but up to 50%

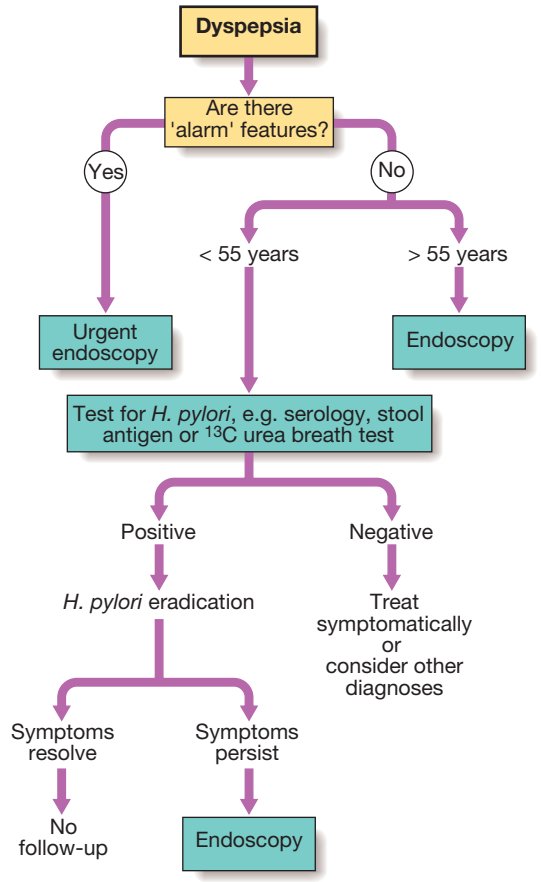

Fig. 22.16 Investigation of dyspepsia.

of patients present with other symptoms, such as chest pain, belching, halitosis, chronic cough or sore throats. In young patients with typical symptoms and a good response to dietary changes, antacids or acid suppression, investigation is not required, but in patients over 55 years of age, those with alarm symptoms or atypical features, urgent endoscopy is necessary.

Vomiting

Vomiting is a complex reflex involving both autonomic and somatic neural pathways. Synchronous contraction of the diaphragm, intercostal muscles and abdominal muscles raises intra-abdominal pressure and, combined with relaxation of the lower oesophageal sphincter, results in forcible ejection of gastric contents. It is important to distinguish true vomiting from regurgitation and to elicit whether the vomiting is acute or chronic (recurrent), as the underlying causes may differ. The major causes are shown in Figure 22.17.

Gastrointestinal bleeding

Acute upper gastrointestinal haemorrhage

This is the most common gastrointestinal emergency, accounting for 50–170 admissions to hospital per 100 000 of the population each year in the UK. The mortality of patients admitted to hospital is about 10% but there is some evidence that outcome is better when patients are treated in specialised units. Risk scoring systems have been developed to stratify risk of needing endoscopic therapy or a poor outcome (Box 22.16). The advantage

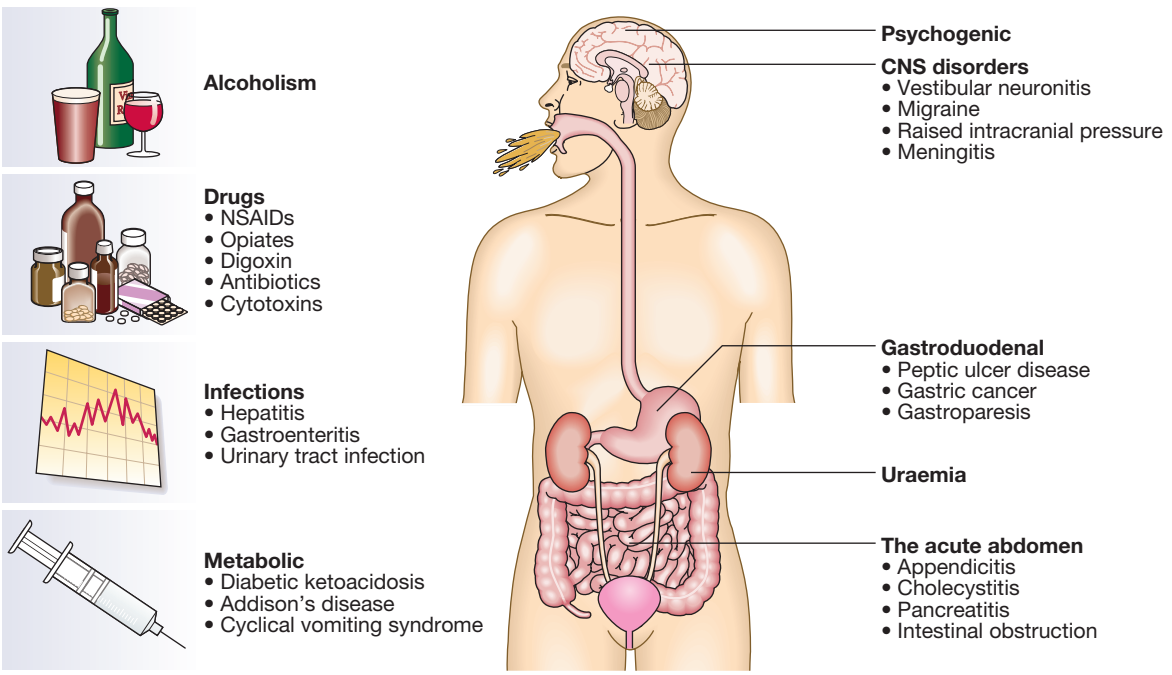

Fig. 22.17 Causes of vomiting.

22.16 Modified Blatchford score: risk stratification in acute upper GI bleeding

Admission risk marker	Score component value
Blood urea	
≥ 25 mmol/L (≥ 70 mg/dL)	6
10–25 mmol/L (28–70 mg/dL)	4
8–10 mmol/L (22.4–28 mg/dL)	3
6·5–8 mmol/L (18.2–22.4 mg/dL)	2
< 6.5 mmol/L (18.2 mg/dL)	0
Haemoglobin for men	
< 100 g/L (10 g/dL)	6
100–119 g/L (10–11.9 g/dL)	3
120–129 g/L (12–12.9 g/dL)	1
≥ 130 g/L (13 g/dL)	0
Haemoglobin for women	
< 100 g/L (10 g/dL)	6
100–119 g/L (10–11.9 g/dL)	1
≥ 120 g/L (12 g/dL)	0
Systolic blood pressure	
< 90 mmHg	3
90–99 mmHg	2
100–109 mmHg	1
> 109 mmHg	0
Other markers	
Presentation with syncope	2
Hepatic disease	2
Cardiac failure	2
Pulse ≥ 100 beats/min	1
Presentation with melaena	1
None of the above	0

of the Blatchford score is that it may be used before endoscopy to predict the need for intervention to treat bleeding. Low scores (2 or less) are associated with a very low risk of adverse outcome. The common causes are shown in Figure 22.18.

Clinical assessment

Haematemesis is red with clots when bleeding is rapid and profuse, or black ('coffee grounds') when less severe. Syncope may occur and is due to hypotension from intravascular volume depletion. Symptoms of anaemia suggest chronic bleeding. Melaena is the passage of black, tarry stools containing altered blood; it is usually caused by bleeding from the upper gastrointestinal tract, although haemorrhage from the right side of the colon is occasionally responsible. The characteristic colour and smell are the result of the action of digestive enzymes and of bacteria upon haemoglobin. Severe acute upper gastrointestinal bleeding can sometimes cause maroon or bright red stool.

Management

The principles of emergency management of non-variceal bleeding are summarised in Box 22.17 and are discussed in detail below. Management of variceal bleeding is discussed on page 946.

1. Intravenous access

The first step is to gain intravenous access using at least one large-bore cannula.

2. Initial clinical assessment

- *Define circulatory status*. Severe bleeding causes tachycardia, hypotension and oliguria. The patient is cold and sweating, and may be agitated.
- *Seek evidence of liver disease* (p. 922). Jaundice, cutaneous stigmata, hepatosplenomegaly and ascites may be present in decompensated cirrhosis.
- *Identify comorbidity*. The presence of cardiorespiratory, cerebrovascular or renal disease is important, both because these may be worsened by acute bleeding and because they increase the hazards of endoscopy and surgical operations.

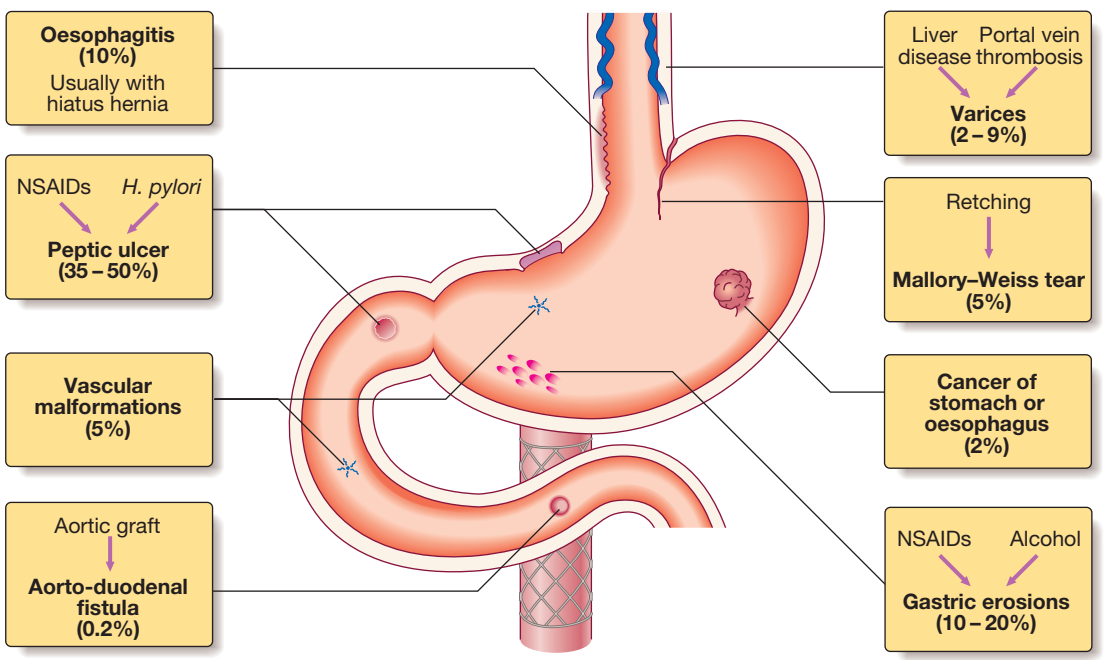

Fig. 22.18 Causes of acute upper gastrointestinal haemorrhage. (Frequency in parentheses.) (NSAIDs = non-steroidal anti-inflammatory drugs)

22.17 Emergency management of acute non-variceal upper gastrointestinal haemorrhage

- Gain IV access with large-bore cannula × 2
- Check full blood count, routine biochemistry and coagulation screen; cross-match blood
- Perform hourly measurements of blood pressure, pulse and urine output; consider central venous pressure monitoring in the high-dependency unit for severe bleeding
- Give IV crystalloids in patients with hypotension and tachycardia
- Transfuse with blood if blood pressure remains low and patient is actively bleeding
- Organise endoscopy for diagnosis and treatment once patient is resuscitated
- Give 72-hr proton pump inhibitor IV infusion for bleeding peptic ulcer
- Consider surgery or interventional radiological intervention (e.g. arterial embolisation) if bleeding recurs

These factors can be combined using the Blatchford score (see Box 22.16), which can be calculated at the bedside. A score of less than 3 is associated with a good prognosis, while progressively higher scores are associated with poorer outcomes.

3. Basic investigations

- *Full blood count.* Chronic or subacute bleeding leads to anaemia, but the haemoglobin concentration may be normal after sudden, major bleeding until haemodilution occurs. Thrombocytopenia may be a clue to the presence of hypersplenism in chronic liver disease.
- *Urea and electrolytes.* This test may show evidence of renal failure. The blood urea rises as the absorbed products of luminal blood are metabolised by the liver; an elevated blood urea with normal creatinine concentration implies severe bleeding.
- *Liver function tests.* These may show evidence of chronic liver disease.
- *Prothrombin time.* Check with clinical suggestion of liver disease or in anticoagulated patients.
- *Cross-matching.* At least 2 units of blood should be cross-matched.

4. Resuscitation

Intravenous crystalloid fluids should be given to raise the blood pressure, and blood should be transfused when the patient is actively bleeding with low blood pressure and tachycardia. Comorbidities should be managed as appropriate. Patients with suspected chronic liver disease should receive broad-spectrum antibiotics. Central venous pressure (CVP) monitoring may be useful in severe bleeding, particularly in patients with cardiac disease, to assist in defining the volume of fluid replacement and in identifying rebleeding.

5. Oxygen

This should be given to all patients in shock.

6. Endoscopy

This should be carried out after adequate resuscitation, ideally within 24 hours, and will yield a diagnosis in 80% of cases. Patients who are found to have major endoscopic stigmata of recent haemorrhage (Fig. 22.19) can be treated endoscopically using a thermal or mechanical modality, such as a 'heater probe' or endoscopic clips, combined with injection of dilute adrenaline (epinephrine) into the bleeding point ('dual therapy'). This may stop active bleeding and, combined with intravenous proton pump inhibitor (PPI) therapy, prevent rebleeding, thus avoiding the need for surgery (Boxes 22.18 and 22.19). Patients found to have bled from varices should be treated by band ligation (p. 946).

7. Monitoring

Patients should be closely observed, with hourly measurements of pulse, blood pressure and urine output.

EBM 22.18 Single versus dual modality endoscopic therapy in high-risk bleeding ulcers

'Adding a second procedure to adrenaline (epinephrine) injection further reduces bleeding rates from 18.5% to 10% (relative risk 0.55) and emergency surgery from 10.8% to 6.7% (relative risk 0.69). Mortality falls from 4.7% to 2.5% (relative risk 0.52; 95% confidence interval 0.38 to 1.05), without statistical significance. The risk of further bleeding decreased, regardless of which second procedure was applied (clips or thermal).'

- Vergara M, et al. Epinephrine injection versus epinephrine injection and a second endoscopic method in high risk bleeding ulcers. Cochrane Database of Systematic Reviews, 2007, issue 2. Art. no. CD005584 (updated 2009).

For further information: www.cochrane.org/cochrane-reviews

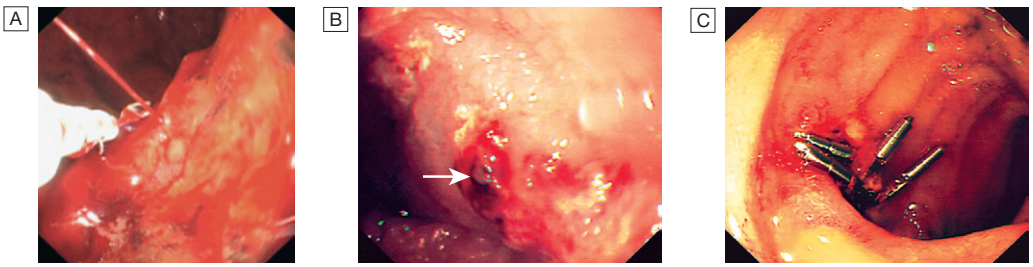

Fig. 22.19 Major stigmata of recent haemorrhage and endoscopic treatment. A Active arterial spurting from a gastric ulcer. An endoscopic clip is about to be placed on the bleeding vessel. When associated with shock, 80% of cases will continue to bleed or rebleed. B 'Visible vessel' (arrow). In reality, this is a pseudoaneurysm of the feeding artery seen here in a pre-pyloric peptic ulcer. It carries a 50% chance of rebleeding. C Haemostasis is achieved after endoscopic clipping of the bleeding vessel in the duodenum.

EBM 22.19 Adjunctive drug therapy for bleeding ulcers

'Intravenous proton pump inhibitor infusions reduce rebleeding ($NNT_B = 12$) and need for surgery ($NNT_B = 20$), but not mortality, in patients who have been subjected to endoscopic therapy for major peptic ulcer haemorrhage. When given prior to endoscopy, they reduce the need for endoscopic therapy and hospital stay, but not the need for surgery or mortality.'

22.20 Causes of lower gastrointestinal bleeding

Severe acute

- Diverticular disease
- Angiodysplasia
- Ischaemia
- Meckel's diverticulum
- Inflammatory bowel disease (rarely)

Moderate, chronic/subacute

- Fissure
- Haemorrhoids
- Inflammatory bowel disease
- Carcinoma
- Large polyps
- Angiodysplasia
- Radiation enteritis
- Solitary rectal ulcer

8. Surgery

Surgery is indicated when endoscopic haemostasis fails to stop active bleeding and if rebleeding occurs on one occasion in an elderly or frail patient, or twice in a younger, fitter patient. If available, angiographic embolisation is an effective alternative to surgery in frail patients.

The choice of operation depends on the site and diagnosis of the bleeding lesion. Duodenal ulcers are treated by under-running, with or without pyloroplasty. Under-running for gastric ulcers can also be carried out (a biopsy must be taken to exclude carcinoma). Local excision may be performed, but when neither is possible, partial gastrectomy is required. Following surgery for ulcer bleeding, all patients should be treated with *H. pylori* eradication therapy if they test positive for it, and should avoid NSAIDs. Successful eradication should be confirmed by urea breath or faecal antigen testing.

Lower gastrointestinal bleeding

This may be due to haemorrhage from the colon, anal canal or small bowel. It is useful to distinguish those patients who present with profuse, acute bleeding from those who present with chronic or subacute bleeding of lesser severity (Box 22.20).

Severe acute lower gastrointestinal bleeding

This presents with profuse red or maroon diarrhoea and with shock. Diverticular disease is the most common cause and is often due to erosion of an artery within the mouth of a diverticulum. Bleeding almost always stops spontaneously, but if it does not, the diseased segment of colon should be resected after confirmation of the site by angiography or colonoscopy. Angiodysplasia is a disease of the elderly, in which vascular malformations develop in the proximal colon. Bleeding can be acute and profuse; it usually stops spontaneously but commonly recurs. Diagnosis is often difficult. Colonoscopy may reveal characteristic vascular spots and, in the acute phase, visceral angiography can show bleeding into the intestinal lumen and an abnormal large, draining vein. In some patients, diagnosis is only achieved by laparotomy with on-table colonoscopy. The treatment of choice is endoscopic thermal ablation, but resection of the affected bowel may be required if bleeding continues. Bowel ischaemia due to occlusion of the inferior mesenteric artery can present with abdominal colic and rectal bleeding. It should be considered in patients (particularly the elderly) who have evidence of generalised atherosclerosis. The diagnosis is made at colonoscopy. Resection is required only in the presence of peritonitis. Meckel's diverticulum with ectopic gastric epithelium may ulcerate and erode into a major artery. The diagnosis should be considered in children or adolescents who present with profuse or recurrent lower gastrointestinal bleeding. A Meckel's ^{99m}Tc-pertechnate scan is sometimes positive but the diagnosis is commonly made only by laparotomy, at which time the diverticulum is excised.

Subacute or chronic lower gastrointestinal bleeding

This can occur at all ages and is usually due to haemorrhoids or anal fissure. Haemorrhoidal bleeding is bright red and occurs during or after defecation. Proctoscopy can be used to make the diagnosis but subjects who have altered bowel habit and those who present over the age of 40 years should undergo colonoscopy to exclude coexisting colorectal cancer. Anal fissure should be suspected when fresh rectal bleeding and anal pain occur during defecation.

Major gastrointestinal bleeding of unknown cause

In some patients who present with major gastrointestinal bleeding, upper endoscopy and colonoscopy fail to reveal a diagnosis. When severe life-threatening bleeding continues, urgent CT mesenteric angiography is indicated. This will usually identify the site if the bleeding rate exceeds 1 mL/min and then formal angiographic embolisation can often stop the bleeding. If angiography is negative or bleeding is less severe, push or double balloon enteroscopy can visualise the small intestine (Fig. 22.20) and treat the bleeding source. Wireless capsule endoscopy is often used to define a source of bleeding prior to enteroscopy. When all else fails, laparotomy with on-table endoscopy is indicated.

Chronic occult gastrointestinal bleeding

In this context, occult means that blood or its breakdown products are present in the stool but cannot be seen by the naked eye. Occult bleeding may reach 200 mL per day and cause iron deficiency anaemia. Any cause of gastrointestinal bleeding may be responsible but the most important is colorectal cancer, particularly carcinoma of the caecum, which may produce no gastrointestinal symptoms. In clinical practice, investigation of

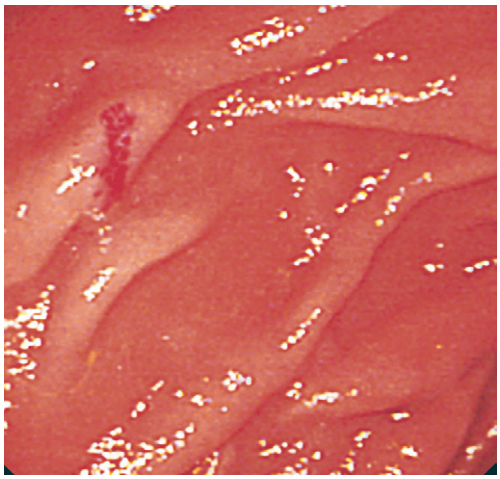

Fig. 22.20 Jejunal angiodysplastic lesion seen at enteroscopy in a patient with recurrent obscure bleeding.

the upper and lower gastrointestinal tract should be considered whenever a patient presents with unexplained iron deficiency anaemia. Testing the stool for the presence of blood is unnecessary and should not influence whether or not the gastrointestinal tract is imaged because bleeding from tumours is often intermittent and a negative faecal occult blood (FOB) test does not exclude the diagnosis. The only value of FOB testing is as a means of population screening for colonic neoplasia in asymptomatic individuals (p. 916).

Diarrhoea

Diarrhoea is defined as the passage of more than 200 g of stool daily, and measurement of stool volume is helpful in confirming this. The most severe symptom in many patients is urgency of defecation, and faecal incontinence is a common event in acute and chronic diarrhoeal illnesses.

Acute diarrhoea

This is extremely common and is usually due to faecal–oral transmission of bacteria or their toxins, viruses or parasites (Ch. 13). Infective diarrhoea is usually short-lived and patients who present with a history of diarrhoea lasting more than 10 days rarely have an infective cause. A variety of drugs, including antibiotics, cytotoxic drugs, PPIs and NSAIDs, may be responsible.

Chronic or relapsing diarrhoea

The most common cause is irritable bowel syndrome (p. 907), which can present with increased frequency of defecation and loose, watery or pellety stools. Diarrhoea rarely occurs at night and is most severe before and after breakfast. At other times, the patient is constipated and there are other characteristic symptoms of irritable bowel syndrome. The stool often contains mucus but never blood, and 24-hour stool volume is less than 200 g. Chronic diarrhoea can be categorised as being due to disease of the colon or small bowel, or to malabsorption (Box 22.21). Clinical presentation, examination of the stool, routine blood tests and imaging reveal a diagnosis in many cases. A series of negative investigations usually implies irritable bowel syndrome but some patients clearly have organic disease and need more extensive investigations.

Malabsorption

Diarrhoea and weight loss in patients with a normal diet is likely to be caused by malabsorption. The symptoms are diverse in nature and variable in severity. A few patients have apparently normal bowel habit but diarrhoea is usual and may be watery and voluminous. Bulky, pale and offensive stools which float in the toilet (steatorrhoea) signify fat malabsorption. Abdominal distension, borborygmi, cramps, weight loss and undigested food in the stool may be present. Some patients complain only of malaise and lethargy. In others,

22.21 Chronic or relapsing diarrhoea

	Colonic	Malabsorption	Small bowel

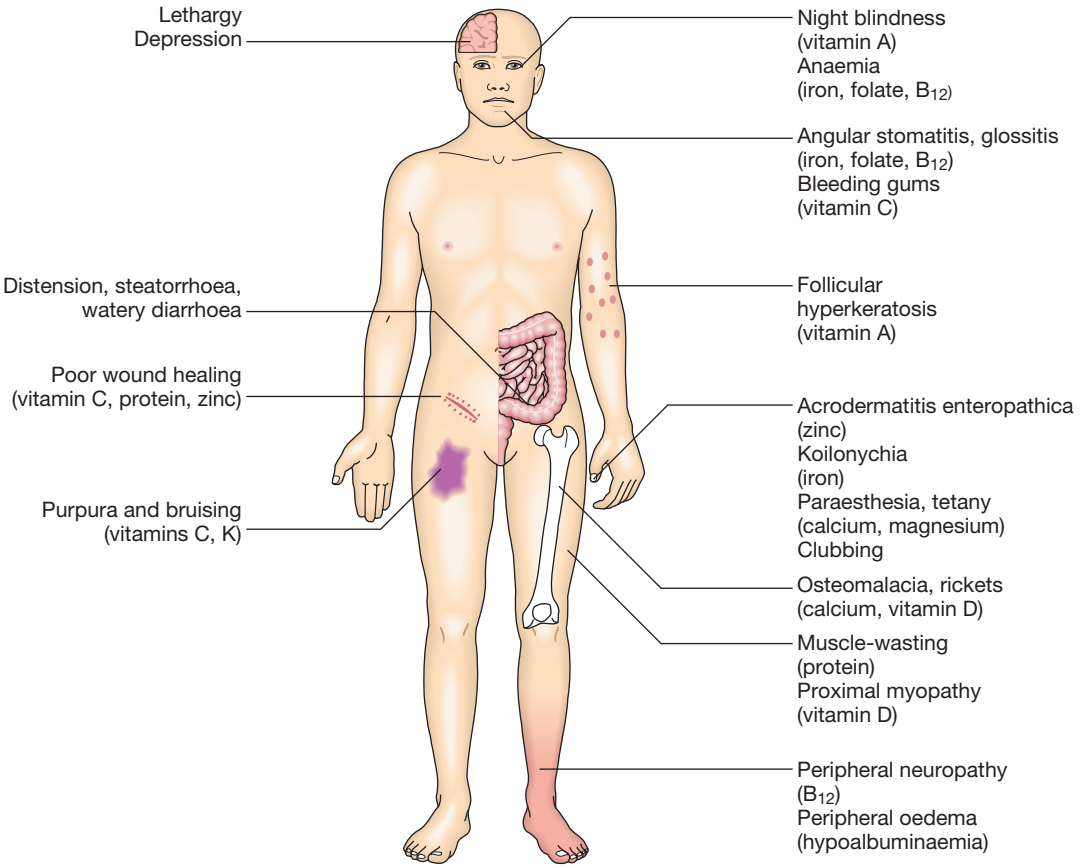

Fig. 22.21 Possible physical consequences of malabsorption.

symptoms related to deficiencies of specific vitamins, trace elements and minerals may occur (Fig. 22.21).

Pathophysiology

Malabsorption results from abnormalities of the three processes which are essential to normal digestion:

1. *Intraluminal maldigestion* occurs when deficiency of bile or pancreatic enzymes results in inadequate solubilisation and hydrolysis of nutrients. Fat and protein malabsorption results. This may also occur with small bowel bacterial overgrowth.
2. *Mucosal malabsorption* results from small bowel resection or conditions which damage the small intestinal epithelium, thereby diminishing the surface area for absorption and depleting brush border enzyme activity.
3. *'Post-mucosal' lymphatic obstruction* prevents the uptake and transport of absorbed lipids into lymphatic vessels. Increased pressure in these vessels results in leakage into the intestinal lumen, leading to protein-losing enteropathy.

Investigations

Investigations should be performed both to confirm the presence of malabsorption and to determine the underlying cause. Routine blood tests may show one or more of the abnormalities listed in Box 22.22. Tests to confirm fat and protein malabsorption should be performed, as described on page 851. An approach to the investigation of malabsorption is shown in Figure 22.22.

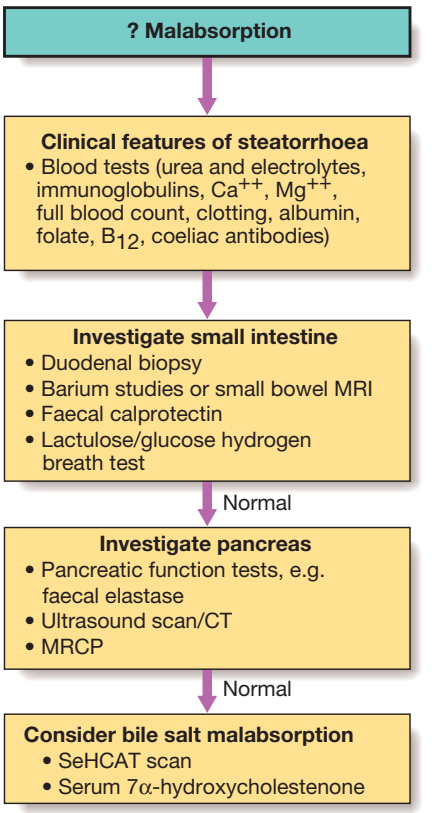

Fig. 22.22 Investigation for suspected malabsorption.

22.22 Routine blood test abnormalities in malabsorption

Haematology

- Microcytic anaemia (iron deficiency)
- Macrocytic anaemia (folate or B_{12} deficiency)
- Increased prothrombin time (vitamin K deficiency)

Biochemistry

- Hypoalbuminaemia
- Hypocalcaemia (p. 768)
- Hypomagnesaemia
- Hypophosphataemia
- Low serum zinc

Weight loss

Weight loss may be physiological, due to dieting, exercise, starvation, or the decreased nutritional intake which accompanies old age. Weight loss of more than 3 kg over 6 months is significant and often indicates the presence of an underlying disease. Hospital and general practice weight records may be valuable in confirming that weight loss has occurred, as may reweighing patients at intervals; sometimes weight is regained or stabilises in those with no obvious cause. Pathological weight loss can be due to psychiatric illness, systemic disease, gastrointestinal causes or advanced disease of many organ systems (Fig. 22.23).

Physiological

Weight loss can occur in the absence of serious disease in healthy individuals who have changes in physical activity or social circumstances. It may be difficult to be sure of this diagnosis in older patients, when the dietary history may be unreliable, and professional help from a dietitian is often valuable under these circumstances.

Psychiatric illness

Features of anorexia nervosa (p. 255), bulimia (p. 256) and affective disorders (p. 243) may only be apparent after formal psychiatric input. Alcoholic patients lose weight as a consequence of self-neglect and poor dietary intake. Depression may cause weight loss.

Systemic diseases

Chronic infections, including tuberculosis (p. 688), recurrent urinary or chest infections, and a range of parasitic and protozoan infections (Ch. 13), should be considered. A history of foreign travel, high-risk activities and specific features, such as fever, night sweats, rigors, productive cough and dysuria, must be sought. Promiscuous sexual activity and drug misuse suggest HIV-related illness (Ch. 14). Weight loss is a late feature of disseminated malignancy, but by the time the patient presents, other features of cancer are often present. Chronic inflammatory diseases, such as rheumatoid arthritis (p. 1096), and polymyalgia rheumatica (p. 1117) are often associated with weight loss.

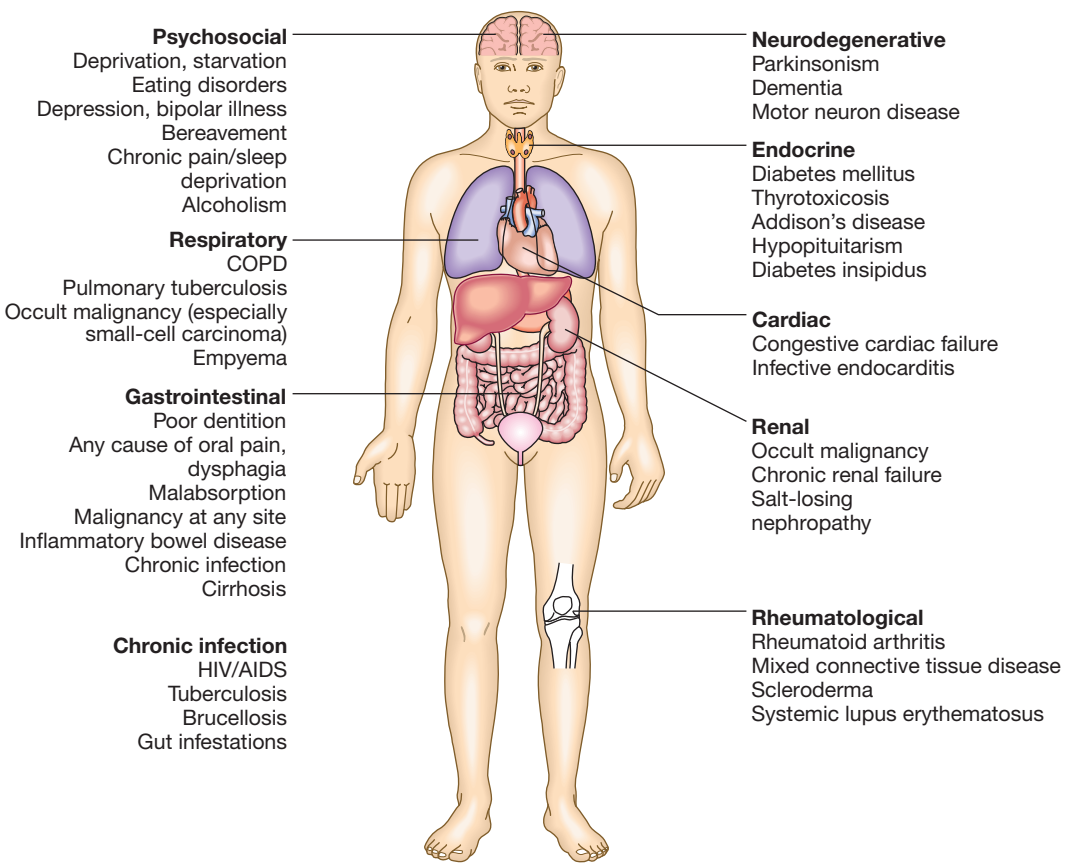

Fig. 22.23 Some important causes of weight loss.

22.23 Some easily overlooked causes of unexplained weight loss

- Depression/anxiety
- Chronic pain or sleep deprivation
- Psychosocial deprivation/malnutrition in the elderly
- Existing conditions (severe chronic obstructive pulmonary disease, cardiac failure)
- Diabetes mellitus/hyperthyroidism
- Occult malignancy
- Anorexia nervosa in atypical groups
- Addison's disease/panhypopituitarism

Gastrointestinal disease

Almost any disease of the gastrointestinal tract can cause weight loss. Dysphagia and gastric outflow obstruction (pp. 851 and 875) cause weight loss by reducing food intake. Malignancy at any site may cause weight loss by mechanical obstruction, anorexia or cytokine-mediated systemic effects. Malabsorption from pancreatic diseases (p. 889) or small bowel causes may lead to profound weight loss with specific nutritional deficiencies (Ch. 5). Inflammatory diseases, such as Crohn's disease or ulcerative colitis (p. 897), cause anorexia, fear of eating and loss of protein, blood and nutrients from the gut.

Metabolic disorders and miscellaneous causes

Weight loss may occur in association with metabolic disorders, as well as end-stage respiratory and cardiac disease. Some easily overlooked causes of weight loss are listed in Box 22.23.

Investigations

In cases where the cause of weight loss is not obvious after thorough history-taking and physical examination, or where an existing condition is considered unlikely, the following investigations are indicated: urinalysis for sugar, protein and blood; blood tests, including liver function tests, random blood glucose and thyroid function tests; CRP and ESR (may be raised in unsuspected infections, such as tuberculosis, connective tissue disorders and malignancy); and faecal calprotectin. Sometimes invasive tests, such as bone marrow aspiration or liver biopsy, may be necessary to identify conditions like cryptic miliary tuberculosis (p. 689). Rarely, abdominal and pelvic imaging by CT may be necessary, but before embarking on invasive or very costly investigations, it is always worth revisiting the patient's history and reweighing at intervals.

Constipation

Constipation is defined as infrequent passage of hard stools. Patients may also complain of straining, a sensation of incomplete evacuation and either perianal or abdominal discomfort. Constipation may occur in many gastrointestinal and other medical disorders (Box 22.24).

Clinical assessment and management

The onset, duration and characteristics are important; for example, a neonatal onset suggests Hirschsprung's disease, while a recent change in bowel activity in middle age should raise the suspicion of organic disorders, such as colonic carcinoma. The presence of rectal bleeding, pain and weight loss is important, as are excessive straining, symptoms suggestive of irritable bowel syndrome, a history of childhood constipation and emotional distress.

22.24 Causes of constipation

Gastrointestinal disorders

Dietary
- Lack of fibre and/or fluid intake

Motility
- Slow-transit constipation
- Irritable bowel syndrome
- Drugs (see below)
- Chronic intestinal pseudo-obstruction

Structural
- Colonic carcinoma
- Diverticular disease
- Hirschsprung's disease

Defecation
- Anorectal disease (Crohn's, fissures, haemorrhoids)
- Obstructed defecation

Non-gastrointestinal disorders

Drugs
- Opiates
- Anticholinergics
- Calcium antagonists
- Iron supplements
- Aluminium-containing antacids

Neurological
- Multiple sclerosis
- Spinal cord lesions
- Cerebrovascular accidents
- Parkinsonism

Metabolic/endocrine
- Diabetes mellitus
- Hypercalcaemia
- Hypothyroidism
- Pregnancy

Others
- Any serious illness with immobility, especially in the elderly
- Depression

Careful examination contributes more to the diagnosis than extensive investigation. A search should be made for general medical disorders, as well as signs of intestinal obstruction. Neurological disorders, especially spinal cord lesions, should be sought. Perineal inspection and rectal examination are essential and may reveal abnormalities of the pelvic floor (abnormal descent, impaired sensation), anal canal or rectum (masses, faecal impaction, prolapse).

It is neither possible nor appropriate to investigate every person with constipation. Most respond to increased fluid intake, dietary fibre supplementation, exercise and the judicious use of laxatives. Middle-aged or elderly patients with a short history or worrying symptoms (rectal bleeding, pain or weight loss) must be investigated promptly, by either barium enema or colonoscopy. For those with simple constipation, investigation will usually proceed along the following lines.

Initial visit

Digital rectal examination, proctoscopy and sigmoidoscopy (to detect anorectal disease), routine biochemistry, including serum calcium and thyroid function tests, and a full blood count should be carried out. If these are normal, a 1-month trial of dietary fibre and/or laxatives is justified.

Next visit

If symptoms persist, then examination of the colon by barium enema or CT colonography is indicated to look for structural disease.

Further investigation

If no cause is found and disabling symptoms are present, then specialist referral for investigation of possible dysmotility may be necessary. The problem may be one of infrequent desire to defecate ('slow transit') or else may result from neuromuscular incoordination and excessive straining ('functional obstructive defecation', p. 913). Intestinal marker studies, anorectal manometry, electrophysiological studies and magnetic resonance proctography can all be used to define the problem.

Abdominal pain

There are four types of abdominal pain:

- *Visceral*. Gut organs are insensitive to stimuli such as burning and cutting but are sensitive to distension, contraction, twisting and stretching. Pain from unpaired structures is usually but not always felt in the midline.
- *Parietal*. The parietal peritoneum is innervated by somatic nerves, and its involvement by inflammation, infection or neoplasia causes sharp, well-localised and lateralised pain.
- *Referred pain*. (For example, gallbladder pain is referred to the back or shoulder tip.)
- *Psychogenic*. Cultural, emotional and psychosocial factors influence everyone's experience of pain. In some patients, no organic cause can be found despite investigation, and psychogenic causes (depression or somatisation disorder) may be responsible (pp. 235 and 245).

The acute abdomen

This accounts for approximately 50% of all urgent admissions to general surgical units. The acute abdomen is a consequence of one or more pathological processes (Box 22.25):

- *Inflammation*. Pain develops gradually, usually over several hours. It is initially rather diffuse until the parietal peritoneum is involved, when it becomes localised. Movement exacerbates the pain; abdominal rigidity and guarding occur.
- *Perforation*. When a viscus perforates, pain starts abruptly; it is severe and leads to generalised peritonitis.
- *Obstruction*. Pain is colicky, with spasms which cause the patient to writhe around and double up. Colicky pain which does not disappear between spasms suggests complicating inflammation.

22.25 Causes of acute abdominal pain

Inflammation	
• Appendicitis	• Pancreatitis
• Diverticulitis	• Pyelonephritis
• Cholecystitis	• Intra-abdominal abscess
• Pelvic inflammatory disease	
Perforation/rupture	
• Peptic ulcer	• Ovarian cyst
• Diverticular disease	• Aortic aneurysm
Obstruction	
• Intestinal obstruction	• Ureteric colic
• Biliary colic	
Other (rare)	
• See Box 22.27	

Initial clinical assessment

If there are signs of peritonitis (guarding and rebound tenderness with rigidity), the patient should be resuscitated with oxygen, intravenous fluids and antibiotics. In other circumstances, further investigations are required (Fig. 22.24).

Investigations

Patients should have a full blood count, urea and electrolytes, and amylase taken to look for evidence of dehydration, leucocytosis and pancreatitis. An erect chest X-ray may show air under the diaphragm, suggestive of perforation, and a plain abdominal film may show evidence of obstruction or ileus. An abdominal ultrasound may help if gallstones or renal stones are suspected. Ultrasonography is also useful in the detection of free fluid and any possible intra-abdominal abscess. Contrast studies, by either mouth or anus, are useful in the further evaluation of intestinal obstruction, and essential in the differentiation of pseudo-obstruction from mechanical large-bowel obstruction. Other investigations commonly used include CT (seeking evidence of pancreatitis, retroperitoneal collections or masses, including an aortic aneurysm) and angiography (mesenteric ischaemia).

Diagnostic laparotomy should be considered when the diagnosis has not been revealed by other investigations. All patients must be carefully and regularly re-assessed (every 2–4 hours) so that any change in condition that might alter both the suspected diagnosis and clinical decision can be observed and acted upon early.

Management

The general approach is to close perforations, treat inflammatory conditions with antibiotics or resection, and relieve obstructions. The speed of intervention and the necessity for surgery depend on the organ that is involved and on a number of other factors, of which the presence or absence of peritonitis is the most important. A treatment summary of some of the more common surgical conditions follows.

Acute appendicitis

This should be treated by early surgery, since there is a risk of perforation and recurrent attacks with non-operative treatment. The appendix can be removed through a conventional right iliac fossa skin crease incision or by laparoscopic techniques.

Acute cholecystitis

This can be successfully treated non-operatively but the high risk of recurrent attacks and the low morbidity of

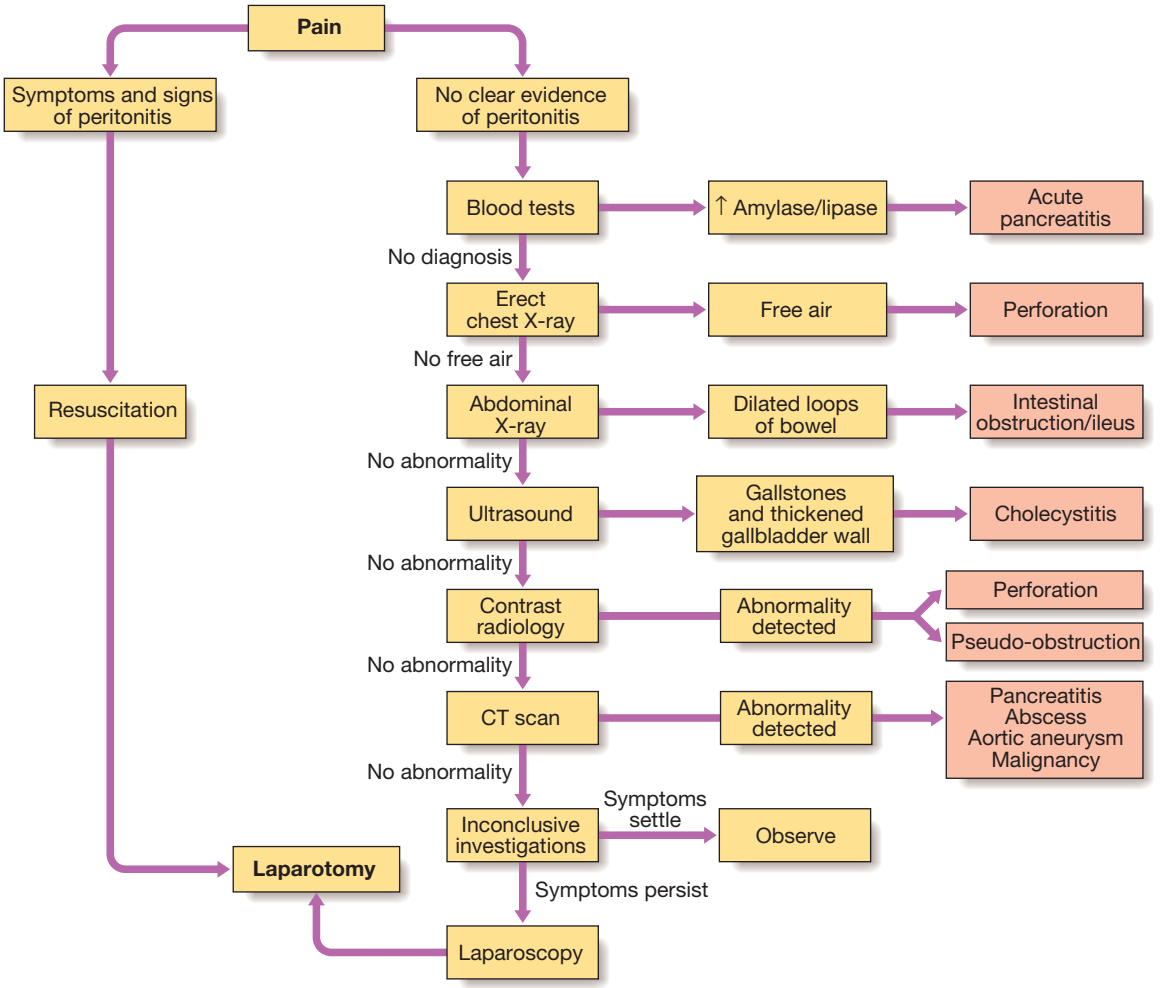

Fig. 22.24 Management of acute abdominal pain: an algorithm.

surgery have made early laparoscopic cholecystectomy the treatment of choice.

Acute diverticulitis

Conservative therapy is standard but if perforation has occurred, resection is advisable. Depending on peritoneal contamination and the state of the patient, primary anastomosis is preferable to a Hartmann's procedure (oversew of rectal stump and end colostomy).

Small bowel obstruction

If the cause is obvious and surgery inevitable (such as with a strangulated hernia), an early operation is appropriate. If the suspected cause is adhesions from previous surgery, only those patients who do not resolve within the first 48 hours or who develop signs of strangulation (colicky pain becomes constant, peritonitis, tachycardia, fever, leucocytosis) should have surgery.

Large bowel obstruction

Pseudo-obstruction should be treated non-operatively. Some patients benefit from colonoscopic decompression, but mechanical obstruction merits resection, usually with a primary anastomosis. Differentiation between the two is made by water-soluble contrast enema.

22.26 Acute abdominal pain in old age

- **Presentation**: severity and localisation may blunt with age. Presentation may be atypical, even with perforation of a viscus.
- **Cancer**: a more common cause of acute pain in those over 70 yrs than in those under 50 yrs. Older people with vague abdominal symptoms should therefore be carefully assessed.
- **Non-specific symptoms**: intra-abdominal inflammatory conditions, such as diverticulitis, may present with non-specific symptoms, such as acute confusion or anorexia and relatively little abdominal tenderness. The reasons for this are not clear but may result from altered sensory perception.
- **Outcome of abdominal surgery**: determined by the degree of comorbid disease and whether surgery is elective or emergency, rather than by chronological age.

Perforated peptic ulcer

Surgical closure of the perforation is standard practice but some patients without generalised peritonitis can be treated non-operatively once a water-soluble contrast meal has confirmed spontaneous sealing of the perforation. Adequate and aggressive resuscitation with

intravenous fluids, antibiotics and analgesia is mandatory before surgery.

For a more detailed discussion of acute abdominal pain, the reader is referred to the sister volume of this text, *Principles and Practice of Surgery*.

Chronic or recurrent abdominal pain

It is essential to take a detailed history, paying particular attention to features of the pain and any associated symptoms (Boxes 22.27 and 22.28).

Note should be made of the patient's general demeanour, mood and emotional state, signs of weight loss, fever, jaundice or anaemia. If a thorough abdominal and rectal examination is normal, a careful search should be made for evidence of disease affecting other structures, particularly the vertebral column, spinal cord, lungs and cardiovascular system.

Investigations will depend on the clinical features elicited during the history and examination:

- Endoscopy and ultrasound are indicated for epigastric pain, and for dyspepsia and symptoms suggestive of gallbladder disease
- Colonoscopy is indicated for patients with altered bowel habit, rectal bleeding or features of obstruction suggesting colonic disease.
- CT or MR angiography should be considered when pain is provoked by food in a patient with widespread atherosclerosis, since this may indicate mesenteric ischaemia.
- Persistent symptoms require exclusion of colonic or small bowel disease. However, young patients with pain relieved by defecation, bloating and alternating bowel habit are likely to have irritable bowel syndrome (p. 907). Simple investigations (blood tests, faecal calprotectin and sigmoidoscopy) are sufficient in the absence of rectal bleeding, weight loss and abnormal physical findings.
- Ultrasound, CT and faecal elastase are required for patients with upper abdominal pain radiating to the back. A history of alcohol misuse, weight loss and diarrhoea suggests chronic pancreatitis or pancreatic cancer.
- Recurrent attacks of pain in the loins radiating to the flanks with urinary symptoms should prompt investigation for renal or ureteric stones by abdominal X-ray, ultrasound and CT urography.
- A past history of psychiatric disturbance, repeated negative investigations or vague symptoms which do not fit any disease or organ pattern suggest a psychological origin for the pain (p. 236). Careful review of case notes and previous investigations, along with open and honest discussion with the patient, reduces the need for further cycles of unnecessary and invasive tests. Care must always be taken, however, not to miss rare pathology or atypical presentations of common diseases.

22.27 Extra-intestinal causes of chronic or recurrent abdominal pain

Retroperitoneal	
• Aortic aneurysm • Malignancy	• Lymphadenopathy • Abscess
Psychogenic	
• Depression • Anxiety	• Hypochondriasis • Somatisation
Locomotor	
• Vertebral compression/ fracture	• Abdominal muscle strain
Metabolic/endocrine	
• Diabetes mellitus • Addison's disease	• Acute intermittent porphyria • Hypercalcaemia
Drugs/toxins	
• Corticosteroids • Azathioprine	• Lead • Alcohol
Haematological	
• Sickle-cell disease	• Haemolytic disorders
Neurological	
• Spinal cord lesions • Tabes dorsalis	• Radiculopathy

22.28 How to assess abdominal pain

- Duration
- Site and radiation
- Severity
- Precipitating and relieving factors (food, drugs, alcohol, posture, movement, defecation)
- Nature (colicky, constant, sharp or dull, wakes patient at night)
- Pattern (intermittent or continuous)
- Associated features (vomiting, dyspepsia, altered bowel habit)

Constant abdominal pain

Patients with chronic pain that is constant or nearly always present usually have features to suggest the underlying diagnosis. In a minority, no cause will be found, despite thorough investigation, leading to the diagnosis of 'chronic functional abdominal pain'. In these patients, there appears to be abnormal CNS processing of normal visceral afferent sensory input, psychosocial factors are often operative (p. 240), and the most important tasks are to provide symptom control, if not relief, and to minimise the effects of the pain on social, personal and occupational life. Patients are best managed in specialised pain clinics where, in addition to psychological support, appropriate use of drugs, including tricyclic antidepressants, gabapentin or pregabalin, ketamine and opioids, may be necessary.

DISEASES OF THE MOUTH AND SALIVARY GLANDS

Aphthous ulceration

Aphthous ulcers are superficial and painful; they occur in any part of the mouth. Recurrent ulcers afflict up to 30% of the population and are particularly common in women prior to menstruation. The cause is unknown, but in severe cases other causes of oral ulceration must be considered (Box 22.29). Occasionally, biopsy is necessary for diagnosis.

22.29 Causes of oral ulceration

Aphthous	
• Idiopathic	• Premenstrual
Infection	
• Fungal (candidiasis) • Viral (herpes simplex, HIV)	• Bacterial, including syphilis, tuberculosis
Gastrointestinal diseases	
• Crohn's disease	• Coeliac disease
Dermatological conditions	
• Lichen planus • Immunobullous disorders (p. 1292)	• Dermatitis herpetiformis • Erythema multiforme
Drugs	
• Nicorandil, NSAIDs, methotrexate, penicillamine, losartan, ACE inhibitors	• Stevens–Johnson syndrome (pp. 1264 and 1302) • Cytotoxic drugs
Systemic diseases	
• Systemic lupus erythematosus (p. 1109)	• Behçet's syndrome (p. 1119)
Neoplasia	
• Carcinoma • Leukaemia	• Kaposi's sarcoma

(ACE = angiotensin-converting enzyme; NSAIDs = non-steroidal anti-inflammatory drugs)

Management is with topical corticosteroids (such as 0.1% triamcinolone in Orabase) or choline salicylate (8.7%) gel. Symptomatic relief is achieved using local anaesthetic mouthwashes. Rarely, patients with very severe, recurrent aphthous ulcers may need oral corticosteroids.

Oral cancer

Squamous carcinoma of the oral cavity is common worldwide and the incidence has increased by 25% in the last decade in the UK. The mortality rate is around 50%, largely as a result of late diagnosis. Poor diet, alcohol excess and smoking or tobacco chewing are the traditional risk factors but high-risk, oncogenic strains of human papillomavirus (HPV-16 and HPV-18) have been identified as responsible for much of the recent increase in incidence, especially in cases affecting the base of tongue, soft palate and tonsils. In parts of Asia, the disease is common among people who chew areca nuts wrapped in leaves of the betel plant ('betel nuts').

Oral cancer may present in many ways (Box 22.30) and a high index of suspicion is required. Patients with suspicious lesions should have all possible sources of local trauma or infection treated and should be reviewed after 2 weeks, with biopsy if the lesion persists. Small cancers can be resected but extensive surgery, with neck dissection to remove involved lymph nodes, may be necessary. Some patients can be treated with radical radiotherapy alone, and sometimes radiotherapy is also given after surgery to treat microscopic residual disease. Some tumours may be amenable to photodynamic therapy (PDT), avoiding the need for surgery.

22.30 Symptoms and signs of oral cancer

- Solitary ulcer without precipitant, e.g. local trauma
- Solitary white patch ('leukoplakia') which fails to wipe off
- Solitary red patch
- Fixed lump
- Lip numbness in absence of trauma or infection
- Trismus (painful/difficult mouth opening)
- Cervical lymphadenopathy

Candidiasis

The yeast *Candida albicans* is a normal mouth commensal but it may proliferate to cause thrush. This occurs in babies, debilitated patients, patients receiving corticosteroid or antibiotic therapy, patients with diabetes and immunosuppressed patients, especially those receiving cytotoxic therapy and those with HIV infection. White patches are seen on the tongue and buccal mucosa. Odynophagia or dysphagia suggests pharyngeal and oesophageal candidiasis. A clinical diagnosis is sufficient to instigate therapy, although brushings or biopsies can be obtained for mycological examination. Oral thrush is treated using nystatin or amphotericin suspensions or lozenges. Resistant cases or immunosuppressed patients may require oral fluconazole.

Parotitis

Parotitis is due to viral or bacterial infection. Mumps causes a self-limiting acute parotitis (p. 319). Bacterial parotitis usually occurs as a complication of major surgery. It is a consequence of dehydration and poor oral hygiene, and can be avoided by good post-operative care. Patients present with painful parotid swelling and this can be complicated by abscess formation. Broad-spectrum antibiotics are required, whilst surgical drainage is necessary for abscesses. Other causes of salivary gland enlargement are listed in Box 22.31.

22.31 Causes of salivary gland swelling

- Infection
  - Mumps
  - Bacterial (post-operative)
- Calculi
- Sjögren's syndrome (p. 1114)
- Sarcoidosis
- Tumours
  - Benign: pleomorphic adenoma (95% of cases)
  - Intermediate: mucoepidermoid tumour
  - Malignant: carcinoma

22.32 Oral health in old age

- **Dry mouth**: affects around 40% of healthy older people.
- **Gustatory and olfactory sensation**: declines and chewing power is diminished.
- **Salivation**: baseline salivary flow falls but stimulated salivation is unchanged.
- **Root caries and periodontal disease**: common partly because oral hygiene deteriorates with increasing frailty.
- **Bacteraemia and septicaemia**: may complicate Gram-negative anaerobic infection in the periodontal pockets of the very frail.

DISEASES OF THE OESOPHAGUS

Gastro-oesophageal reflux disease

Gastro-oesophageal reflux resulting in heartburn affects approximately 30% of the general population.

Pathophysiology

Occasional episodes of gastro-oesophageal reflux are common in healthy individuals. Reflux is normally followed by oesophageal peristaltic waves which efficiently clear the gullet, alkaline saliva neutralises residual acid, and symptoms do not occur. Gastro-oesophageal reflux disease develops when the oesophageal mucosa is exposed to gastroduodenal contents for prolonged periods of time, resulting in symptoms and, in a proportion of cases, oesophagitis. Several factors are known to be involved in the development of gastro-oesophageal reflux disease and these are shown in Figure 22.25.

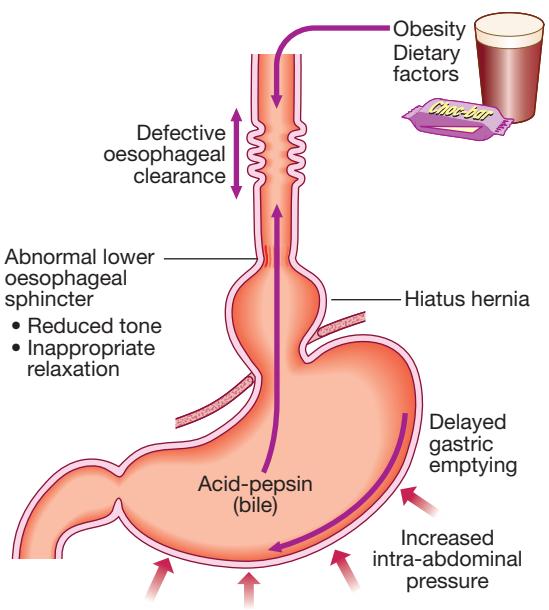

Fig. 22.25 Factors associated with the development of gastro-oesophageal reflux disease.

Abnormalities of the lower oesophageal sphincter

The lower oesophageal sphincter is tonically contracted under normal circumstances, relaxing only during swallowing (p. 840).

Some patients with gastro-oesophageal reflux disease have reduced lower oesophageal sphincter tone, permitting reflux when intra-abdominal pressure rises. In others, basal sphincter tone is normal but reflux occurs in response to frequent episodes of inappropriate sphincter relaxation.

Hiatus hernia

Hiatus hernia (Box 22.33 and Fig. 22.26) causes reflux because the pressure gradient between the abdominal and thoracic cavities, which normally pinches the hiatus, is lost. In addition, the oblique angle between the cardia and oesophagus disappears. Many patients who have large hiatus hernias develop reflux symptoms, but the relationship between the presence of a hernia and symptoms is poor. Hiatus hernia is very common in individuals who have no symptoms, and some symptomatic patients have only a very small or no hernia. Nevertheless, almost all patients who develop oesophagitis, Barrett's oesophagus or peptic strictures have a hiatus hernia.

Delayed oesophageal clearance

Defective oesophageal peristaltic activity is commonly found in patients who have oesophagitis. It is a primary abnormality, since it persists after oesophagitis has been healed by acid-suppressing drug therapy. Poor oesophageal clearance leads to increased acid exposure time.

22.33 Important features of hiatus hernia

- Herniation of the stomach through the diaphragm into the chest
- Occurs in 30% of the population over the age of 50 yrs
- Often asymptomatic
- Heartburn and regurgitation can occur
- Gastric volvulus may complicate large para-oesophageal hernias

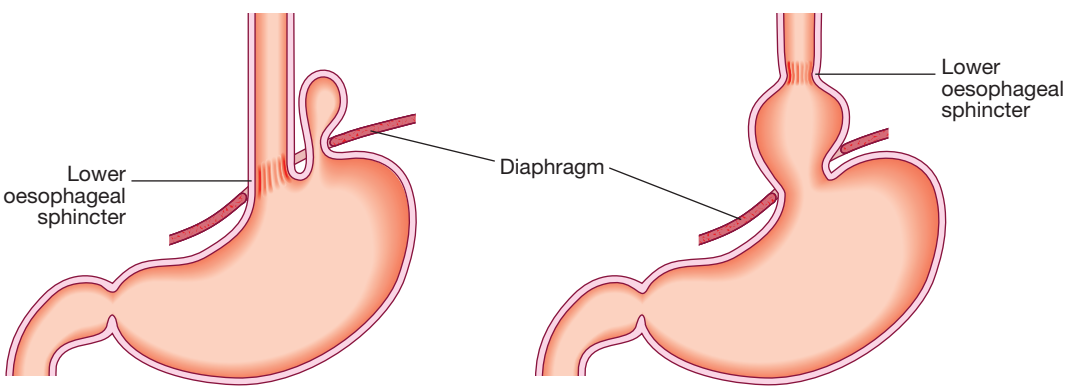

Fig. 22.26 Types of hiatus hernia.

Gastric contents

Gastric acid is the most important oesophageal irritant and there is a close relationship between acid exposure time and symptoms. Pepsin and bile also contribute to mucosal injury.

Defective gastric emptying

Gastric emptying is delayed in patients with gastro-oesophageal reflux disease. The reason is unknown.

Increased intra-abdominal pressure

Pregnancy and obesity are established predisposing causes. Weight loss may improve symptoms.

Dietary and environmental factors

Dietary fat, chocolate, alcohol and coffee relax the lower oesophageal sphincter and may provoke symptoms. The foods that trigger symptoms vary widely between affected individuals.

Patient factors

Visceral sensitivity and patient vigilance play a role in determining symptom severity and consulting behaviour in individual patients.

Clinical features

The major symptoms are heartburn and regurgitation, often provoked by bending, straining or lying down. 'Waterbrash', which is salivation due to reflex salivary gland stimulation as acid enters the gullet, is often present. The patient is often overweight. Some patients are woken at night by choking as refluxed fluid irritates the larynx. Others develop odynophagia or dysphagia. A variety of other features have been described, such as atypical chest pain which may be severe and can mimic angina, and may be due to reflux-induced oesophageal spasm. Others include hoarseness ('acid laryngitis'), recurrent chest infections, chronic cough and asthma (Box 22.34). The true relationship of these features to gastro-oesophageal reflux disease remains unclear.

Complications

Oesophagitis

A range of endoscopic findings, from mild redness to severe, bleeding ulceration with stricture formation, are recognised, although appearances may be completely normal (Fig. 22.27). There is a poor correlation between symptoms and histological and endoscopic findings.

Barrett's oesophagus

Barrett's oesophagus is a pre-malignant condition, in which the normal squamous lining of the lower oesophagus is replaced by columnar mucosa (columnar lined oesophagus; CLO) that may contain areas of intestinal metaplasia (Fig. 22.28). It is an adaptive response to chronic gastro-oesophageal reflux and is found in 10% of patients undergoing gastroscopy for reflux symptoms. Community-based epidemiological studies suggest that the true prevalence may be up to 1.5–5% of the population, as the condition is often asymptomatic until discovered when the patient presents with oesophageal cancer. The relative risk of oesophageal cancer is 40–120-fold increased but the absolute risk is low (0.1–0.5% per year). The epidemiology and aetiology of CLO are poorly understood. The prevalence is increasing, and it is more common in men (especially white), the obese and those over 50 years of age. It is weakly associated with smoking but not alcohol intake. The risk of cancer seems to relate to the severity and duration of reflux rather than the presence of CLO per se and it has been suggested that duodenogastro-oesophageal reflux of bile, pancreatic enzymes and pepsin, as well as gastric acid, may be important in pathogenesis. The molecular events underlying progression of CLO to dysplasia and cancer are incompletely understood but inactivation of the tumour suppression protein p16 by loss of heterozygosity or promoter hypermethylation is a key event, followed by somatic inactivation of p53, which promotes

EBM 22.34 The association between gastro-oesophageal reflux disease and asthma

'Reflux is significantly more common in asthma patients (odds ratio 5.5) and asthma is more common in patients with gastro-oesophageal reflux disease (odds ratio 2.3), compared to controls. Evidence for the direction of causality, however, is lacking.'

- Havemann BD, et al. Gut 2007; 56:1654–1664.

For further information: www.evidbasedgastro.com

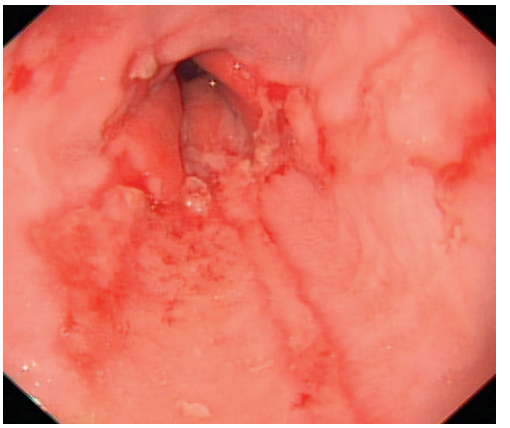

Fig. 22.27 Severe reflux oesophagitis. There is near-circumferential superficial ulceration and inflammation extending up the gullet.

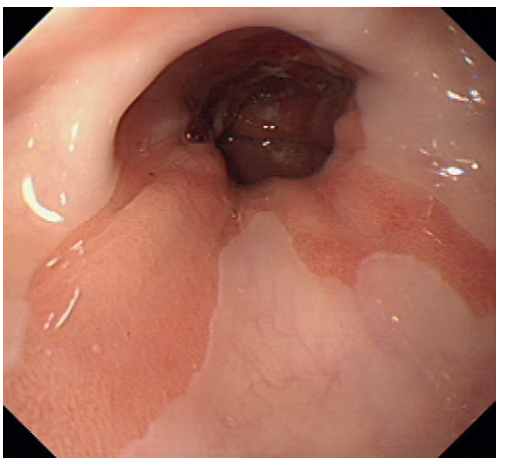

Fig. 22.28 Barrett's oesophagus. Tongues of pink columnar mucosa are seen extending upwards above the oesophago-gastric junction.

aneuploidy and tumour progression. Studies are in progress to develop biomarkers that will allow detection of those at higher cancer risk.

Diagnosis. This requires multiple systematic biopsies to maximise the chance of detecting intestinal metaplasia and/or dysplasia.

Management. Neither potent acid suppression nor anti-reflux surgery stops progression or induces regression of CLO, and treatment is only indicated for symptoms of reflux or complications, such as stricture. Endoscopic therapies, such as radiofrequency ablation or photodynamic therapy, can induce regression but, at present, are used only for those with dysplasia or intramucosal cancer. Regular endoscopic surveillance can detect dysplasia at an early stage and may improve survival but, because most CLO is undetected until cancer develops, surveillance strategies are unlikely to influence the overall mortality rate of oesophageal cancer. Surveillance is expensive and cost-effectiveness studies have been conflicting, but it is currently recommended that patients with CLO without dysplasia should undergo endoscopy at 3–5-yearly intervals and those with low-grade dysplasia at 6–12-monthly intervals.

For those with high-grade dysplasia (HGD) or intramucosal carcinoma, the treatment options are either oesophagectomy or endoscopic therapy with a combination of endoscopic resection (ER) of any visibly abnormal areas and radiofrequency ablation (RFA) of the remaining Barrett's mucosa as an 'organ-preserving' alternative to surgery. These cases should be discussed in a multidisciplinary team meeting and managed in specialist centres.

Anaemia

Iron deficiency anaemia can occur as a consequence of occult blood loss from long-standing oesophagitis. Most patients have a large hiatus hernia and bleeding can stem from subtle erosions in the neck of the sac ('Cameron lesions'). Nevertheless, hiatus hernia is very common and other causes of blood loss, particularly colorectal cancer, must be considered in anaemic patients, even when endoscopy reveals oesophagitis.

Benign oesophageal stricture

Fibrous strictures can develop as a consequence of long-standing oesophagitis, especially in the elderly and those with poor oesophageal peristaltic activity. The typical presentation is with dysphagia that is worse for solids than for liquids. Bolus obstruction following ingestion of meat causes absolute dysphagia. A history of heartburn is common but not invariable; many elderly patients presenting with strictures have no preceding heartburn.

Diagnosis is by endoscopy, when biopsies of the stricture can be taken to exclude malignancy. Endoscopic balloon dilatation or bouginage is helpful. Subsequently, long-term therapy with a PPI drug at full dose should be started to reduce the risk of recurrent oesophagitis and stricture formation. The patient should be advised to chew food thoroughly, and it is important to ensure adequate dentition.

Gastric volvulus

Occasionally, a massive intrathoracic hiatus hernia may twist upon itself, leading to a gastric volvulus. This gives rise to complete oesophageal or gastric obstruction and the patient presents with severe chest pain, vomiting and dysphagia. The diagnosis is made by chest X-ray (air bubble in the chest) and barium swallow. Most cases spontaneously resolve but recurrence is common, and surgery is usually advised after the acute episode has been treated by nasogastric decompression.

Investigations

Young patients who present with typical symptoms of gastro-oesophageal reflux, without worrying features such as dysphagia, weight loss or anaemia, can be treated empirically without investigation. Investigation is advisable if patients present over the age of 50–55 years, if symptoms are atypical or if a complication is suspected. Endoscopy is the investigation of choice. This is performed to exclude other upper gastrointestinal diseases that can mimic gastro-oesophageal reflux and to identify complications. A normal endoscopy in a patient with compatible symptoms should not preclude treatment for gastro-oesophageal reflux disease.

Twenty-four-hour pH monitoring is indicated if the diagnosis is unclear or surgical intervention is under consideration. This involves tethering a slim catheter with a terminal radiotelemetry pH-sensitive probe above the gastro-oesophageal junction. The intraluminal pH is recorded whilst the patient undergoes normal activities, and episodes of symptoms are noted and related to pH. A pH of less than 4 for more than 6–7% of the study time is diagnostic of reflux disease. In a few patients with difficult reflux, impedance testing can detect weakly acidic or alkaline reflux that is not revealed by standard pH testing.

Management

A treatment algorithm for gastro-oesophageal reflux is outlined in Figure 22.29. Lifestyle advice, including weight loss, avoidance of dietary items that the patient finds worsen symptoms, elevation of the bed head in those who experience nocturnal symptoms, avoidance of late meals and giving up smoking, should be recommended. Patients who fail to respond to these measures should be offered PPIs, which are usually effective in resolving symptoms and healing oesophagitis. Recurrence of symptoms is common when therapy is stopped and some patients require life-long treatment at the lowest acceptable dose. When dysmotility features are prominent, domperidone can be helpful. There is no evidence that *H. pylori* eradication has any therapeutic value. Proprietary antacids and alginates can also provide symptomatic benefit. H_2-receptor antagonist drugs also help symptoms without healing oesophagitis.

Long-term PPI therapy is associated with reduced absorption of iron, B_{12} and magnesium, and a small but increased risk of osteoporosis and fractures (odds ratio 1.2–1.5). The drugs also predispose to enteric infections with *Salmonella*, *Campylobacter* and possibly *Clostridium difficile*. Long-term therapy increases the risk of *Helicobacter*-associated progression of gastric mucosal atrophy (see below) and *H. pylori* eradication is advised in patients requiring PPIs for more than 1 year.

Patients who fail to respond to medical therapy, those who are unwilling to take long-term PPIs and those

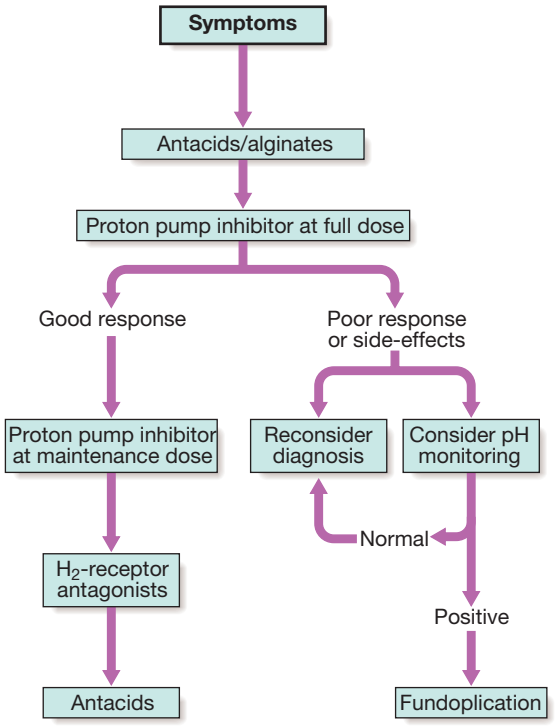

Fig. 22.29 Treatment of gastro-oesophageal reflux disease: a 'step-down' approach.

22.35 Gastro-oesophageal reflux disease in old age

- **Prevalence**: higher.
- **Severity of symptoms**: does not correlate with the degree of mucosal inflammation.
- **Complications**: late complications, such as peptic strictures or bleeding from oesophagitis, are more common.
- **Recurrent pneumonia**: consider aspiration from occult gastro-oesophageal reflux disease.

whose major symptom is severe regurgitation should be considered for laparoscopic anti-reflux surgery (see *Principles and Practice of Surgery*). Although heartburn and regurgitation are alleviated in most patients, a small minority develop complications, such as inability to vomit and abdominal bloating ('gas-bloat' syndrome').

Other causes of oesophagitis

Infection

Oesophageal candidiasis occurs in debilitated patients and those taking broad-spectrum antibiotics or cytotoxic drugs. It is a particular problem in patients with HIV-AIDS, who are also susceptible to a spectrum of other oesophageal infections (p. 399).

Corrosives

Suicide attempt by strong household bleach or battery acid is followed by painful burns of the mouth and pharynx and by extensive erosive oesophagitis. This may be complicated by oesophageal perforation with mediastinitis and by stricture formation. At the time of presentation, treatment is conservative, based upon analgesia and nutritional support; vomiting and endoscopy should be avoided because of the high risk of oesophageal perforation. After the acute phase, a barium swallow should be performed to demonstrate the extent of stricture formation. Endoscopic dilatation is usually necessary but it is difficult and hazardous because strictures are often long, tortuous and easily perforated.

Drugs

Potassium supplements and NSAIDs may cause oesophageal ulcers when the tablets are trapped above an oesophageal stricture. Liquid preparations of these drugs should be used in such patients. Bisphosphonates cause oesophageal ulceration and should be used with caution in patients with known oesophageal disorders.

Eosinophilic oesophagitis

This is more common in children but increasingly recognised in young adults. It occurs more often in atopic individuals and is characterised by eosinophilic infiltration of the oesophageal mucosa. Patients present with dysphagia or food bolus obstruction more often than heartburn, and other symptoms, such as chest pain and vomiting, may be present. Endoscopy is usually normal but mucosal rings (that sometimes need endoscopic dilatation), strictures or a narrow-calibre oesophagus can occur. Children may respond to elimination diets but these are less successful in adults, who should first be treated with PPIs. The condition can be treated with 8–12 weeks of therapy with topical corticosteroids, such as fluticasone or betamethasone. The usual approach is to prescribe a metered-dose inhaler but to tell the patient to spray this into the mouth and swallow it rather than inhale it. Refractory symptoms sometimes respond to montelukast, a leukotriene inhibitor.

Motility disorders

Pharyngeal pouch

This occurs because of incoordination of swallowing within the pharynx, which leads to herniation through the cricopharyngeus muscle and formation of a pouch. It is rare, affecting 1 in 100 000 people; it usually develops in middle life but can arise at any age. Many patients have no symptoms, but regurgitation, halitosis and dysphagia can be present. Some notice gurgling in the throat after swallowing. The investigation of choice is a barium swallow, which demonstrates the pouch and reveals incoordination of swallowing, often with pulmonary aspiration. Endoscopy may be hazardous, since the instrument may enter and perforate the pouch. Surgical myotomy ('diverticulotomy'), with or without resection of the pouch, is indicated in symptomatic patients.

Achalasia of the oesophagus

Pathophysiology

Achalasia is characterised by:

- a hypertonic lower oesophageal sphincter, which fails to relax in response to the swallowing wave
- failure of propagated oesophageal contraction, leading to progressive dilatation of the gullet.

The cause is unknown. Defective release of nitric oxide by inhibitory neurons in the lower oesophageal

sphincter has been reported, and there is degeneration of ganglion cells within the sphincter and the body of the oesophagus. Loss of the dorsal vagal nuclei within the brainstem can be demonstrated in later stages. Infection with *Trypanosoma cruzi* in Chagas' disease (p. 360) causes a syndrome that is clinically indistinguishable from achalasia.

Clinical features

The presentation is with dysphagia. This develops slowly, is initially intermittent, and is worse for solids and eased by drinking liquids, and by standing and moving around after eating. Heartburn does not occur because the closed oesophageal sphincter prevents gastro-oesophageal reflux. Some patients experience episodes of chest pain due to oesophageal spasm. As the disease progresses, dysphagia worsens, the oesophagus empties poorly and nocturnal pulmonary aspiration develops. Achalasia predisposes to squamous carcinoma of the oesophagus.

Investigations

Endoscopy should always be carried out because carcinoma of the cardia can mimic the presentation and radiological and manometric features of achalasia ('pseudo-achalasia'). A barium swallow shows tapered narrowing of the lower oesophagus and, in late disease, the oesophageal body is dilated, aperistaltic and food-filled (Fig. 22.30A). Manometry confirms the high-pressure, non-relaxing lower oesophageal sphincter with poor contractility of the oesophageal body (Fig. 22.30B).

Management

Endoscopic

Forceful pneumatic dilatation using a 30–35-mm diameter fluoroscopically positioned balloon disrupts the oesophageal sphincter and improves symptoms in 80% of patients. Some patients require more than one dilatation but those needing frequent dilatation are best treated surgically. Endoscopically directed injection of botulinum toxin into the lower oesophageal sphincter induces clinical remission but relapse is common.

Surgical

Surgical myotomy (Heller's operation), performed either laparoscopically or as an open operation, is effective but is more invasive than endoscopic dilatation. Both pneumatic dilatation and myotomy may be complicated by gastro-oesophageal reflux, and this can lead to severe oesophagitis because oesophageal clearance is so poor. For this reason, Heller's myotomy is accompanied by a partial fundoplication anti-reflux procedure. PPI therapy is often necessary after surgery. Recently, a complex endoscopic technique has been developed in specialist centres (peroral endoscopic myotomy, POEM).

Other oesophageal motility disorders

Diffuse oesophageal spasm presents in late middle age with episodic chest pain that may mimic angina, but is sometimes accompanied by transient dysphagia. Some cases occur in response to gastro-oesophageal reflux. Treatment is based upon the use of PPI drugs when gastro-oesophageal reflux is present. Oral or sublingual nitrates or nifedipine may relieve attacks of pain. The results of drug therapy are often disappointing, as are the alternatives: pneumatic dilatation and surgical myotomy. 'Nutcracker' oesophagus is a condition in which extremely forceful peristaltic activity leads to episodic chest pain and dysphagia. Treatment is with nitrates or nifedipine. Some patients present with oesophageal motility disorders which do not fit into a specific disease entity. The patients are usually elderly and present with dysphagia and chest pain. Manometric abnormalities, ranging from poor peristalsis to spasm, occur. Treatment is with dilatation and/or vasodilators for chest pain.

Secondary causes of oesophageal dysmotility

In systemic sclerosis or CREST syndrome, the muscle of the oesophagus is replaced by fibrous tissue, which causes failure of peristalsis leading to heartburn and dysphagia. Oesophagitis is often severe, and benign fibrous strictures occur. These patients require

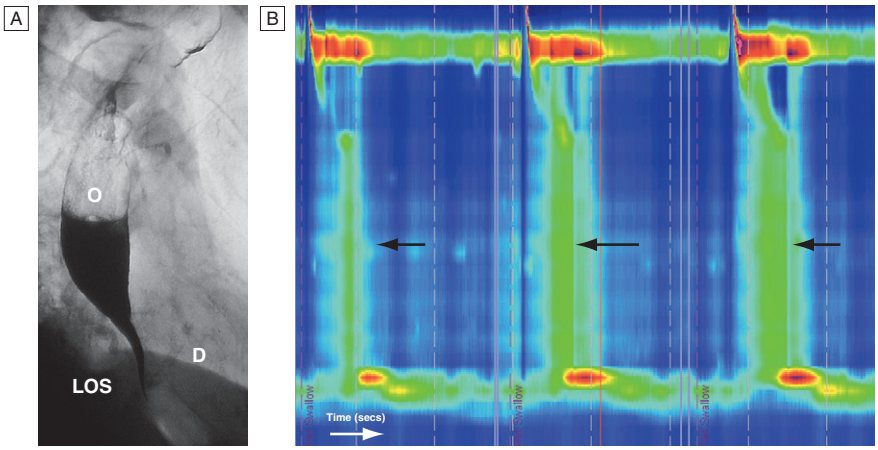

Fig. 22.30 Achalasia. A X-ray showing a dilated, barium-filled oesophagus (O) with fluid level and distal tapering, and a closed lower oesophageal sphincter (LOS). (D = diaphragm) B High-resolution manometry in achalasia showing absence of peristaltic swallowing wave in oesophageal body (black arrows) and raised LOS pressure with failure of relaxation on swallowing (white arrow). Compare with normal appearances in Figure 22.1 (p. 840).

long-term therapy with PPIs. Dermatomyositis, rheumatoid arthritis and myasthenia gravis may also cause dysphagia.

Benign oesophageal stricture

Benign oesophageal stricture is usually a consequence of gastro-oesophageal reflux disease (Box 22.36) and occurs most often in elderly patients who have poor oesophageal clearance. Rings, due to submucosal fibrosis, are found at the oesophago-gastric junction ('Schatzki ring') and cause intermittent dysphagia, often starting in middle age. A post-cricoid web is a rare complication of iron deficiency anaemia (Paterson–Kelly or Plummer–Vinson syndrome), and may be complicated by the development of squamous carcinoma. Benign strictures can be treated by endoscopic dilatation, in which wire-guided bougies or balloons are used to disrupt the fibrous tissue of the stricture.

22.36 Causes of oesophageal stricture

- Gastro-oesophageal reflux disease
- Webs and rings
- Carcinoma of the oesophagus or cardia
- Eosinophilic oesophagitis
- Extrinsic compression from bronchial carcinoma
- Corrosive ingestion
- Post-operative scarring following oesophageal resection
- Post-radiotherapy
- Following long-term nasogastric intubation
- Bisphosphonates

Tumours of the oesophagus

Benign tumours

The most common is a leiomyoma. This is usually asymptomatic but may cause bleeding or dysphagia.

Carcinoma of the oesophagus

Squamous oesophageal cancer (Box 22.37) is relatively rare in Caucasians (4:100 000) but is more common in Iran, parts of Africa and China (200:100 000). Squamous cancer can occur in any part of the oesophagus, and almost all tumours in the upper oesophagus are squamous cancers. Adenocarcinomas typically arise in the lower third of the oesophagus from Barrett's oesophagus or from the cardia of the stomach. The incidence is increasing and is now approximately 5:100 000 in the UK; this is possibly because of the high prevalence of gastro-oesophageal reflux and Barrett's oesophagus in Western populations. Despite modern treatment, the overall 5-year survival of patients presenting with oesophageal cancer is only 13%.

Clinical features

Most patients have a history of progressive, painless dysphagia for solid foods. Others present acutely because of food bolus obstruction. In late stages, weight loss is often extreme; chest pain or hoarseness suggests mediastinal invasion. Fistulation between the oesophagus and the trachea or bronchial tree leads to coughing after swallowing, pneumonia and pleural effusion. Physical signs may be absent but, even at initial presentation, cachexia, cervical lymphadenopathy or other evidence of metastatic spread is common.

22.37 Squamous carcinoma: aetiological factors

- Smoking
- Alcohol excess
- Chewing betel nuts or tobacco
- Achalasia of the oesophagus
- Coeliac disease
- Post-cricoid web
- Post-caustic stricture
- Tylosis (familial hyperkeratosis of palms and soles)

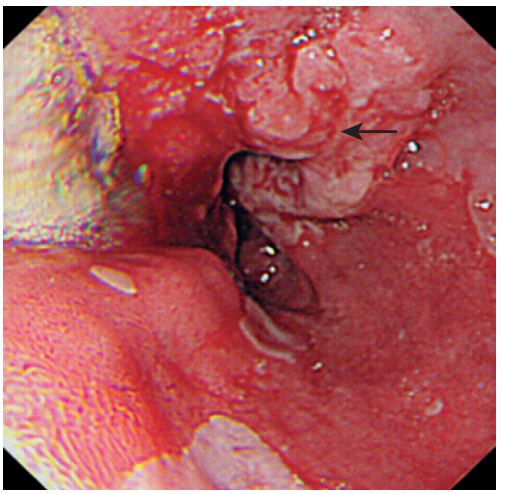

Fig. 22.31 Adenocarcinoma of the lower oesophagus.
Adenocarcinoma in association with Barrett's oesophagus (arrow).

Investigations

The investigation of choice is upper gastrointestinal endoscopy (Fig. 22.31) with biopsy. A barium swallow demonstrates the site and length of the stricture but adds little useful information. Once a diagnosis has been made, investigations should be performed to stage the tumour and define operability. Thoracic and abdominal CT, often combined with positron emission tomography (CT-PET), should be carried out to identify metastatic spread and local invasion. Invasion of the aorta, major airways or coeliac axis usually precludes surgery, but patients with resectable disease on imaging should undergo EUS to determine the depth of penetration of the tumour into the oesophageal wall and to detect locoregional lymph node involvement (Fig. 22.32). These investigations will define the TNM stage of the disease (p. 268).

Management

The treatment of choice is surgery if the patient presents at a point at which resection is possible. Patients with tumours that have extended beyond the wall of the oesophagus (T3) or which have lymph node involvement (N1) have a 5-year survival of around 10%. However, this figure improves significantly if the tumour is confined to the oesophageal wall and there is no spread to lymph nodes. Overall survival following

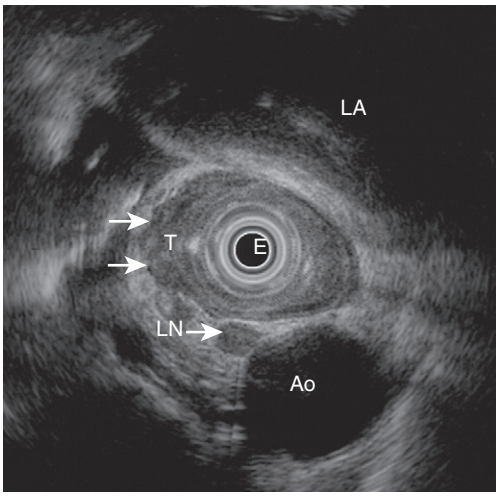

Fig. 22.32 Endoscopic ultrasound staging of oesophageal carcinoma. The tumour (T) has extended through the oesophageal wall (stage T3, arrows). A small peritumoral lymph node (LN) is also seen. (Ao = aorta; LA = left atrium; E = echoendoscope)

'potentially curative' surgery (all macroscopic tumour removed) is about 30% at 5 years, but recent studies have suggested that this can be improved by neoadjuvant chemotherapy. Although squamous carcinomas are radiosensitive, radiotherapy alone is associated with a 5-year survival of only 5%, but combined chemoradiotherapy for these tumours can achieve 5-year survival rates of 25–30%.

Approximately 70% of patients have extensive disease at presentation; in these, treatment is palliative and should focus on relief of dysphagia and pain. Endoscopic laser therapy or self-expanding metallic stents can be used to improve swallowing. Palliative radiotherapy may induce shrinkage of both squamous cancers and adenocarcinomas but symptomatic response may be slow. Quality of life can be improved by nutritional support and appropriate analgesia.

Perforation of the oesophagus

The most common cause is endoscopic perforation complicating dilatation or intubation. Malignant, corrosive or post-radiotherapy strictures are more likely to be perforated than peptic strictures. A perforated peptic stricture is managed conservatively using broad-spectrum antibiotics and parenteral nutrition; most cases heal within days. Malignant, caustic and radiotherapy stricture perforations require resection or stenting.

Spontaneous oesophageal perforation ('Boerhaave's syndrome') results from forceful vomiting and retching. Severe chest pain and shock occur as oesophago-gastric contents enter the mediastinum and thoracic cavity. Subcutaneous emphysema, pleural effusions and pneumothorax develop. The diagnosis can be made using a water-soluble contrast swallow but, in difficult cases, both CT and careful endoscopy (usually in an intubated patient) may be required. Treatment is surgical. Delay in diagnosis is a key factor in the high mortality associated with this condition.

DISEASES OF THE STOMACH AND DUODENUM

Gastritis

Gastritis is a histological diagnosis, although it can sometimes be recognised at endoscopy.

Acute gastritis

Acute gastritis is often erosive and haemorrhagic. Neutrophils are the predominant inflammatory cell in the superficial epithelium. Many cases result from aspirin or NSAID ingestion (Box 22.38). Acute gastritis often produces no symptoms but may cause dyspepsia, anorexia, nausea or vomiting, and haematemesis or melaena. Many cases resolve quickly and do not merit investigation; in others, endoscopy and biopsy may be necessary to exclude peptic ulcer or cancer. Treatment should be directed at the underlying cause. Short-term symptomatic therapy with antacids, and acid suppression using PPIs, prokinetics (domperidone) or antiemetics (metoclopramide) may be necessary.

Chronic gastritis due to *Helicobacter pylori* infection

This is the most common cause of chronic gastritis (see Box 22.38). The predominant inflammatory cells are lymphocytes and plasma cells. Correlation between symptoms and endoscopic or pathological findings is poor. Most patients are asymptomatic and do not require treatment, but patients with dyspepsia may benefit from *H. pylori* eradication.

Autoimmune chronic gastritis

This involves the body of the stomach but spares the antrum; it results from autoimmune damage to parietal

22.38 Common causes of gastritis

Acute gastritis (often erosive and haemorrhagic)
• Aspirin, NSAIDs • *H. pylori* (initial infection) • Alcohol • Other drugs, e.g. iron preparations • Severe physiological stress, e.g. burns, multi-organ failure, CNS trauma • Bile reflux, e.g. following gastric surgery • Viral infections, e.g. CMV, herpes simplex virus in HIV-AIDS (p. 399)
Chronic non-specific gastritis
• *H. pylori* infection • Autoimmune (pernicious anaemia) • Post-gastrectomy
Chronic 'specific' forms (rare)
• Infections, e.g. CMV, tuberculosis • Gastrointestinal diseases, e.g. Crohn's disease • Systemic diseases, e.g. sarcoidosis, graft-versus-host disease • Idiopathic, e.g. granulomatous gastritis

(CMV = cytomegalovirus; NSAIDs = non-steroidal anti-inflammatory drugs)

cells. The histological features are diffuse chronic inflammation, atrophy and loss of fundic glands, intestinal metaplasia and sometimes hyperplasia of enterochromaffin-like (ECL) cells. Circulating antibodies to parietal cell and intrinsic factor may be present. In some patients, the degree of gastric atrophy is severe, and loss of intrinsic factor secretion leads to pernicious anaemia (p. 1025). The gastritis itself is usually asymptomatic. Some patients have evidence of other organ-specific autoimmunity, particularly thyroid disease. Long-term, there is a two- to threefold increase in the risk of gastric cancer (see also p. 877).

Ménétrier's disease

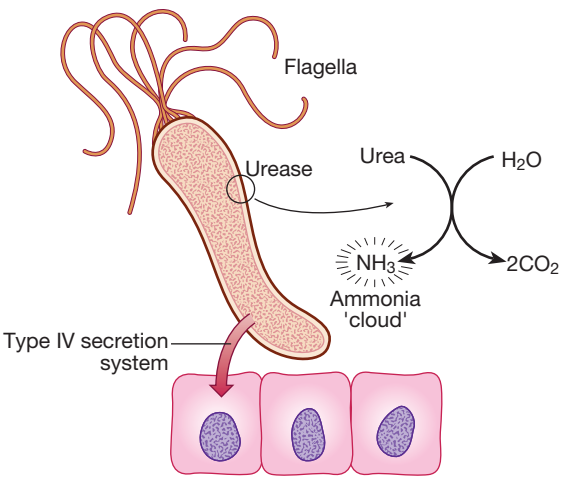
In this rare condition, the gastric pits are elongated and tortuous, with replacement of the parietal and chief cells by mucus-secreting cells. The cause is unknown but there is excessive production of TGF-α. As a result, the mucosal folds of the body and fundus are greatly enlarged. Most patients are hypochlorhydric. Whilst some patients have upper gastrointestinal symptoms, the majority present in middle or old age with protein-losing enteropathy (p. 886) due to exudation from the gastric mucosa. Endoscopy shows enlarged, nodular and coarse folds, although biopsies may not be deep enough to show all the histological features. Treatment with antisecretory drugs, such as PPIs with or without octreotide, may reduce protein loss and *H. pylori* eradication may be effective, but unresponsive patients require partial gastrectomy.

Peptic ulcer disease

The term 'peptic ulcer' refers to an ulcer in the lower oesophagus, stomach or duodenum, in the jejunum after surgical anastomosis to the stomach or, rarely, in the ileum adjacent to a Meckel's diverticulum. Ulcers in the stomach or duodenum may be acute or chronic; both penetrate the muscularis mucosae but the acute ulcer shows no evidence of fibrosis. Erosions do not penetrate the muscularis mucosae.

Gastric and duodenal ulcer

The prevalence of peptic ulcer (0.1–0.2%) is decreasing in many Western communities as a result of widespread use of *Helicobacter pylori* eradication therapy but it remains high in developing countries. The male-to-female ratio for duodenal ulcer varies from 5:1 to 2:1, whilst that for gastric ulcer is 2:1 or less. Chronic gastric ulcer is usually single; 90% are situated on the lesser curve within the antrum or at the junction between body and antral mucosa. Chronic duodenal ulcer usually occurs in the first part of the duodenum and 50% are on the anterior wall. Gastric and duodenal ulcers coexist in 10% of patients and more than one peptic ulcer is found in 10–15% of patients.



Pathophysiology

H. pylori

Peptic ulceration is strongly associated with *H. pylori* infection. The prevalence in developed nations rises with age, and in the UK approximately 50% of people over the age of 50 years are infected. In the developing world, infection is more common, affecting up to 90% of adults. These infections are probably acquired in childhood by person-to-person contact. The vast majority of colonised people remain healthy and asymptomatic and only a minority develop clinical disease. Around 90% of duodenal ulcer patients and 70% of gastric ulcer patients are infected with *H. pylori*. The remaining 30% of gastric ulcers are caused by NSAIDs and this proportion is increasing in Western countries as a result of *H. pylori* eradication strategies.

H. pylori is Gram-negative and spiral, and has multiple flagella at one end, which make it motile, allowing it to burrow and live beneath the mucus layer adherent to the epithelial surface. It uses an adhesin molecule (BabA) to bind to the Lewis b antigen on epithelial cells. Here the surface pH is close to neutral and any acidity is buffered by the organism's production of the enzyme urease. This produces ammonia from urea and raises the pH around the bacterium and between its two cell membrane layers. *H. pylori* exclusively colonises gastric-type epithelium and is only found in the duodenum in association with patches of gastric metaplasia. It causes chronic gastritis by provoking a local inflammatory response in the underlying epithelium (Fig. 22.33). This depends on numerous factors, notably expression of bacterial *cagA* and *vacA* genes. The cagA gene product is injected into epithelial cells, interacting with numerous cell-signalling pathways involved in cell replication and apoptosis. *H. pylori* strains expressing cagA ($cagA^+$) are more often associated with disease than $cagA^-$ strains. Most strains also secrete a large pore-forming protein called vacA, which causes increased cell permeability, efflux of micronutrients from the epithelium, induction of apoptosis and suppression of local immune cell activity. Several forms of vacA exist and pathology is most strongly associated with the s1/ml form of the toxin.

In most people, *H. pylori* causes localised antral gastritis associated with depletion of somatostatin (from D cells) and increased gastrin release from G cells. The subsequent hypergastrinaemia stimulates increased acid

Other factors

- Vacuolating cytotoxin (vacA)
- Cytotoxin-associated gene (cagA)
- Adhesins (BabA)
- Outer inflammatory protein A (oipA)

Fig. 22.33 Factors that influence the virulence of *H. pylori*.

production by parietal cells but, in the majority of cases, this has no clinical consequences. In a minority of patients, this effect is exaggerated, leading to duodenal ulceration (Fig. 22.34). In 1% of infected people, *H. pylori* causes a pangastritis, leading to gastric atrophy and hypochlorhydria. This allows other bacteria to proliferate within the stomach; these produce mutagenic nitrites from dietary nitrates, predisposing to the development of gastric cancer (Fig. 22.35). The effects of *H. pylori* are more complex in gastric ulcer patients compared to those with duodenal ulcers. The ulcer probably arises because of impaired mucosal defence resulting from a combination of *H. pylori* infection, NSAIDs and smoking, rather than excess acid.

NSAIDs

Treatment with NSAIDs is associated with peptic ulcers due to impairment of mucosal defences, as discussed on page 1078.

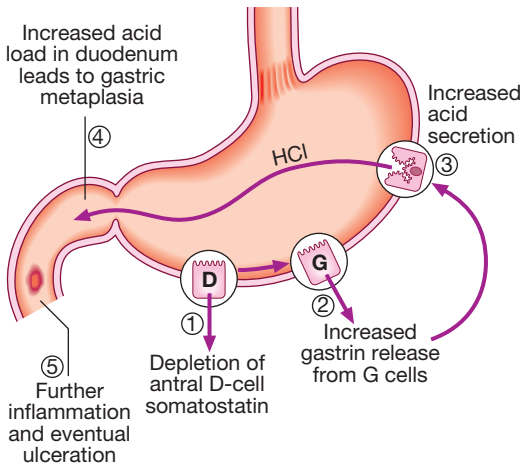


Fig. 22.34 Sequence of events in the pathophysiology of duodenal ulceration.

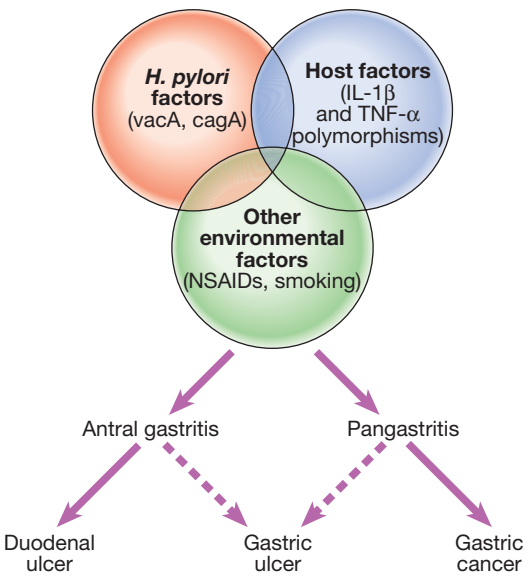

Fig. 22.35 Consequences of *H. pylori* infection.

Smoking

Smoking confers an increased risk of gastric ulcer and, to a lesser extent, duodenal ulcer. Once the ulcer has formed, it is more likely to cause complications and less likely to heal if the patient continues to smoke.

Clinical features

Peptic ulcer disease is a chronic condition with spontaneous relapses and remissions lasting for decades, if not for life. The most common presentation is with recurrent abdominal pain which has three notable characteristics: localisation to the epigastrium, relationship to food and episodic occurrence. Occasional vomiting occurs in about 40% of ulcer subjects; persistent daily vomiting suggests gastric outlet obstruction. In one-third, the history is less characteristic, especially in elderly people or those taking NSAIDs. In them, pain may be absent or so slight that it is experienced only as a vague sense of epigastric unease. Occasionally, the only symptoms are anorexia and nausea, or early satiety after meals. In some patients, the ulcer is completely 'silent', presenting for the first time with anaemia from chronic undetected blood loss, as an abrupt haematemesis or as acute perforation; in others, there is recurrent acute bleeding without ulcer pain. The diagnostic value of individual symptoms for peptic ulcer disease is poor; the history is therefore a poor predictor of the presence of an ulcer.

Investigations

Endoscopy is the preferred investigation. Gastric ulcers may occasionally be malignant and therefore must always be biopsied and followed up to ensure healing. Patients should be tested for *H. pylori* infection. The current options available are listed in Box 22.39. Some are invasive and require endoscopy; others are non-invasive. They vary in sensitivity and specificity. Breath tests or faecal antigen tests are best because of accuracy, simplicity and non-invasiveness.

22.39 Methods for the diagnosis of *Helicobacter pylori* infection

Test	Advantages	Disadvantages
Non-invasive		
Serology	Rapid office kits available Good for population studies	Lacks specificity Cannot differentiate current from past infection
^{13}C-urea breath tests	High sensitivity and specificity	Requires expensive mass spectrometer
Faecal antigen test	Cheap, specific (> 95%)	Acceptability
Invasive (antral biopsy)		
Histology	Specificity	False negatives Takes several days to process
Rapid urease tests	Cheap, quick, specific (> 95%)	Sensitivity 85%
Microbiological culture	'Gold standard' Defines antibiotic sensitivity	Slow and laborious Lacks sensitivity

Management

The aims of management are to relieve symptoms, induce healing and prevent recurrence. *H. pylori* eradication is the cornerstone of therapy for peptic ulcers, as this will successfully prevent relapse and eliminate the need for long-term therapy in the majority of patients.

H. pylori *eradication*

All patients with proven ulcers who are *H. pylori*-positive should be offered eradication as primary therapy. Treatment is based upon a PPI taken simultaneously with two antibiotics (from amoxicillin, clarithromycin and metronidazole) for 7 days (Box 22.40). High-dose, twice-daily PPI therapy increases efficacy of treatment, as does extending treatment to 10–14 days. Success is achieved in 80–90% of patients, although compliance, side-effects (Box 22.41) and antibiotic resistance influence this. Resistance to amoxicillin is rare but rates of metronidazole resistance reach 40% in some countries and, recently, rates of clarithromycin resistance of 20–40% have appeared. Where the latter exceed 15–20%, a quadruple therapy regimen, consisting of omeprazole (or another PPI), bismuth subcitrate, metronidazole and tetracycline (OBMT) for 10–14 days, is recommended. In areas of low clarithromycin resistance, this regimen should also be offered as second-line therapy to those who remain infected after initial therapy, once compliance has been checked. For those who are still colonised after two treatments, the choice lies between a third attempt guided by antimicrobial sensitivity testing, rescue therapy (levofloxacin, PPI and clarithromycin) or long-term acid suppression.

H. pylori and NSAIDs are independent risk factors for ulcer disease and patients requiring long-term NSAID therapy should first undergo eradication therapy to reduce ulcer risk. Subsequent co-prescription of a PPI along with the NSAID is advised but is not always necessary for patients being given low-dose aspirin, in whom the risk of ulcer complications is lower.

EBM 22.40 *H. pylori* eradication and peptic ulcer healing

'Compared to ulcer-healing drugs, *H. pylori* eradication therapy is superior for healing duodenal ulcers (RR 0.66) and affords equivalent protection against recurrence of both duodenal and gastric ulcers.'

- Ford AC, et al. Eradication therapy for peptic ulcer disease in *Helicobacter pylori* positive patients. Cochrane Database of Systematic Reviews, 2006, issue 2. Art. no. CD003840.

For further information: www.cochrane.org/cochrane-reviews

22.41 Common side-effects of *H. pylori* eradication therapy

- Diarrhoea: 30–50% of patients; usually mild but *Clostridium difficile*-associated diarrhoea can occur
- Flushing and vomiting when taken with alcohol (metronidazole)
- Nausea, vomiting
- Abdominal cramps
- Headache
- Rash

22.42 Indications for *H. pylori* eradication

Definite

- Peptic ulcer
- Extranodal marginal-zone lymphomas of MALT type
- Family history of gastric cancer
- Previous resection for gastric cancer
- *H. pylori*-positive dyspepsia
- Long-term NSAID or low-dose aspirin users
- Chronic (> 1 yr) PPI users
- Extragastric disorders:
  - Unexplained vitamin B_{12} deficiency*
  - Idiopathic thrombocytopenic purpura*
  - Iron deficiency anaemia* (see text)

Not indicated

- Gastro-oesophageal reflux disease
- Asymptomatic people without gastric cancer risk factors

*If *H. pylori*-positive on testing.

Other indications for *H. pylori* eradication are shown in Box 22.42. Eradication of the infection has proven benefits in several extragastric disorders, including unexplained B_{12} deficiency and iron deficiency anaemia, once sources of gastrointestinal bleeding have been looked for and excluded. Platelet counts improve and may normalise after eradication therapy in patients with idiopathic thrombocytopenic purpura (ITP, p. 1050); the mechanism for this is unclear.

General measures

Cigarette smoking, aspirin and NSAIDs should be avoided. Alcohol in moderation is not harmful and no special dietary advice is required.

Maintenance treatment

Continuous maintenance treatment should not be necessary after successful *H. pylori* eradication. For the minority who do require it, the lowest effective dose of PPI should be used.

Surgical treatment

Surgery is now rarely required for peptic ulcer disease but it is needed in some cases (Box 22.43).

The operation of choice for a chronic non-healing gastric ulcer is partial gastrectomy, preferably with a Billroth I anastomosis, in which the ulcer itself and the ulcer-bearing area of the stomach are resected. The reason for this is to exclude an underlying cancer. In an emergency, 'under-running' the ulcer for bleeding or 'oversewing' (patch repair) for perforation is all that is required, in addition to taking a biopsy. For giant

22.43 Indications for surgery in peptic ulcer

Emergency

- Perforation
- Haemorrhage

Elective

- Gastric outflow obstruction
- Persistent ulceration despite adequate medical therapy
- Recurrent ulcer following gastric surgery

duodenal ulcers, partial gastrectomy using a 'Polya' or Billroth II reconstruction may be required.

Complications of gastric resection or vagotomy

Up to 50% of patients who undergo gastric surgery for peptic ulcer surgery experience long-term adverse effects. In most cases, these are minor, but in 10% they significantly impair quality of life.

Dumping. Rapid gastric emptying leads to distension of the proximal small intestine as the hypertonic contents draw fluid into the lumen. This leads to abdominal discomfort and diarrhoea after eating. Autonomic reflexes release a range of gastrointestinal hormones that provoke vasomotor features, such as flushing, palpitations, sweating, tachycardia and hypotension. Patients should therefore avoid large meals with high carbohydrate content.

Chemical (bile reflux) gastropathy. Duodenogastric bile reflux leads to chronic gastropathy. Treatment with aluminium-containing antacids or sucralfate may be effective. A few patients require revisional surgery with creation of a Roux en Y loop to prevent bile reflux.

Diarrhoea and maldigestion. Diarrhoea may develop after any peptic ulcer operation and usually occurs 1–2 hours after eating. Poor mixing of food in the stomach, with rapid emptying, inadequate mixing with pancreaticobiliary secretions, rapid transit and bacterial overgrowth, may lead to malabsorption. Diarrhoea often responds to small, dry meals with a reduced intake of refined carbohydrates. Antidiarrhoeal drugs, such as codeine phosphate (15–30 mg 4–6 times daily) or loperamide (2 mg after each loose stool), are helpful.

Weight loss. Most patients lose weight shortly after surgery and 30–40% are unable to regain all the weight that is lost. The usual cause is reduced intake because of a small gastric remnant, but diarrhoea and mild steatorrhoea also contribute.

Anaemia. Anaemia is common many years after subtotal gastrectomy. Iron deficiency is the most common cause; folic acid and B_{12} deficiency are much less frequent. Inadequate dietary intake of iron and folate, lack of acid and intrinsic factor secretion, mild chronic low-grade blood loss from the gastric remnant and recurrent ulceration are responsible.

Metabolic bone disease. Both osteoporosis and osteomalacia can occur as a consequence of calcium and vitamin D malabsorption.

Gastric cancer. An increased risk of gastric cancer has been reported from several epidemiological studies. Surgery itself is an independent risk factor for late development of malignancy in the gastric remnant but the risk is higher in those with hypochlorhydria, duodenogastric reflux of bile, smoking and *H. pylori* infection. Although the relative risk is increased, the absolute risk of cancer remains low and endoscopic surveillance is not indicated following gastric surgery.

Complications of peptic ulcer disease

Perforation

When perforation occurs, the contents of the stomach escape into the peritoneal cavity, leading to peritonitis. This is more common in duodenal than in gastric ulcers, and is usually found with ulcers on the anterior wall. About one-quarter of all perforations occur in acute ulcers and NSAIDs are often incriminated. Perforation can be the first sign of ulcer, and a history of recurrent epigastric pain is uncommon. The most striking symptom is sudden, severe pain; its distribution follows the spread of the gastric contents over the peritoneum. The pain initially develops in the upper abdomen and rapidly becomes generalised; shoulder tip pain is caused by irritation of the diaphragm. The pain is accompanied by shallow respiration due to limitation of diaphragmatic movements and by shock. The abdomen is held immobile and there is generalised 'board-like' rigidity. Bowel sounds are absent and liver dullness to percussion decreases due to the presence of gas under the diaphragm. After some hours, symptoms may improve, although abdominal rigidity remains. Later, the patient's condition deteriorates as general peritonitis develops. In at least 50% of cases, an erect chest X-ray shows free air beneath the diaphragm. If not, a water-soluble contrast swallow will confirm leakage of gastroduodenal contents. After resuscitation, the acute perforation should be treated surgically, either by simple closure or by converting the perforation into a pyloroplasty if it is large. On rare occasions, a 'Polya' partial gastrectomy is required. Following surgery, *H. pylori* should be treated (if present) and NSAIDs avoided. Perforation carries a mortality of 25%, reflecting the advanced age and significant comorbidity of the population that are affected.

Gastric outlet obstruction

The causes are shown in Box 22.45. The most common is an ulcer in the region of the pylorus. The presentation is with nausea, vomiting and abdominal distension. Large quantities of gastric content are often vomited, and food eaten 24 hours or more previously may be recognised. Physical examination may show evidence of wasting and dehydration. A succussion splash may be elicited 4 hours or more after the last meal or drink.

22.44 Peptic ulcer disease in old age

- **Gastroduodenal ulcers**: have a greater incidence, admission rate and mortality.
- **Causes**: high prevalence of *H. pylori*, NSAID use and impaired defence mechanisms.
- **Atypical presentations**: pain and dyspepsia are frequently absent or atypical. Older people often develop complications, such as bleeding or perforation, without a dyspeptic history.
- **Bleeding**: older patients require more intensive management (including measurement of central venous pressure) than younger because they tolerate hypovolaemic shock poorly.

22.45 Differential diagnosis and management of gastric outlet obstruction

Cause	Management
Fibrotic stricture from duodenal ulcer (pyloric stenosis)	Balloon dilatation or surgery
Oedema from pyloric channel or duodenal ulcer	PPI therapy
Carcinoma of antrum	Surgery
Adult hypertrophic pyloric stenosis	Surgery

Visible gastric peristalsis is diagnostic of gastric outlet obstruction. Loss of gastric contents leads to dehydration with low serum chloride and potassium, and raised serum bicarbonate and urea concentrations. This results in enhanced renal absorption of Na^+ in exchange for H^+ and paradoxical aciduria. Endoscopy should be performed after the stomach has been emptied by a wide-bore nasogastric tube. Intravenous correction of dehydration is undertaken and, in severe cases, at least 4 L of isotonic saline and 80 mmol of potassium may be necessary during the first 24 hours. In some patients, PPI drugs heal ulcers, relieve pyloric oedema and overcome the need for surgery. Endoscopic balloon dilatation of benign stenoses may be possible in some patients, but in others partial gastrectomy is necessary, although this is best done after a 7-day period of nasogastric aspiration, which enables the stomach to return to normal size. A gastroenterostomy is an alternative operation but, unless this is accompanied by vagotomy, patients will require long-term PPI therapy to prevent stomal ulceration.

Bleeding

See page 853.

Zollinger–Ellison syndrome

This is a rare disorder characterised by the triad of severe peptic ulceration, gastric acid hypersecretion and a non-β cell islet tumour of the pancreas ('gastrinoma'). It probably accounts for about 0.1% of all cases of duodenal ulceration. The syndrome occurs in either sex at any age, although it is most common between 30 and 50 years of age.

Pathophysiology

The tumour secretes gastrin, which stimulates acid secretion to its maximal capacity and increases the parietal cell mass three- to sixfold. The acid output may be so great that it reaches the upper small intestine, reducing the luminal pH to 2 or less. Pancreatic lipase is inactivated and bile acids are precipitated. Diarrhoea and steatorrhoea result. Around 90% of tumours occur in the pancreatic head or proximal duodenal wall. At least half are multiple, and tumour size can vary from 1 mm to 20 cm. Approximately one-half to two-thirds are malignant but are often slow-growing. Adenomas of the parathyroid and pituitary glands (multiple endocrine neoplasia, MEN type 1; p. 795) are present in 20–60% of patients.

Clinical features

The presentation is with severe and often multiple peptic ulcers in unusual sites, such as the post-bulbar duodenum, jejunum or oesophagus. There is a poor response to standard ulcer therapy. The history is usually short; bleeding and perforations are common. Diarrhoea is seen in one-third or more of patients and can be the presenting feature.

Investigations

Hypersecretion of acid under basal conditions, with little increase following pentagastrin, may be confirmed by gastric aspiration. Serum gastrin levels are grossly elevated (10- to 1000-fold). Injection of the hormone secretin normally causes no change or a slight decrease in circulating gastrin concentrations, but in Zollinger–Ellison syndrome produces a paradoxical and dramatic increase in gastrin. Tumour localisation is best achieved by EUS and radio-labelled somatostatin receptor scintigraphy.

Management

Some 30% of small and single tumours can be localised and resected but many tumours are multifocal. Some patients present with metastatic disease and, in these circumstances, surgery is inappropriate. In the majority of these patients, continuous therapy with omeprazole or other PPIs can be successful in healing ulcers and alleviating diarrhoea, although double the normal dose is required. The synthetic somatostatin analogue, octreotide, given by subcutaneous injection, reduces gastrin secretion and is of value. Overall 5-year survival is 60–75% and all patients should be monitored for the later development of other manifestations of MEN 1.

Functional disorders

Functional dyspepsia

This is defined as chronic dyspepsia in the absence of organic disease. Other commonly reported symptoms include early satiety, fullness, bloating and nausea. 'Ulcer-like' and 'dysmotility-type' subgroups are often reported, but there is overlap between these and with irritable bowel syndrome.

Pathophysiology

The cause is poorly understood but probably covers a spectrum of mucosal, motility and psychiatric disorders.

Clinical features

Patients are usually young (< 40 years) and women are affected twice as commonly as men. Abdominal discomfort is associated with a combination of other 'dyspeptic' symptoms, the most common being nausea, satiety and bloating after meals. Morning symptoms are characteristic and pain or nausea may occur on waking. Direct enquiry may elicit symptoms suggestive of irritable bowel syndrome. Peptic ulcer disease must be considered, whilst in older subjects intra-abdominal malignancy is a prime concern. There are no diagnostic signs, apart perhaps from inappropriate tenderness on abdominal palpation. Symptoms may appear disproportionate to clinical well-being and there is no weight loss. Patients often appear anxious. A drug history should be taken and the possibility of a depressive illness should be considered. Pregnancy should be ruled out in young women before radiological studies are undertaken. Alcohol misuse should be suspected when early morning nausea and retching are prominent.

Investigations

The history will often suggest the diagnosis. All patients should be checked for *H. pylori* infection and patients over the age of 55 years should undergo endoscopy to exclude mucosal disease. While an ultrasound scan may detect gallstones, these are rarely responsible for dyspeptic symptoms.

Management

The most important elements are explanation and reassurance. Possible psychological factors should be explored and the concept of psychological influences on gut function should be explained. Idiosyncratic and restrictive diets are of little benefit, but smaller portions and fat restriction may help.

Up to 10% of patients benefit from *H. pylori* eradication therapy and this should be offered to infected patients. Eradication also removes a major risk factor for gastric cancer but at the cost of a small risk of side-effects and worsening symptoms of underlying gastro-oesophageal reflux disease. Drug treatment is not especially successful but merits trial. Antacids, such as hydrotalcite, are sometimes helpful. Prokinetic drugs, such as metoclopramide (10 mg 3 times daily) or domperidone (10–20 mg 3 times daily), may be given before meals if nausea, vomiting or bloating is prominent. Metoclopramide may induce extrapyramidal side-effects, including tardive dyskinesia in young subjects. H_2-receptor antagonist drugs may be tried if night pain or heartburn is troublesome. Low-dose tricyclic agents, such as amitriptyline, are of value in up to two-thirds.

Symptoms that can be associated with an identifiable cause of stress resolve with appropriate counselling. Some patients have major psychological disorders that result in persistent or recurrent symptoms and need behavioural or other formal psychotherapy (p. 240).

Functional causes of vomiting

Psychogenic retching or vomiting may arise in anxiety. It typically occurs on wakening or immediately after breakfast and only rarely later in the day. The disorder is probably a reaction to facing up to the worries of everyday life; in the young, it can be due to school phobia. Early morning vomiting also occurs in pregnancy, alcohol misuse and depression. Although functional vomiting may occur regularly over long periods, there is little or no weight loss. Children, and less often adults, sometimes suffer from acute and recurrent disabling bouts of vomiting for days at a time. The cause of this cyclical vomiting syndrome is unknown, but in some adults it is associated with cannabis use.

In all patients, it is essential to exclude other common causes (p. 853). Tranquillisers and antiemetic drugs (metoclopramide 10 mg 3 times daily, domperidone 10 mg 3 times daily, prochlorperazine 5–10 mg 3 times daily) have only a secondary place in management. Antidepressants in full dose may be effective (p. 244).

Gastroparesis

Defective gastric emptying without mechanical obstruction of the stomach or duodenum can occur as a primary event, due to inherited or acquired disorders of the gastric pacemaker, or can be secondary to disorders of autonomic nerves (particularly diabetic neuropathy) or the gastroduodenal musculature (systemic sclerosis, myotonic dystrophies and amyloidosis). Drugs such as opiates, calcium channel antagonists and those with anticholinergic activity (tricyclics, phenothiazines) can also cause gastroparesis. Early satiety and recurrent vomiting are the major symptoms; abdominal fullness and a succussion splash may be present on examination. Treatment is based upon small, frequent, low-fat meals and the use of metoclopramide and domperidone. In severe cases, nutritional failure can occur and long-term jejunostomy feeding or total parenteral nutrition is required. Surgical insertion of a gastric neurostimulator has been successful in some cases, especially those complicating diabetic autonomic neuropathy.

Tumours of the stomach

Gastric carcinoma

Gastric carcinoma is the fourth leading cause of cancer death worldwide, but there is marked geographical variation in incidence. It is most common in China, Japan, Korea (incidence 40/100 000 males), Eastern Europe and parts of South America (20/100 000). Rates in the UK are 12/100 000 for men. In most countries, the incidence is 50% lower in women. In both sexes, it rises sharply after 50 years of age. Studies of Japanese migrants to the USA have revealed a much lower incidence in second-generation migrants, confirming the importance of environmental factors. The overall prognosis is poor, with less than 30% surviving 5 years, and the best hope for improved survival lies in more efficient detection of tumours at an earlier stage.

Pathophysiology

Infection with *H. pylori* plays a key pathogenic role. It is associated with chronic atrophic gastritis, gastric mucosal atrophy and with gastric cancer (Fig. 22.36). It has been estimated that *H. pylori* infection may contribute to the occurrence of gastric cancer in 60–70% of cases and that acquisition of infection at an early age may be important. Although *H. pylori* infection is common in Africa, gastric cancer is uncommon and this enigma may be explained by lower life expectancy in this part of the

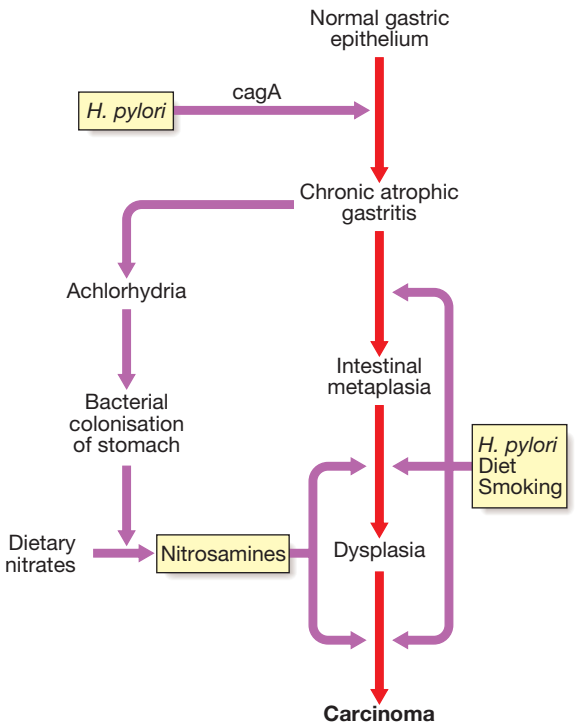

Fig. 22.36 Gastric carcinogenesis: a possible mechanism.

22.46 Risk factors for gastric cancer

- *H. pylori*
- Smoking
- Alcohol
- Dietary associations (see text)
- Autoimmune gastritis (pernicious anaemia)
- Adenomatous gastric polyps
- Previous partial gastrectomy (> 20 yrs)
- Ménétrier's disease
- Hereditary diffuse gastric cancer families (*HDC-1* mutations)
- Familial adenomatous polyposis (FAP, p. 911)

world. Although the majority of *H. pylori*-infected individuals have normal or increased acid secretion, a few become hypo- or achlorhydric and these people are thought to be at greatest risk. Chronic inflammation with generation of reactive oxygen species and depletion of the normally abundant antioxidant ascorbic acid are also important. There is strong evidence that *H. pylori* eradication, especially if achieved before irreversible pre-neoplastic changes have developed, reduces the risk of cancer development in high-risk populations and is cost-effective.

Diets rich in salted, smoked or pickled foods and the consumption of nitrites and nitrates may increase cancer risk. Carcinogenic N-nitroso-compounds are formed from nitrates by the action of nitrite-reducing bacteria which colonise the achlorhydric stomach. Diets lacking fresh fruit and vegetables, as well as vitamins C and A, may also contribute. Other risk factors are listed in Box 22.46. No predominant genetic abnormality has been identified, although cancer risk is increased two- to threefold in first-degree relatives of patients, and links with blood group A have been reported. Rarely, gastric cancer may be inherited in an autosomal dominant manner in association with mutations of the *E-cadherin* (*CDH1*) gene.

Virtually all tumours are adenocarcinomas arising from mucus-secreting cells in the base of the gastric crypts. Most develop upon a background of chronic atrophic gastritis with intestinal metaplasia and dysplasia. Cancers are either 'intestinal', arising from areas of intestinal metaplasia with histological features reminiscent of intestinal epithelium, or 'diffuse', arising from normal gastric mucosa. Intestinal carcinomas are more common and arise against a background of chronic mucosal injury. Diffuse cancers tend to be poorly differentiated and occur in younger patients. In the developing world, 50% of gastric cancers develop in the antrum; 20–30% occur in the gastric body, often on the greater curve; and 20% are found in the cardia. In Western populations, however, proximal gastric tumours are becoming more common than those arising in the body and distal stomach. This change in disease pattern may be a reflection of changes in lifestyle or the decreasing prevalence of *H. pylori* in the West. Diffuse submucosal infiltration by a scirrhous cancer (linitis plastica) is uncommon. Early gastric cancer is defined as cancer confined to the mucosa or submucosa (Fig. 22.37A). It is more often recognised in Japan, where widespread screening is practised. Some cases can be cured by endoscopic mucosal or submucosal resection

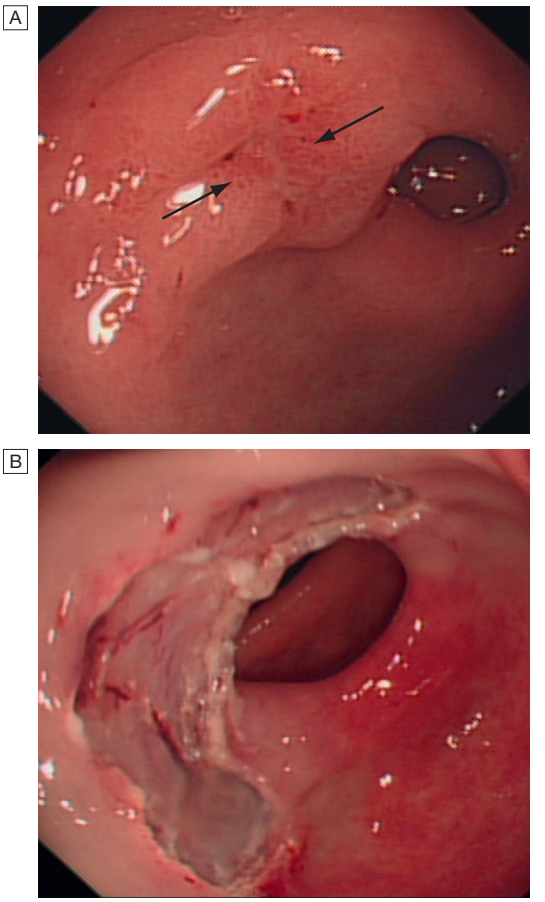

Fig. 22.37 Gastric carcinoma. A Endoscopic image of a small superficial pre-pyloric cancer (arrows). B Appearance after endoscopic mucosal resection (EMR). The tumour has been completely removed.

(Fig. 22.37B). The majority of patients (> 80%) in the West, however, present with advanced gastric cancer.

Clinical features

Early gastric cancer is usually asymptomatic but may be discovered during endoscopy for investigation of dyspepsia. Two-thirds of patients with advanced cancers have weight loss and 50% have ulcer-like pain. Anorexia and nausea occur in one-third, while early satiety, haematemesis, melaena and dyspepsia alone are less common. Dysphagia occurs in tumours of the gastric cardia which obstruct the gastro-oesophageal junction. Anaemia from occult bleeding is also common. Examination may reveal no abnormalities but signs of weight loss, anaemia and a palpable epigastric mass are not infrequent. Jaundice or ascites signify metastatic spread. Occasionally, tumour spread occurs to the supraclavicular lymph nodes (Troisier's sign), umbilicus (Sister Joseph's nodule) or ovaries (Krukenberg tumour). Paraneoplastic phenomena, such as acanthosis nigricans, thrombophlebitis (Trousseau's sign) and dermatomyositis, occur rarely. Metastases arise most commonly in the liver, lungs, peritoneum and bone marrow.

Investigations

Upper gastrointestinal endoscopy is the investigation of choice and should be performed promptly in any

dyspeptic patient with 'alarm features' (see Box 22.15, p. 852). Multiple biopsies from the edge and base of a gastric ulcer are required. Barium meal is a poor alternative since any abnormalities must be followed by endoscopy and biopsy. Once the diagnosis is made, further imaging is necessary for staging and assessment of resectability. CT will provide evidence of intra-abdominal spread or liver metastases. Even with these techniques, laparoscopy with peritoneal washings is required to determine whether the tumour is resectable, as it is the only modality that will reliably detect peritoneal spread.

Management

Surgery

Resection offers the only hope of cure, and this can be achieved in about 90% of patients with early gastric cancer. For the majority of patients with locally advanced disease, total gastrectomy with lymphadenectomy is the operation of choice, preserving the spleen if possible. Proximal tumours involving the oesophago-gastric junction also require a distal oesophagectomy. Small, distally sited tumours can be managed by a partial gastrectomy with lymphadenectomy and either a Billroth I or a Roux en Y reconstruction. More extensive lymph node resection may increase survival rates but carries greater morbidity. Even for those who cannot be cured, palliative resection may be necessary when patients present with bleeding or gastric outflow obstruction. Following surgery, recurrence is much more likely if serosal penetration has occurred, although complete removal of all macroscopic tumour combined with lymphadenectomy will achieve a 50–60% 5-year survival. Recent evidence suggests that perioperative chemotherapy with epirubicin, cisplatin and fluorouracil (ECF) improves survival rates.

Palliative treatment

In patients with inoperable tumours, survival can be improved and palliation of symptoms achieved with chemotherapy using 5-fluorouracil and cisplatin, ECF or other platinum and taxane-based regimens. The biological agent trastuzumab may benefit some patients whose tumours over-express HER2 (see p. 268 and Box 22.47). Endoscopic laser ablation for control of dysphagia or recurrent bleeding benefits some patients. Carcinomas at the cardia or pylorus may require endoscopic dilatation or insertion of expandable metallic stents for relief of dysphagia or vomiting. A nasogastric tube may offer temporary relief of vomiting due to gastric outlet obstruction (Box 22.48).

EBM 22.47 Chemotherapy for advanced gastric cancer

'Chemotherapy significantly improves survival in comparison to best supportive care. In addition, combination chemotherapy improves survival compared to single-agent 5-fluorouracil (5-FU). All patients should be tested for their HER2 status and trastuzumab should be added to a standard 5-FU/cisplatin regimen in patients with HER2-positive tumours.'

- Wagner AD, et al. Chemotherapy for advanced gastric cancer. Cochrane Database of Systematic Reviews, 2010, issue 3. Art. no. CD004064.

22.48 How to insert a nasogastric tube

Equipment

- 8–9F 'fine-bore' tube for feeding or 16–18F 'wide-bore' tube for drainage
- Lubricant jelly
- Cup of water and straw for sipping
- Adhesive tape
- pH (not litmus) paper
- Sickness bowl and tissues
- Catheter drainage bag and clamp (for drainage)

Technique

- A clear explanation and a calm patient are essential
- Establish a 'stop signal' for the patient to use, if needed
- Ask the patient to sit semi-upright
- Examine the nose for deformity or blockage to determine which side to use
- Measure the distance from ear to xiphoid process via the nose and mark the position on the tube
- Advance the lubricated tube tip slowly along the floor of the nasal passage to the oropharynx
- Ask the patient to sip water and advance the tube 2–3 cm with each swallow
- Stop, withdraw and retry if the patient is distressed or coughing, as the tube may have entered the larynx
- Advance until the mark on the tube reaches the tip of the nose and secure with tape
- Aspirate the contents and check pH (gastric acid confirmed if pH < 5). If in doubt, perform a chest X-ray to confirm tube position (usually necessary with feeding tubes)
- Attach the catheter drainage bag, if necessary, and clamp

Aftercare

- Flush the tube daily after feeding or drug dosing
- Check position regularly and look for signs of displacement
- Check with the pharmacist what drugs, if any, can be safely given via the tube

Gastric lymphoma

This is a rare tumour accounting for less than 5% of all gastric malignancies. The stomach is, however, the most common site for extranodal non-Hodgkin lymphoma and 60% of all primary gastrointestinal lymphomas occur at this site. Lymphoid tissue is not found in the normal stomach but lymphoid aggregates develop in the presence of *H. pylori* infection. Indeed, *H. pylori* infection is closely associated with the development of a low-grade lymphoma (classified as extranodal marginal-zone lymphomas of MALT type). EUS plays an important role in staging these lesions by accurately defining the depth of invasion into the gastric wall.

The clinical presentation is similar to that of gastric cancer, and endoscopically the tumour appears as a polypoid or ulcerating mass. While initial treatment of low-grade lesions confined to the superficial layers of the gastric wall consists of *H. pylori* eradication and close observation, 25% contain t(11:18) chromosomal translocations. In these cases, additional radiotherapy or chemotherapy is usually necessary. High-grade B-cell lymphomas should be treated by a combination of

rituximab, chemotherapy, surgery and radiotherapy. The choice depends on the site and extent of tumour, the presence of comorbid illnesses, and other factors, such as symptoms of bleeding and gastric outflow obstruction. The prognosis depends on the stage at diagnosis. Features predicting a favourable prognosis are stage I or II disease, small resectable tumours, tumours with low-grade histology, and age below 60 years.

Other tumours of the stomach

Gastrointestinal stromal cell tumours (GIST), arising from the interstitial cells of Cajal, are occasionally found at upper gastrointestinal endoscopy. They are differentiated from other mesenchymal tumours by expression of the *c-kit* proto-oncogene, which encodes a tyrosine kinase receptor. These tumours are usually benign and asymptomatic, but may occasionally be responsible for dyspepsia, ulceration and gastrointestinal bleeding. Small lesions (< 2 cm) are usually followed by endoscopy, while larger ones require surgical resection. Very large lesions should be treated pre-operatively with imatinib (a tyrosine kinase inhibitor) to reduce their size and make surgery easier. Imatinib can also be used for palliation of metastatic GISTs.

A variety of polyps occur. Hyperplastic polyps and fundic cystic gland polyps are common and of no consequence. Adenomatous polyps are rare but have malignant potential and should be removed endoscopically.

Occasionally, gastric carcinoid tumours are seen in the fundus and body in patients with long-standing pernicious anaemia. These benign tumours arise from ECL or other endocrine cells, and are often multiple but rarely invasive. Unlike carcinoid tumours arising elsewhere in the gastrointestinal tract, they usually run a benign and favourable course. However, large (> 2 cm) carcinoids may metastasise and should be removed. Rarely, small nodules of ectopic pancreatic exocrine tissue are found. These 'pancreatic rests' may be mistaken for gastric neoplasms and usually cause no symptoms. EUS is the most useful investigation.

DISEASES OF THE SMALL INTESTINE

Disorders causing malabsorption

Coeliac disease

Coeliac disease is an inflammatory disorder of the small bowel occurring in genetically susceptible individuals, which results from intolerance to wheat gluten and similar proteins found in rye, barley and, to a lesser extent, oats. It can result in malabsorption and responds to a gluten-free diet. The condition occurs worldwide but is more common in northern Europe. The prevalence in the UK is approximately 1%, although 50% of these people are asymptomatic. These include both undiagnosed 'silent' cases of the disease and cases of 'latent' coeliac disease – genetically susceptible people who may later develop clinical coeliac disease.

Pathophysiology

The precise mechanism of mucosal damage is unclear but immunological responses to gluten play a key role (Fig. 22.38). Tissue transglutaminase (tTG) is now recognised as the autoantigen for anti-endomysial antibodies, which are often used in serological diagnosis.

Clinical features

Coeliac disease can present at any age. In infancy, it occurs after weaning on to cereals and typically presents with diarrhoea, malabsorption and failure to thrive. In

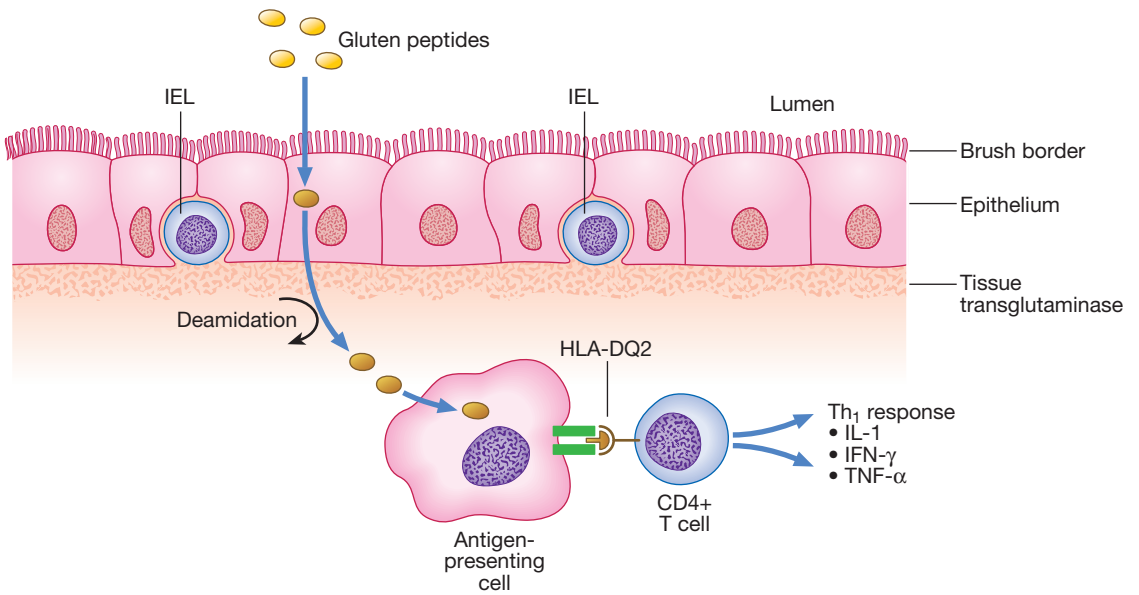

Fig. 22.38 Pathophysiology of coeliac disease. After being taken up by epithelial cells, gluten peptides are deamidated by the enzyme tissue transglutaminase in the subepithelial layer. They are then able to fit the antigen-binding motif on human leucocyte antigen (HLA)-DQ2-positive antigen-presenting cells. Recognition by CD4+ T cells triggers a Th_1 immune response with generation of pro-inflammatory cytokines – interleukin-1 (IL-1), interferon-gamma (IFN-γ) and tumour necrosis factor-alpha (TNF-α). Lymphocytes infiltrate the lamina propria, and increased intra-epithelial lymphocytes (IEL), crypt hyperplasia and villous atrophy ensue.

older children, it may present with non-specific features, such as delayed growth. Features of malnutrition are found on examination and mild abdominal distension may be present. Affected children have growth and pubertal delay, leading to short stature in adulthood.

In adults, the disease usually presents during the third or fourth decade and females are affected twice as often as males. The presentation is highly variable, depending on the severity and extent of small bowel involvement. Some have florid malabsorption, while others develop non-specific symptoms, such as tiredness, weight loss, folate deficiency or iron deficiency anaemia. Other presentations include oral ulceration, dyspepsia and bloating. Unrecognised coeliac disease is associated with mild under-nutrition and osteoporosis.

Coeliac disease is associated with other human leucocyte antigen (HLA)-linked autoimmune disorders and with certain other diseases (Box 22.49).

Investigations

These are performed to confirm the diagnosis and to look for consequences of malabsorption.

Duodenal biopsy

Endoscopic small bowel biopsy is the gold standard. The histological features are usually characteristic but other causes of villous atrophy should be considered (Box 22.50 and Fig. 22.39). Sometimes the villi appear normal but there are excess numbers of intra-epithelial lymphocytes.

Antibodies

Anti-endomysial antibodies of the IgA class are detectable by immunofluorescence in most untreated cases. They are sensitive (85–95%) and specific (approximately 99%) for the diagnosis, except in very young infants. IgG antibodies, however, must be analysed in patients with coexisting IgA deficiency. The tTG assay has replaced other blood tests in many countries, as it is easier to perform, semi-quantitative and more accurate in patients with IgA deficiency. These antibody tests constitute a valuable screening tool in patients with diarrhoea but are not a substitute for small bowel biopsy; they usually become negative with successful treatment.

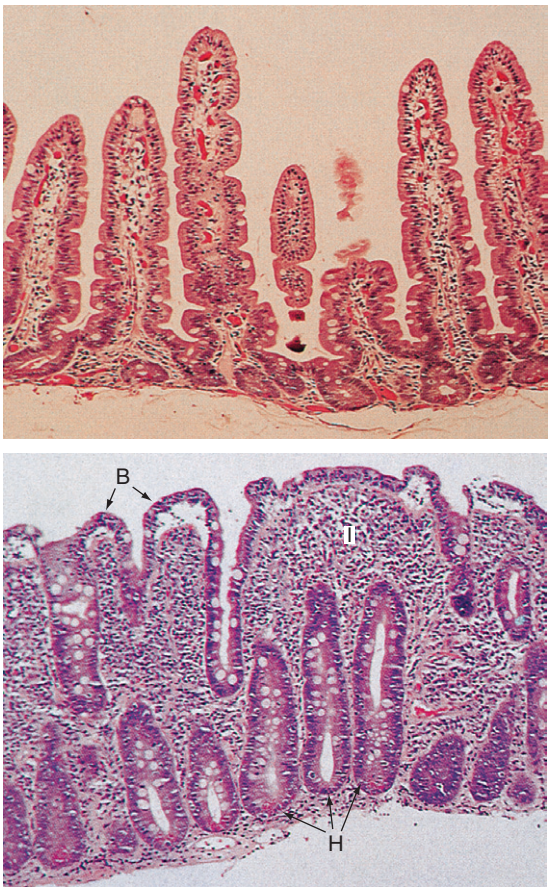

Fig. 22.39 Jejunal mucosa. A Normal. B Subtotal villous atrophy in coeliac disease. There is blunting of villi (B), crypt hyperplasia (H) and inflammatory infiltration of the lamina propria (I). From Hayes and Simpson 1995 – see p. 920.

22.49 Disease associations of coeliac disease

- Insulin-dependent diabetes mellitus (2–8%)
- Thyroid disease (5%)
- Primary biliary cirrhosis (3%)
- Sjögren's syndrome (3%)
- IgA deficiency (2%)
- Pernicious anaemia
- Sarcoidosis
- Neurological complications: encephalopathy, cerebellar atrophy, peripheral neuropathy, epilepsy
- Myasthenia gravis
- Dermatitis herpetiformis
- Down's syndrome
- Enteropathy-associated T-cell lymphoma
- Small bowel carcinoma
- Squamous carcinoma of oesophagus
- Ulcerative jejunitis
- Pancreatic insufficiency
- Microscopic colitis
- Splenic atrophy

22.50 Important causes of subtotal villous atrophy

- Coeliac disease
- Tropical sprue
- Dermatitis herpetiformis
- Lymphoma
- HIV-related enteropathy
- Giardiasis
- Hypogammaglobulinaemia
- Radiation
- Whipple's disease
- Zollinger–Ellison syndrome

Haematology and biochemistry

A full blood count may show microcytic or macrocytic anaemia from iron or folate deficiency and features of hyposplenism (target cells, spherocytes and Howell–Jolly bodies). Biochemical tests may reveal reduced concentrations of calcium, magnesium, total protein, albumin or vitamin D.

Other investigations

Measurement of bone density should be considered to look for evidence of osteoporosis, especially in older patients and post-menopausal women.

Management

The aims are to correct existing deficiencies of iron, folate, calcium and/or vitamin D, and to commence a life-long gluten-free diet. This requires the exclusion of wheat, rye, barley and initially oats, although oats may be re-introduced safely in most patients after 6–12 months. Initially, frequent dietary counselling is

required to make sure the diet is being observed, as the most common reason for failure to improve with dietary treatment is accidental or unrecognised gluten ingestion. Mineral and vitamin supplements are also given when indicated but are seldom necessary when a strict gluten-free diet is adhered to. Booklets produced by coeliac societies in many countries, containing diet sheets and recipes for the use of gluten-free flour, are of great value. Patients should be followed up after initiation of a gluten-free diet, with assessment of symptoms, weight and nutritional status, and blood taken for measurement of tTG or anti-endomysial antibodies. Repeat small bowel biopsies are not required routinely but should be considered in patients whose symptoms fail to improve and those in whom antibody levels remain high. Dietary compliance should be carefully assessed in these circumstances. If the diet is satisfactory, then other conditions, such as pancreatic insufficiency or microscopic colitis, should be sought, as should complications of coeliac disease, such as ulcerative jejunitis or enteropathy-associated T-cell lymphoma. There remain a small number of patients who fail to respond adequately to a gluten-free diet, and these require therapy with corticosteroids or immunosuppressive drugs.

Complications

A twofold-increased risk of malignancy, particularly of enteropathy-associated T-cell lymphoma, small bowel carcinoma and squamous carcinoma of the oesophagus, has been reported.

A few patients develop ulcerative jejuno-ileitis. This may present with fever, pain, obstruction or perforation. This diagnosis can be made by barium studies or enteroscopy, but laparotomy and full-thickness biopsy may be required. Treatment is difficult. Corticosteroids are used with mixed success and some patients require surgical resection and parenteral nutrition. The course is often progressive and relentless.

Osteoporosis and osteomalacia may occur in patients with long-standing, poorly controlled coeliac disease. These complications are less common in patients who adhere strictly to a gluten-free diet.

Dermatitis herpetiformis

This is characterised by crops of intensely itchy blisters over the elbows, knees, back and buttocks (p. 1294). Immunofluorescence shows granular or linear IgA deposition at the dermo-epidermal junction. Almost all patients have partial villous atrophy on duodenal biopsy, identical to that seen in coeliac disease, even though they usually have no gastrointestinal symptoms. In contrast, fewer than 10% of coeliac patients have evidence of dermatitis herpetiformis, although both disorders are associated with the same histocompatibility antigen groups. The rash usually responds to a gluten-free diet but some patients require additional treatment with dapsone (100–150 mg daily).

Tropical sprue

Tropical sprue is defined as chronic, progressive malabsorption in a patient in or from the tropics, associated with abnormalities of small intestinal structure and function. The disease occurs mainly in the West Indies and in southern India, Malaysia and Indonesia.

Pathophysiology

The epidemiological pattern and occasional epidemics suggest that an infective agent may be involved. Although no single bacterium has been isolated, the condition often begins after an acute diarrhoeal illness. Small bowel bacterial overgrowth with *Escherichia coli*, *Enterobacter* and *Klebsiella* is frequently seen. The changes closely resemble those of coeliac disease.

Clinical features

There is diarrhoea, abdominal distension, anorexia, fatigue and weight loss. In visitors to the tropics, the onset of severe diarrhoea may be sudden and accompanied by fever. When the disorder becomes chronic, the features of megaloblastic anaemia (folic acid malabsorption) and other deficiencies, including ankle oedema, glossitis and stomatitis, are common. Remissions and relapses may occur. The differential diagnosis in the indigenous tropical population is an infective cause of diarrhoea. The important differential diagnosis in visitors to the tropics is giardiasis (p. 368).

Management

Tetracycline (250 mg 4 times daily for 28 days) is the treatment of choice and brings about long-term remission or cure. In most patients, pharmacological doses of folic acid (5 mg daily) improve symptoms and jejunal morphology. In some cases, treatment must be prolonged before improvement occurs, and occasionally patients must leave the tropics.

Small bowel bacterial overgrowth ('blind loop syndrome')

The normal duodenum and jejunum contain fewer than 10^4/mL organisms, which are usually derived from saliva. The count of coliform organisms never exceeds 10^3/mL. In bacterial overgrowth, there may be 10^8–10^{10}/mL organisms, most of which are normally found only in the colon. Disorders which impair the normal physiological mechanisms controlling bacterial proliferation in the intestine predispose to bacterial overgrowth (Box 22.51).

22.51 Causes of small bowel bacterial overgrowth

Mechanism	Examples
Hypo- or achlorhydria	Pernicious anaemia Partial gastrectomy Long-term PPI therapy
Impaired intestinal motility	Scleroderma Diabetic autonomic neuropathy Chronic intestinal pseudo-obstruction
Structural abnormalities	Gastric surgery (blind loop after Billroth II operation) Jejunal diverticulosis Enterocolic fistulae* Extensive small bowel resection Strictures*
Impaired immune function	Hypogammaglobulinaemia

*Most commonly caused by Crohn's disease.

The most important are loss of gastric acidity, impaired intestinal motility and structural abnormalities which allow colonic bacteria to gain access to the small intestine or provide a secluded haven from the peristaltic stream.

Pathophysiology

Bacterial overgrowth can occur in patients with small bowel diverticuli. Another cause is diabetic autonomic neuropathy (p. 831), which reduces small bowel motility and affects enterocyte secretion. In scleroderma, bacterial overgrowth arises because the circular and longitudinal layers of the intestinal muscle are fibrosed and motility is abnormal. In idiopathic hypogammaglobulinaemia, bacterial overgrowth occurs because the IgA and IgM levels in serum and jejunal secretions are reduced. Chronic diarrhoea and malabsorption occur because of bacterial overgrowth and recurrent gastrointestinal infections (particularly giardiasis, p. 368).

Clinical features

The patient presents with watery diarrhoea and/or steatorrhoea, with anaemia due to B_{12} deficiency. These arise because of deconjugation of bile acids, which impairs micelle formation, and because of bacterial utilisation of vitamin B_{12}. There may also be symptoms from the underlying intestinal cause.

Investigations

The diagnosis of blind loops or fistulae can often be made by barium follow-through or small bowel enema. Endoscopic duodenal biopsies are useful in excluding coeliac disease. Jejunal contents for bacteriological examination can also be aspirated at endoscopy but the laboratory analysis requires anaerobic and aerobic culture techniques. Bacterial overgrowth can also be diagnosed non-invasively using hydrogen breath tests. This simple, non-radioactive test involves serial measurement of breath samples for hydrogen after oral ingestion of 50 g glucose or lactulose; if bacteria are present within the small bowel, they rapidly metabolise the glucose, causing an early rise in exhaled hydrogen, in advance of that normally resulting from metabolism by colonic flora. Biochemical analysis may reveal low serum levels of vitamin B_{12}, with normal or elevated folate levels because the bacteria produce folic acid. Hypogammaglobulinaemia can be diagnosed by measurement of serum immunoglobulins and by intestinal biopsy, which shows reduced or absent plasma cells and nodular lymphoid hyperplasia.

22.52 Malabsorption in old age

- **Coeliac disease**: symptoms such as dyspepsia tend to be vague; only 25% present classically with diarrhoea and weight loss. Metabolic bone disease, folate or iron deficiency, coagulopathy and small bowel lymphoma are more common.
- **Small bowel bacterial overgrowth**: more common due to atrophic gastritis, resulting in hypo- or achlorhydria; increased prevalence of jejunal diverticulosis; and long-term adverse effects of gastric surgery for ulcer disease.

Management

The underlying cause of small bowel bacterial overgrowth should be addressed, where possible. Tetracycline (250 mg 4 times daily for 7 days) is then the treatment of choice, although up to 50% of patients do not respond adequately. Metronidazole (400 mg 3 times daily) or ciprofloxacin (250 mg twice daily) is an alternative. Some patients require up to 4 weeks of treatment and, in a few, continuous rotating courses of antibiotics are necessary. Intramuscular vitamin B_{12} supplementation may be needed in chronic cases. Patients with motility disorders, such as diabetes and scleroderma, can sometimes benefit from antidiarrhoeal drugs (diphenoxylate (5 mg 3 times daily orally) or loperamide (2 mg 4–6 times daily) orally). Giardiasis should be controlled in patients with hypogammaglobulinaemia using metronidazole or tinidazole, but if symptoms fail to respond adequately, immunoglobulin infusions may be required.

Whipple's disease

This rare condition is characterised by infiltration of small intestinal mucosa by 'foamy' macrophages, which stain positive with periodic acid–Schiff (PAS) reagent. The disease is a multisystem one and almost any organ can be affected, sometimes long before gastrointestinal involvement becomes apparent (Box 22.53).

Pathophysiology

Whipple's disease is caused by infection with the Gram-positive bacillus *Tropheryma whipplei*, which becomes resident within macrophages in the bowel mucosa. Villi are widened and flattened, containing densely packed macrophages in the lamina propria, which obstruct lymphatic drainage and cause fat malabsorption.

22.53 Clinical features of Whipple's disease

Gastrointestinal (> 70%)	
• Diarrhoea (75%)	• Protein-losing enteropathy
• Steatorrhoea	• Ascites
• Weight loss (90%)	• Hepatosplenomegaly (< 5%)
Musculoskeletal (65%)	
• Seronegative large joint arthropathy	• Sacroiliitis
Cardiac (10%)	
• Pericarditis	• Endocarditis
• Myocarditis	• Coronary arteritis
Neurological (10–40%)	
• Apathy	• Myoclonus
• Fits	• Meningitis
• Dementia	• Cranial nerve lesions
Pulmonary (10–20%)	
• Chronic cough	• Pulmonary infiltrates
• Pleurisy	
Haematological (60%)	
• Anaemia	• Lymphadenopathy
Other (40%)	
• Fever	• Pigmentation

Clinical features

Middle-aged men are most frequently affected and the presentation depends on the pattern of organ involvement. Low-grade fever is common and most patients have joint symptoms to some degree, often as the first manifestation. Occasionally, neurological manifestations may predominate.

Diagnosis

This is made by the characteristic features on small bowel biopsy, with characterisation of the bacillus by polymerase chain reaction (PCR).

Management

Whipple's disease is often fatal if untreated but responds well, at least initially, to intravenous ceftriaxone (2 g daily for 2 weeks), followed by oral co-trimoxazole for at least 1 year. Symptoms usually resolve quickly and biopsy changes revert to normal in a few weeks. Long-term follow-up is essential, as clinical relapse occurs in up to one-third of patients, often within the CNS; in this case, the same therapy is repeated or else treatment with doxycycline and hydroxychloroquine is necessary.

Ileal resection

Malabsorption can occur as a complication of small bowel resection. The most common scenario is in patients with Crohn's disease who have undergone ileal resection, leading to malabsorption of vitamin B_{12} and bile salts (Fig. 22.40). Unabsorbed bile salts pass into the colon, stimulating water and electrolyte secretion and causing diarrhoea. If hepatic synthesis of new bile salts cannot keep pace with faecal losses, fat malabsorption occurs. Another consequence is the formation of lithogenic bile, leading to gallstones. Renal calculi, rich in oxalate, develop. Normally, oxalate in the colon is bound to and precipitated by calcium. Unabsorbed bile salts preferentially bind calcium, leaving oxalate to be absorbed, with development of urinary oxalate calculi.

Patients have urgent watery diarrhoea or mild steatorrhoea. Contrast studies and tests of B_{12} and bile acid absorption (p. 850) are useful investigations. Parenteral vitamin B_{12} supplementation is necessary. Diarrhoea usually responds well to colestyramine, a resin which binds bile salts in the intestinal lumen. Aluminium hydroxide can be used as an alternative.

Short bowel syndrome

Short bowel syndrome is defined as malabsorption resulting from extensive small intestinal resection or disease. The syndrome has many causes (Box 22.54) but, in adults, it usually results from extensive surgery undertaken for Crohn's disease or mesenteric infarction. Irrespective of the underlying cause, three main types of patient are seen:

- jejunal resection with an intact ileum and colon
- jejunal and ileal resection with an intact colon (jejunum–colon)
- jejunal and ileal resection and colectomy (jejunostomy).

Pathophysiology

Patients who undergo a jejunal resection but who have an intact ileum and colon are rarely encountered and seldom require nutritional support. Those who have undergone both jejunal and ileal resection have in

22.54 Aetiology of short bowel syndrome

Children	
• Congenital anomalies (mid-gut volvulus, atresia)	• Necrotising enterocolitis
Adults	
• Crohn's disease • Mesenteric infarction	• Radiation enteritis • Volvulus

– absent; +/– can occur; + common; ++ major problem.

common the fact that they have lost a large amount of surface area for digestion and absorption, but there are important differences between jejunum–colon and jejunostomy patients (Box 22.55). Digestion and absorption are normally completed within the first 100 cm of jejunum, and enteral feeding is usually still possible if this amount of small intestine remains. The proximal small bowel normally reabsorbs most of the 8 L of fluid it receives daily (see Fig. 22.7, p. 843), and patients with a high jejunostomy are at great risk of hypovolaemia, dehydration and electrolyte losses. The presence of some or all of the colon can markedly improve these losses by increased water reabsorption. The presence of an intact ileocaecal valve ameliorates the clinical picture by slowing small intestinal transit and reducing bacterial overgrowth.

Clinical features

Severely affected patients have large volumes of jejunostomy fluid losses or, if the colon is preserved, diarrhoea and steatorrhoea. Dehydration and signs of hypovolaemia are common, as are weight loss, loss of muscle bulk and malnutrition. Some patients remain in satisfactory but precarious fluid balance until a minor intercurrent illness or intestinal upset occurs, when they can become rapidly dehydrated.

Management

In the immediate post-operative period, total parenteral nutrition (TPN) should be started and PPI therapy given to reduce gastric secretions. Enteral feeding should be cautiously introduced after 1–2 weeks under careful supervision and slowly increased as tolerated. For patients with a jejunostomy, parenteral saline is likely to be necessary if less than 100 cm of jejunum remains. If less than 75 cm of small bowel remains, TPN is also needed.

The principles of long-term management are:

- Detailed nutritional assessments at regular intervals.
- Monitoring of fluid and electrolyte balance. Patients can usually be taught how to do this for themselves. A readily available supply of oral rehydration solution is useful for intercurrent illness.
- Adequate calorie and protein intake. Fats are a good energy source and should be taken as tolerated. Medium-chain triglyceride supplements are given because they are more easily absorbed.
- Use of oral/enteral rather than parenteral nutrition whenever possible.
- Replacement of vitamin B_{12}, calcium, vitamin D, magnesium, zinc and folic acid.
- Loperamide (2–4 mg 4 times daily) or codeine phosphate (30 mg 4–6 times daily) for diarrhoea.

Octreotide (50–200 µg 2–3 times daily by subcutaneous injection) reduces gastrointestinal secretions and is useful in patients who are unable to maintain positive fluid balance. Despite these measures, some require long-term home TPN for survival and this is best managed in specialist centres. Small bowel transplantation is an option but rejection and graft-versus-host disease (p. 1017) remain significant hurdles.

Radiation enteritis and proctocolitis

Intestinal damage occurs in 10–15% of patients undergoing radiotherapy for abdominal or pelvic malignancy. The risk varies with total dose, dosing schedule and the use of concomitant chemotherapy.

Pathophysiology

The rectum, sigmoid colon and terminal ileum are most frequently involved. Radiation causes acute inflammation, shortening of villi, oedema and crypt abscess formation. These usually resolve completely but some patients develop an obliterative endarteritis affecting the endothelium of submucosal arterioles over 2–12 months. In the longer term, this can provoke a fibrotic reaction, leading to adhesions, ulceration, strictures, obstruction or fistula to adjacent organs.

Clinical features

In the acute phase, there is nausea, vomiting, cramping abdominal pain and diarrhoea. When the rectum and colon are involved, rectal mucus, bleeding and tenesmus occur. The chronic phase develops after 5–10 years in some patients and produces one or more of the problems listed in Box 22.56.

Investigations

In the acute phase, the rectal changes at sigmoidoscopy resemble ulcerative proctitis (see Fig. 22.56, p. 902). The extent of the lesion can be assessed by colonoscopy. Barium follow-through can be of diagnostic value in showing small bowel strictures, ulcers and fistulae.

22.56 Chronic complications of intestinal irradiation

- Proctocolitis
- Bleeding from telangiectasia
- Small bowel strictures
- Fistulae: rectovaginal, colovesical, enterocolic
- Adhesions
- Malabsorption: bacterial overgrowth, bile salt malabsorption (ileal damage)

Management

Diarrhoea in the acute phase should be treated with codeine phosphate, diphenoxylate or loperamide. Local corticosteroid enemas can help proctitis, and antibiotics may be required for bacterial overgrowth. Nutritional supplements are necessary when malabsorption is present. Colestyramine (4 g as a single sachet) is useful for bile salt malabsorption. Endoscopic argon plasma coagulation therapy may reduce bleeding from proctitis. Surgery should be avoided, if possible, because the injured intestine is difficult to resect and anastomose, but may be necessary for obstruction, perforation or fistula.

Abetalipoproteinaemia

This rare autosomal recessive disorder is caused by deficiency of apolipoprotein B, which results in failure of chylomicron formation. It leads to fat malabsorption and deficiency of fat-soluble vitamins. Jejunal biopsy reveals enterocytes distended with resynthesised triglyceride and normal villous morphology. Serum cholesterol and triglyceride levels are low. A number of other abnormalities occur in this syndrome, including acanthocytosis, retinitis pigmentosa and a progressive neurological disorder with cerebellar and dorsal column signs. Symptoms may be improved by a low-fat diet supplemented with medium-chain triglycerides and vitamins A, D, E and K.

Motility disorders

Chronic intestinal pseudo-obstruction

Small intestinal motility is disordered in conditions which affect the smooth muscle or nerves of the intestine. Many cases are 'primary' (idiopathic), while others are 'secondary' to a variety of disorders or drugs (Box 22.57).

Clinical features

There are recurrent episodes of nausea, vomiting, abdominal discomfort and distension, often worse after food. Alternating constipation and diarrhoea occur and weight loss results from malabsorption (due to bacterial overgrowth) and fear of eating. There may also be symptoms of dysmotility affecting other parts of the gastrointestinal tract, such as dysphagia, and, in primary cases, features of bladder dysfunction. Some patients develop severe abdominal pain for reasons that are poorly understood and this can be difficult to manage.

Investigations

The diagnosis is often delayed and a high index of suspicion is needed. Plain X-rays show distended loops of bowel and air–fluid levels, but barium studies demonstrate no mechanical obstruction. Laparotomy is sometimes required to exclude obstruction and to obtain full-thickness biopsies of the intestine. Examination of biopsy material using specialised techniques, such as electron microscopy, and immunohistochemistry can diagnose the many rare diseases of enteric smooth muscle and nerves that can cause this syndrome.

Management

This is often difficult. Underlying causes should be addressed and further surgery avoided. Metoclopramide or domperidone may enhance motility, and antibiotics are given for bacterial overgrowth. Nutritional and psychological support is also necessary.

22.57 Causes of chronic intestinal pseudo-obstruction

Primary or idiopathic

- Rare familial visceral myopathies or neuropathies
- Congenital aganglionosis

Secondary

- Drugs (opiates, tricyclic antidepressants, phenothiazines)
- Smooth muscle disorders (scleroderma, amyloidosis, mitochondrial myopathies)
- Myenteric plexus disorders, e.g. paraneoplastic syndrome in small-cell lung cancer
- CNS disorders (Parkinson's disease autonomic neuropathy)
- Endocrine and metabolic disorders, (hypothyroidism, phaeochromocytoma, acute intermittent porphyria)

Miscellaneous disorders of the small intestine

Protein-losing enteropathy

This term is used when there is excessive loss of protein into the gut lumen, sufficient to cause hypoproteinaemia. Protein-losing enteropathy occurs in many gut disorders but is most common in those in which ulceration occurs (Box 22.58). In other disorders, protein loss can result from increased mucosal permeability or obstruction of intestinal lymphatic vessels. Patients present with peripheral oedema and hypoproteinaemia in the presence of normal liver function and without proteinuria. The diagnosis can be confirmed by measurement of faecal clearance of α_1-antitrypsin or ^{51}Cr-labelled albumin after intravenous injection. Other investigations should be performed to determine the underlying cause. Treatment is that of the underlying disorder, with nutritional support and measures to control peripheral oedema.

22.58 Causes of protein-losing enteropathy

With mucosal erosions or ulceration

- Crohn's disease
- Ulcerative colitis
- Radiation damage
- Oesophageal, gastric or colonic cancer
- Lymphoma

Without mucosal erosions or ulceration

- Ménétrier's disease
- Bacterial overgrowth
- Coeliac disease
- Tropical sprue
- Eosinophilic gastroenteritis
- Systemic lupus erythematosus

With lymphatic obstruction

- Intestinal lymphangiectasia
- Constrictive pericarditis
- Lymphoma
- Whipple's disease

Intestinal lymphangiectasia

This may be primary, resulting from congenital malunion of lymphatics, or secondary to lymphatic obstruction due to lymphoma, filariasis or constrictive pericarditis. Impaired drainage of intestinal lymphatic vessels leads to discharge of protein and fat-rich lymph into the gastrointestinal lumen. The condition presents with peripheral lymphoedema, pleural effusions or chylous ascites, and steatorrhoea. Investigations reveal hypoalbuminaemia, lymphocytopenia and reduced serum immunoglobulin concentrations. The diagnosis can be made by CT scanning and by enteroscopy and jejunal biopsy, which shows greatly dilated lacteals. Treatment consists of a low-fat diet with medium-chain triglyceride supplements.

Ulceration of the small intestine

Small bowel ulcers are uncommon and are either idiopathic or secondary to underlying intestinal disorders (Box 22.59). Ulcers are more common in the ileum, and cause bleeding, perforation, stricture formation or obstruction. Barium studies and enteroscopy confirm the diagnosis.

22.59 Causes of small intestinal ulcers

- Idiopathic
- Inflammatory bowel disease
- NSAIDs
- Ulcerative jejuno-ileitis
- Lymphoma and carcinoma
- Infections, (tuberculosis, typhoid, *Yersinia enterocolitica*)
- Others (radiation, vasculitis)

NSAID-associated small intestinal toxicity

These drugs cause a spectrum of small intestinal lesions ranging from erosions and ulcers to mucosal webs, strictures and, rarely, a condition known as 'diaphragm disease', in which intense submucosal fibrosis results in circumferential stricturing. The condition can present with pain, obstruction, bleeding or anaemia, and may mimic Crohn's disease, carcinoma or lymphoma. Enteroscopy or capsule endoscopy can reveal the diagnosis but sometimes this is only discovered at laparotomy.

Eosinophilic gastroenteritis

This disorder of unknown aetiology can affect any part of the gastrointestinal tract; it is characterised by eosinophil infiltration involving the gut wall, in the absence of parasitic infection or eosinophilia of other tissues. Peripheral blood eosinophilia is present in 80% of cases.

Clinical features

There are features of obstruction and inflammation, such as colicky pain, nausea and vomiting, diarrhoea and weight loss. Protein-losing enteropathy occurs and up to 50% of patients have a history of other allergic disorders. Serosal involvement may produce eosinophilic ascites.

Investigations and management

The diagnosis is made by histological assessment of multiple endoscopic biopsies, although full-thickness biopsies are occasionally required. Other investigations should be performed to exclude parasitic infection and other causes of eosinophilia. The serum IgE concentration is often raised. Dietary manipulations are rarely effective, although elimination diets, especially of milk, may benefit a few patients. Severe symptoms are treated with prednisolone (20–40 mg daily) and/or sodium cromoglicate, which stabilises mast cell membranes. The prognosis is good in the majority of patients.

Meckel's diverticulum

This is the most common congenital anomaly of the gastrointestinal tract and occurs in 0.3–3% of people, but the vast majority of affected individuals are asymptomatic throughout life. The diverticulum results from failure of closure of the vitelline duct, with persistence of a blind-ending sac arising from the anti-mesenteric border of the ileum; it usually occurs within 100 cm of the ileocaecal valve and is up to 5 cm long. Approximately 50% contain ectopic gastric mucosa; rarely, colonic, pancreatic or endometrial tissue is present. Complications most commonly occur in the first 2 years of life but are occasionally seen in young adults. Bleeding can result from ulceration of ileal mucosa adjacent to the ectopic parietal cells and presents as recurrent melaena or altered blood per rectum. The diagnosis can be made by scanning the abdomen using a gamma counter following an intravenous injection of ^{99m}Tc-pertechnate, which is concentrated by ectopic parietal cells. Other complications include intestinal obstruction, diverticulitis, intussusception and perforation. Intervention is unnecessary unless complications occur.

Adverse food reactions

Adverse food reactions are common and are subdivided into food intolerance and food allergy, the former being much more common. In food intolerance, there is an adverse reaction to food which is not immune-mediated and results from pharmacological (histamine, tyramine or monosodium glutamate), metabolic (lactase deficiency) or other mechanisms (toxins or chemical contaminants in food).

Lactose intolerance
